## Abstract

We proposed the first threshold GQ signature scheme. The scheme is unforgeable and robust against any adaptive adversary if the base GQ signature scheme is unforgeable under the chosen message attack and computing the discrete logarithm modulo a safe prime is hard. Our scheme achieve optimal resilience, that is, the adversary can corrupt up to a half of the players. As an extension of our work, we proposed a threshold forward-secure signature scheme, which is the threshold version of the most efficient forward-secure signature scheme up to now.

Keywords: threshold signature, GQ signature, forward-secure signature.

## 1 Introduction

A threshold cryptographic protocol involves a set of players together, who each possesses a secret share, to accomplish a cryptographic task via exchange of messages among them. Threshold cryptographic protocols provide strong security assurance and robustness against a number of malicious attackers under a threshold. For example, in a  $(t, n)$ -threshold signature scheme, as long as  $t + 1$  servers agree, they can jointly produce a signature for a given message even some other servers intend to spoil such process. Also, as long as the adversary corrupts less than  $t + 1$  servers, it cannot forge any valid signature.

The signature scheme proposed by Guillou and Quisquater [GQ88], called the GQ signature scheme here, are used in many cryptographic protocols, such as, in [IR01]. To our best knowledge, there are no threshold versions of this important signature scheme in the open literature. Therefore, in this paper we study the threshold signature protocol based on the GQ signature scheme. Our GQ-based threshold signature protocol is secure in the adaptive adversary model. Our scheme achieve optimal resilience, that is, the adversary can corrupt up to a half of the players. We also extend our work

to the forward signature paradigm. In particular, we propose a threshold version of the optimal forward signature scheme [IR01], which is based on the GQ signature scheme.

*Related work.* The first general notion of efficient threshold cryptography was introduced by Desmedt [Des87]. It started many studies on threshold computation models and concrete threshold schemes based on the basic schemes, such as RSA, DSA, ElGamal, etc [CMI93, GJKR96b, CGJ<sup>+</sup>99, JL00, Jar01, DF91, GJKR96a, Rab98, FMY99, Sho00, DK01]. These protocols develop many techniques for designing secure threshold protocols. We use some of them and develop new ones for our schemes.

There are two types of forward signature schemes. The first type is a general construction based on arbitrary signature schemes. It mainly uses the master public key to certify the public key of the current time period. The second type modifies the concrete signature schemes. Currently, there are three such forward-secure signature schemes [BM99, AR00, IR01], which are based on Fiat-Shamir-,  $2^t$ -th-root- and GQ-identification schemes, respectively. The GQ-based forward-secure signature scheme is the most efficient one with respect to the key size, and signing and verification time. There are threshold versions for the first two schemes [TT01, AMN01]. In this paper we propose the threshold version for the third one.

## 2 Preliminaries

The GQ signature scheme is as follows.

1. Key generation: let  $p = 2p' + 1$  and  $q = 2q' + 1$  be two safe primes and  $n = pq$ . The private key of a player is  $(n, e, s)$  and the corresponding public key is  $(n, e, v)$ , where  $v = 1/s^e \pmod n$ . Note that the user need not know  $p$  and  $q$  and thus  $n$  can be used by all users.
2. Signing: let  $h$  be a publicly defined cryptographic strong hash function, such as SHA-1. Given a message  $M$ , the signer computes the signature  $(r, z)$  as follows:
  - Randomly select a number  $r \in Z_n^*$  and compute  $y = r^e \pmod n$  and  $\sigma = h(y||M)$ .
  - Compute  $z = r \cdot s^\sigma \pmod n$ .
3. Verification: the verifier checks whether  $h(M||z^e v^\sigma \pmod n) = r$ .

A *threshold signature scheme* consists of the following three components:

1. Key generation: there are two categories in generating the keys and distributing shares of them to the participated players. In the dealer model, a dealer chooses the keys and distributes the shares to the

players. In the distributed key generation model, all players together compute their key shares together.

2. Distributed signing: there are two phases: partial signature generation and signature construction. In the partial signature generation phase, the players communicate with each other and each produces a partial signature for the given message  $M$ . Then, in the signature construction, any one who has a number of valid partial signatures over a threshold can compute a valid signature for  $M$ .
3. Verification: any one can verify the validity of a signature for a message given the public key.

An *adaptive adversary* is a probabilistic polynomial time Turing machine which can corrupt players dynamically, that is, it can corrupt a player at any time during execution of the protocol. Nevertheless, the total number of players it can corrupt is under the threshold.

Two distribution ensembles  $\{X_n\}$  and  $\{Y_n\}$  are (computationally) *indistinguishable* if for any probabilistic polynomial-time distinguisher  $D$  and any polynomial  $p(n)$ , there is an integer  $n_0$  such that for any  $n \geq n_0$ ,

$$|\Pr[D(X_n) = 1] - \Pr[D(Y_n) = 1]| < 1/p(n).$$

The *discrete logarithm* over a safe prime problem is to solve  $DLog_{\tilde{g}}\tilde{h} \bmod \tilde{p}$  from given  $(\tilde{p}, \tilde{g}, \tilde{h})$ , where  $\tilde{p} = 2\tilde{p}' + 1$  is prime,  $\tilde{p}'$  is also prime, and  $\tilde{g}$  is a generator of the quadratic subgroup  $G_{\tilde{p}'}$  of  $Z_{\tilde{p}}^*$ . We assume that no probabilistic polynomial-time Turing machine can solve a significant portion of the input. Let  $I_n$  be the (uniform) distribution of the size- $n$  input. Then, for any probabilistic polynomial-time Turing  $A$  and polynomial  $p(n)$ , there is  $n_0$  such that for any  $n \geq n_0$ ,

$$\Pr_{\tilde{p}, \tilde{g}, \tilde{h} \in I_n} [A(\tilde{p}, \tilde{g}, \tilde{h}) = DLog_{\tilde{g}}\tilde{h} \bmod \tilde{p}] < 1/p(n).$$

### 3 Threshold GQ signature scheme

In our threshold GQ signature scheme, the dealer generates a public/secret key pair and distributes shares of the secret key to the players. To sign a message distributively, each player produces a partial signature. If there are more than  $t + 1$  valid partial signatures, we can construct the signature of the message from the valid partial signatures.

#### 3.1 Generating keys

The *key generation* process is shown in Figure 1. Let  $\{P_i\}$  be the set of  $l$  participating players and  $L = !l$ . There are two security parameters  $k_1$  and

**Input:** security parameters  $k_1, k_2$ .

The dealer generates and distributes keys as follows:

1. Choose two  $\lceil k_1/2 \rceil$ -bit random primes  $p, q$  such that  $p = 2p' + 1, q = 2q' + 1$ , where  $p', q'$  are also primes. Let  $n = pq, m = p'q'$ , and  $g$  a generator of  $G_n$ .
2. Choose a random polynomial  $f(x) = a_0 + a_1x + \dots + a_tx^t$  over  $Z_m$  of degree  $t$ . Let  $s = g^{a_0} \bmod n$  be the main secret and hand  $s_i = g^{f(i)} \bmod n$  to player  $P_i$  secretly.
3. Randomly choose a  $(k_2 + 1)$ -bit value  $e$ , such that  $\gcd(e, \phi(n)) = 1$  and  $\gcd(e, L^2) = 1$ , where  $L = !$ . Compute  $v = 1/s^e \bmod n$ .
4. Let  $SK_i = (n, e, g, s_i)$  be the secret key of player  $P_i$ , and broadcast the public key  $PK = (n, e, g, v)$ .

Figure 1: TH-GQ-KeyGen: Generating keys

$k_2$ . The dealer chooses two safe primes  $p = 2p' + 1$  and  $q = 2q' + 1$ , each of length  $\lceil k_1/2 \rceil$  bits, where  $p'$  and  $q'$  are also primes. Let  $n = pq, m = p'q'$ ,  $Q_n$  the set of all quadratic residues modulo  $n$ , and  $g$  a generator of  $Q_n$ . The order of  $Q_n$  is  $m$ . Hereafter, all group computations are done in  $Q_n$  and the corresponding exponent arithmetic is done in  $Z_m$ .

The dealer then chooses a random degree- $t$  polynomial  $f(x)$  over  $Z_m$  and gives the share  $s_i = g^{f(i)}$  to the player  $P_i$ . Note that the share given to player  $P_i$  is  $g^{f(i)}$ , instead of  $f(i)$ . The shared secret key is thus  $s = g^{f(0)}$ . The dealer then chooses a random  $(k_2 + 1)$ -bit value  $e$  with  $\gcd(e, \phi(n)) = 1$  and  $\gcd(e, L^2) = 1$  and computes  $v = 1/s^e \bmod n$ . In summary, the public key  $PK$  of the scheme is  $(n, e, g, v)$  and the secret share of player  $P_i$  is  $SK_i = (n, e, g, s_i)$ .

### 3.2 Signing messages

The message signing protocol consists of two phases: *distributed signing* and *signature construction*, shown in Figure 2.

#### 3.2.1 Distributed signing

To sign a message  $M$ , all players execute INT-JOINT-EXP-RVSS, shown in Figure 7, to jointly generate a random value  $y = g^{f_r(0) \cdot e}$ , where  $f_r(x)$  is the sharing polynomial. Each  $P_i$  gets a share  $r_i = g^{f_r(i)}$ . Then, each player computes  $\sigma = H(y, M)$ , where  $H$  is the chosen one-way hash function.

All players together run INT-JOINT-ZVSS<sup>1</sup> such that they share a zero-constant degree- $t$  polynomial  $f_c(x)$  and each player  $P_i$  holds a share  $c_i = g^{L \cdot f_c(i)} \bmod n$ , where  $f_c(0) = 0$ . Then, all other secret information generated

<sup>1</sup>INT-JOINT-ZVSS is just like INT-JOINT-RVSS in Figure 6, except that each player sets his secret  $a_{i0}, b_{i0}$  to be zero.

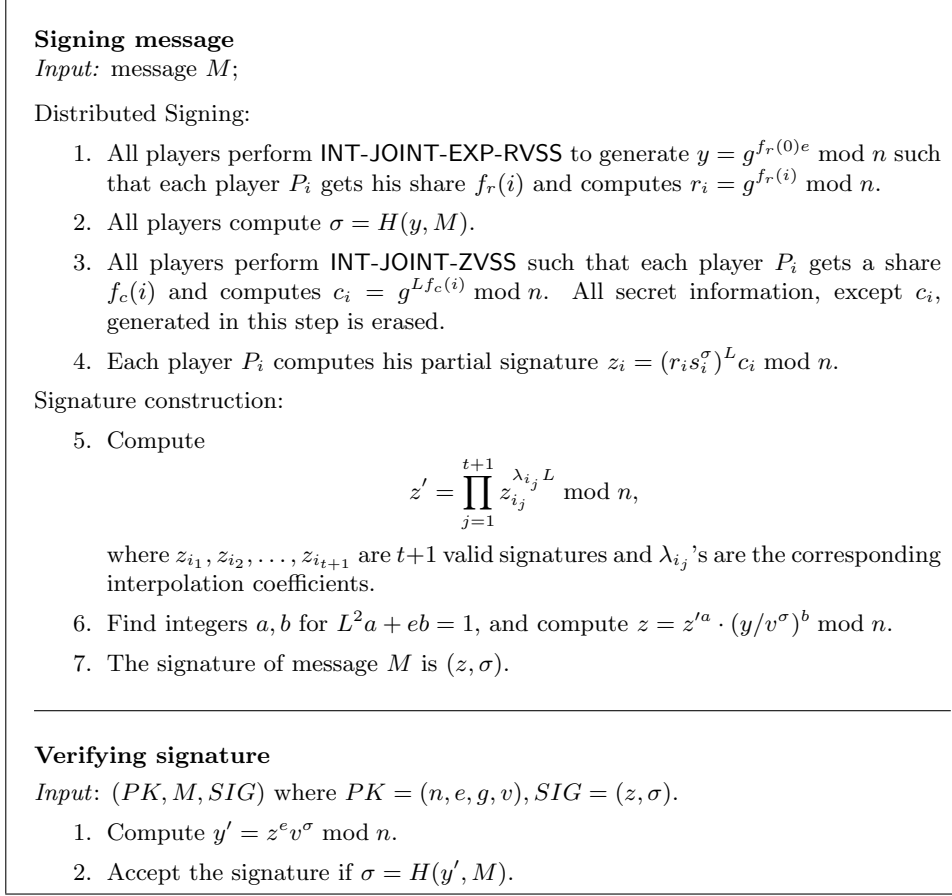

Figure 2: TH-GQ-Sig & TH-GQ-Ver: Signing and verifying message

in INT-JOINT-ZVSS are erased (the erasing technique [CFGN96, CGJ<sup>+</sup>99]). Finally, each player  $P_i$  computes his partial signature  $z_i = (r_i s_i^\sigma)^L c_i \bmod n$ .

### 3.2.2 Signature construction

To compute the signature for  $M$ , we choose  $t + 1$  valid partial signatures  $z_{i_1}, z_{i_2}, \dots, z_{i_{t+1}}$  and compute their interpolation

$$\begin{aligned}
 z' &= \prod_{j=1}^{t+1} z_{i_j}^{\lambda_{i_j} L} \bmod n \\
 &= (g^{\sum_{j=1}^{t+1} \lambda_{i_j} (f_r(i_j) + \sigma f(i_j) + f_c(i_j))})^{L^2} \bmod n \\
 &= (r s^\sigma)^{L^2} \bmod n,
 \end{aligned}$$

where  $\lambda_{i_j}$  is the  $j$ th interpolation coefficient for the set  $\{i_1, i_2, \dots, i_{t+1}\}$ . Since  $\lambda_{i_j} \cdot L$  is an integer, we can compute  $z'$  even without knowing the

factorization of  $n$ . Since  $\gcd(L^2, e) = 1$ , we find integers  $a$  and  $b$  such that  $L^2a + eb = 1$  and compute the signature  $z$  for  $M$  as:

$$z = z'^a \cdot (y/v^\sigma)^b = (rs^\sigma)^{L^2a} (rs^\sigma)^{eb} = rs^\sigma \pmod n$$

*Remark.* Since the sharing polynomials  $f(x)$ ,  $f_r(x)$ , and  $f_c(x)$  are over the exponents, the partial signature  $z_i = (r_i s_i^\sigma)^{L} c_i$  is a share of a degree- $t$  polynomial in the exponent. Thus, we need only  $t + 1$  shares to interpolate  $z'$ .

### 3.3 Verifying signatures

The verification procedure is straightforward, as defined by the GQ signature scheme, shown in Figure 2.

### 3.4 Security analysis

Our threshold GQ signature scheme is secure against the chosen message attack in the adaptive adversary model. That is, as long as the adaptive adversary controls less than  $t + 1$  players, it cannot forge a valid signature without interacting with un-corrupted players. The adversary cannot interrupt the un-corrupted players to cooperatively obtain a valid signature for a message, either.

We need a simulator  $\text{SIM}_{\text{TH-GQ-Sig}}$  to simulate the view of execution of the TH-GQ-Sig scheme producing a signature  $(\sigma, z)$  for a message  $M$ . The simulator is shown in Figure 3.

**Lemma 1** *If the adaptive adversary corrupts at most  $t$  players, its view of an execution of TH-GQ-Sig on input message  $M$  and output signature  $(\sigma, z)$  is the same as the view of an execution of  $\text{SIM}_{\text{TH-GQ-Sig}}$  on input  $M$  and signature  $(\sigma, z)$ .*

**Proof.** Assume that  $\mathcal{B}$  is the set of corrupted players and  $\mathcal{G}$  is the set of un-corrupted (honest) players up to now. In the beginning (the key generation stage), the simulator emulates the dealer to randomly assign  $s_i \in Q_n$  to player  $P_i$ ,  $1 \leq i \leq l$ . These  $s_i$ 's remain fixed for many rounds of simulation of TH-GQ-Sig. Let  $y = z^e v^\sigma \pmod n$ , which is the correct  $r^e \pmod n$ . Since  $y$  is distributively computed by all players in TH-GQ-Sig, the simulator runs  $\text{SIM}_{\text{INT-JOINT-EXP-RVSS}}$  (Figure 8) on input  $y$  to simulate the execution of INT-JOINT-EXP-RVSS protocol. In Step 3, the simulator runs INT-JOINT-ZVSS on behalf of honest players and assigns each corrupted player  $P_i$  a share  $c_i = g^{f_c(i)} \pmod n$ , where  $f_c(x)$  has a zero constant. Now, the corrupted players  $P_i$  get  $s_i$ ,  $r_i$  and  $c_i$ . Their partial signatures  $z_i = (r_i s_i^\sigma)^{L} c_i \pmod n$  need be fixed since the adversary corrupts them. Let  $\Lambda' \supseteq \mathcal{B}$  be a set of  $t$  players. We fix the partial signatures of the players in  $\Lambda'$ . For un-corrupted players  $P_j \notin \Lambda'$ , we set their partial signatures to be compatible with those

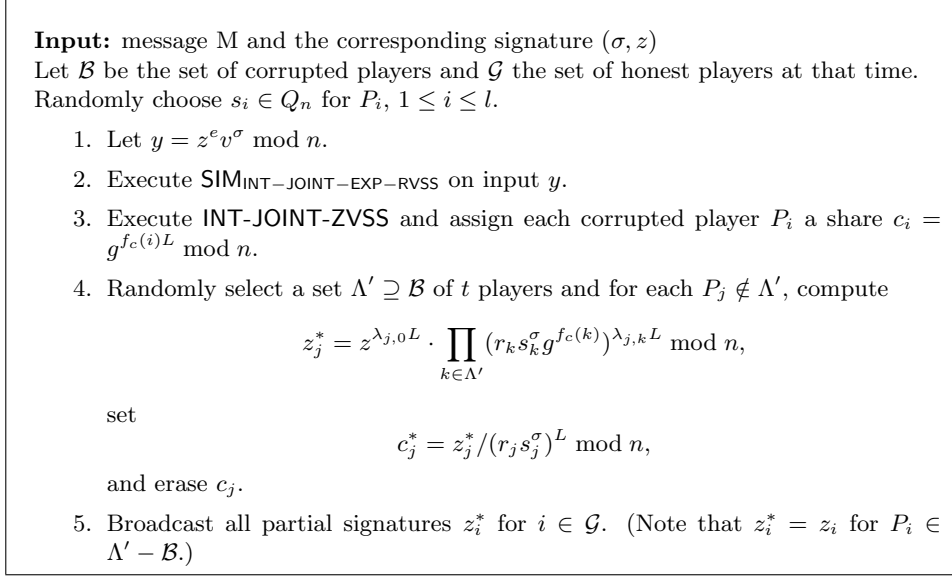

Figure 3:  $\text{SIM}_{\text{TH-GQ-Sig}}$ : Simulator of TH-GQ-Sig

in  $\Lambda'$ , that is, the shares of any  $t + 1$  players result in the same signature. This is done by setting their partial signatures as

$$z_j^* = z^{\lambda_{j,0}L} \cdot \prod_{k \in \Lambda'} (r_k s_k^\sigma g^{f_c(k)})^{\lambda_{j,k}L} \bmod n,$$

where  $\lambda_{j,k}$ 's are the interpolation coefficients for computing the  $j$ th share from the set of shares  $\{0\} \cup \{k | P_k \in \Lambda'\}$ . The simulator also sets the new shares  $c_j^* = z_j^* / (r_j s_j^\sigma)^L$  to the players  $P_j \notin \Lambda'$  and erases the old shares  $c_j$ . These  $c_j^*$  make the un-corrupted players have the consistent relation for  $r_j$ ,  $s_j$ ,  $c_j^*$  and  $z_j^*$ .

We see how the simulator produces an indistinguishable distribution for the adversary:

1. The simulator runs  $\text{SIM}_{\text{INT-JOINT-EXP-RVSS}}$  which generates  $y$  in the proper distribution.
2. The simulator performs  $\text{INT-JOINT-ZVSS}$  on behalf of honest players. This is the same as what TH-GQ-Sig does in Step 3. Thus, the distribution for  $c_i$ 's is the same.
3. The partial signatures  $z_i$ 's of all players are consistent since the shares of any  $t + 1$  players produces the right signature  $(\sigma, z)$  (by adjusting  $c_i$ 's). Therefore, they have the right distribution.
4. The erasing technique (for  $c_i$ 's) is employed. As long as the simulated distribution is indistinguishable for the adversary after it corrupts a

new player, the entire distribution is indistinguishable for the adversary after it corrupts up to  $t$  players. There is no inconsistency problem between corruptions of players.

5. The shares  $c_j$ 's are adjusted to  $c_j^*$ 's for the un-corrupted players (up to now) so that even the adversary corrupts it later, the partial signature  $z_j^*$  is consistent with the possible check of equation  $z_j^* = (r_j s_j^\sigma)^L c_j^*$ .

In conclusion, the simulator  $\text{SIM}_{\text{TH-GQ-Sig}}$  produces an indistinguishable distribution for the adversary, who corrupts up to  $t$  players in an adaptive way.  $\square$

We now show that our threshold GQ signature scheme is secure against the adaptive adversary under the chosen message attack.

For unforgeability, let  $\mathcal{O}_{sig}$  be the signing oracle that a forger (in the centralized version) queries for signatures of messages. When  $\mathcal{O}_{sig}$  returns  $(\sigma, z)$  for a message  $M$ , the simulator, on input  $M$  and  $(\sigma, z)$ , outputs a transcript with an indistinguishable distribution for the adaptive adversary (in the distributed version). Thus, the adversary, who engaged several executions of the TH-GQ-Sig protocol, cannot produce an additional valid signature without cooperation of un-corrupted players.

**Theorem 1** *If the underlying GQ signature scheme is unforgeable under the adaptive chosen message attack, the threshold GQ signature scheme in Figures 1 and 2 is unforgeable against the adaptive adversary who corrupts up to  $t$  players.*

**Proof.** (sketch) Assume that the adversary  $\mathcal{A}$ , who controls up to  $t$  players during execution of the TH-GQ-Sig scheme and thus obtains signatures for  $M_1, M_2, \dots$ , produces a valid signature for  $M$ ,  $M \neq M_i$  for  $i \geq 1$ . We construct a forger  $\mathcal{F}$  to forge a signature for an un-queried message using the signing oracle  $\mathcal{O}_{sig}$  for the underlying GQ signature scheme.

Let  $(n, e, g, v)$  be the public key of the underlying GQ signature scheme. This is used in the (simulated) threshold GQ signature scheme also. First, in the key generation stage  $\mathcal{F}$  assigns each player  $P_i$  a random secret share  $s_i \in Q_n$ . Then, it simulates all players and the adversary. When the players intend to execute TH-GQ-Sig to produce a valid signature for  $M_i$ ,  $\mathcal{F}$  queries  $\mathcal{O}_{sig}$  to obtain a signature  $(\sigma_i, z_i)$  and runs the simulator  $\text{SIM}_{\text{TH-GQ-Sig}}$ , on input  $M_i$  and  $(\sigma_i, z_i)$ , to produce a transcript  $T_i$  with right distribution (by Lemma 1) for  $\mathcal{A}$ . Then,  $\mathcal{F}$  simulates  $\mathcal{A}$ , on input of these transcripts  $T_i$ 's, to produce a valid signature  $(\sigma, z)$  for a new message  $M$ ,  $M \neq M_i, i \geq 1$ . Thus, the underlying GQ signature is not unforgeable under the chosen message attack, which is a contradiction.  $\square$

**Theorem 2** *If computing the discrete logarithm modulo a safe prime is hard, the TH-GQ-Sig scheme in Figure 2 is robust against the adaptive adversary who corrupts up to  $t$  players.*

**Proof.** (Sketch) If there is an adversary  $\mathcal{A}'$  who participates the TH-GQ-Sig scheme on the input messages that it selected such that the honest players fail to generate a valid signature for a given message, then we can construct an extractor  $\mathcal{E}$  to solve the discrete-log problem modulo a safe prime. That is, on input  $(\tilde{p}, \tilde{g}, \tilde{h})$ ,  $\mathcal{E}$  can compute  $\text{DLog}_{\tilde{g}} \tilde{h} \bmod \tilde{p}$  as follows, where  $\tilde{p} = 2\tilde{p}' + 1$ .

First,  $\mathcal{E}$  lets the dealer generate the related keys as usual except that the dealer chooses (1)  $p = \tilde{p}$  (and thus  $p' = \tilde{p}'$ ) (2)  $g = \tilde{g}^2 \bmod n$ . Without loss of generality, we assume that  $g \not\equiv 1 \pmod{q}$ . Since  $\tilde{g}$  is the generator of  $G_{\tilde{p}'}$  and  $g \bmod q$  is a generator for  $G_{\tilde{q}'}$ ,  $g$  is a generator of  $Q_n$ . Then  $\mathcal{E}$  simulates  $h$ -generation protocol with  $\mathcal{A}'$  and outputs  $h = \tilde{h}$  [Jar01]. Using the instance  $(g, h)$ ,  $\mathcal{E}$  performs TH-GQ-Sig with  $\mathcal{A}'$  on behalf of the honest players. Now, we show that if  $\mathcal{A}'$  hinders the signing protocol from producing a valid signature,  $\mathcal{E}$  can compute  $\mathcal{D} = \text{DLog}_g h \bmod n$ , and then outputs  $\text{DLog}_{\tilde{g}} \tilde{h} = 2\mathcal{D} \bmod \tilde{p}$ .

Let us consider where the protocol may fail to produce the valid signature. First, in executing the INT-JOINT-RVSS scheme (or INT-JOINT-ZVSS, see Figure 6), if a corrupted player  $P_i$  distributes his shares  $(f_i(j), f'_i(j))$ ,  $1 \leq j \leq n$ , that pass the verification equation (1), but do not lie on a  $t$ -degree polynomial, the extractor  $\mathcal{E}$  can solve the system of  $t + 2$  linearly independent equations of the form  $c_0 + c_1j + c_2j^2 + \dots + c_tj^t = f_i(j) + \mathcal{D}f'_i(j)$  with  $t + 2$  unknown variables  $c_0, c_1, \dots, c_t$  and  $\mathcal{D}$ . Then, the extractor outputs  $\mathcal{D}$ .

Another situation that  $\mathcal{A}'$  may cheat is on the zero-knowledge proof in executing INT-JOINT-EXP-RVSS. If the corrupted player  $P_i$  broadcasts  $(A_i^*, B_i^*) \neq (g^{a_{i0}e}, h^{b_{i0}e})$  in Step 2,  $\mathcal{E}$  extracts  $\mathcal{D} = \text{DLog}_g h$  as follows. Assume that  $A_i^* = g^{a'} \bmod n$  and  $B_i^* = h^{b'} \bmod n$ . After executing Steps 2a-2c,  $\mathcal{E}$  gets  $R_i = r_i + da'e$  and  $R'_i = r'_i + db'e$ . Then  $\mathcal{E}$  rewinds  $\mathcal{A}'$  to run Steps 2b-2c again. This gives  $\mathcal{E}$  another two equations  $R_i^* = r_i + d^*a'e$  and  $R'_i{}^* = r'_i + d^*b'e$ . As long as  $d \neq d^*$  (the probability of equality is negligible),  $\mathcal{E}$  can solve the equations and get the four unknown variables  $r_i, r'_i, a', b'$ . Since  $\mathcal{E}$  knows the value  $m$ , the extractor computes  $\mathcal{D}$  from  $a_{i0} + \mathcal{D}b_{i0} = a' + \mathcal{D}b' \bmod m$ .  $\square$

### 3.5 Achieving optimal resilience

The protocols presented up to now have not yet achieved optimal resilience since in Step 5 of TH-FIG-Sig we need find  $t + 1$  valid partial signatures. Also, Step 2(b) of INT-JOINT-EXP-RVSS need reconstruct the challenge  $d$ . With the simple majority vote, the threshold  $t$  is  $n/3$  at most.

We describe how to modify them to achieve optimal resilience ( $n \geq 2t + 1$ ). The main difference is that each player proves correctness of its partial signature when it is issued. For this proof, in the key generation stage the dealer shares  $f(i)$  (instead of  $g^{f(i)}$ ) to player  $P_i$ . In addition, the

dealer shares another random polynomial  $f'(x)$  and broadcasts the coefficient references of  $f(x)$  and  $f'(x)$  in the unconditionally-secure form, that is,  $A_i = g^{f(i)L}h^{f'(i)L}$ . When signing a partial signature, each player presents a non-interactive zero-knowledge proof of knowledge of  $f(i)$ ,  $f_r(i)$  and  $f_c(i)$ . Therefore, in signature construction one can verify validity of partial signatures.

To resolve the case for Step 2(b) of INT-JOINT-EXP-RVSS, we can use the non-interactive zero-knowledge proof technique similarly. We can also replace the INT-JOINT-RVSS of jointly generating the challenge  $d$  with a coin-flip protocol (e.g. in additive form).

## 4 Threshold forward-secure signature

Based on our threshold GQ signature scheme and Itkis and Reyzin's forward signature scheme [IR01], we construct a threshold forward-secure signature scheme TH-FS-GQ.

### 4.1 Key generation

The key generation process is in Figure 4. Let  $T$  be the total number of time periods. The first three steps are the same as those of TH-GQ-Sig. Each player  $P_i$  gets  $s_i$  as his initial share. The dealer chooses primes  $e_j$ ,  $1 \leq j \leq T$ , in the range between  $2^{k_2}(1 + (j-1)/T)$  and  $2^{k_2}(1 + j/T)$ . That is, we divide the interval between  $2^{k_2}$  and  $2^{k_2+1}$  into  $T$  buckets, and choose each prime  $e_j$  from the  $j$ -th bucket. The public key is

$$v = 1/s^{e_1 e_2 \dots e_T} \pmod n.$$

At time period  $j$ ,  $1 \leq j \leq T$ , the player  $P_i$ ,  $1 \leq i \leq n$ , holds two secrets:

$$\begin{aligned} s_{ij} &= s_i^{e_1 \dots e_{j-1} e_{j+1} \dots e_T} \pmod n, \text{ and} \\ t_{ij} &= s_i^{e_1 e_2 \dots e_j} \pmod n \end{aligned}$$

where  $s_{ij}$  is the signing share and  $t_{ij}$  is an auxiliary secret for share update.

In the beginning, the dealer sends the player  $P_i$  two shares  $s_{i1}$  and  $t_{i1}$ . Hence, the secret key for player  $P_i$  at time period 1 is  $SK_{i1} = (1, T, n, s_{i1}, t_{i1}, e_1)$  and the system public key is  $PK = (n, v, T)$ .

### 4.2 Key update

To compute the keys of the  $j+1$ th time period, each player  $P_i$  computes the exponents  $e_{j+1}, e_{j+2}, \dots, e_T$  for evolving the secret<sup>2</sup>. Then,  $P_i$  computes its

<sup>2</sup>We can also take all  $e_j$ 's as the part of secret key, but this would increase the storage space linear in  $T$ . Therefore, we only put  $e_j$  into the secret key for each message signing, and regenerate others for key update. Note that the dealer chooses these primes by a deterministic algorithm such that players can regenerate  $e_{j+1}, \dots, e_T$  based on  $e_j$ .

### Generating Keys

*Input:* security parameters  $(k_1, k_2, T)$ .

The dealer generates and distributes keys as follows:

1. Choose two  $\lceil k_1/2 \rceil$ -bit random primes  $p, q$  such that  $p = 2p' + 1, q = 2q' + 1$ , where  $p', q'$  are also primes. Let  $n = pq, m = p'q'$ .
2. Choose a random value  $g \in Q_n$  and a random polynomial  $f(x) = a_0 + a_1x + \dots + a_tx^t$  over  $Z_m$  of degree  $t$ . Let  $s = g^{a_0} \bmod n$  be the main secret and hand  $s_i = g^{f(i)} \bmod n$  to player  $P_i$  secretly.
3. For  $j = 1, \dots, T$ , choose primes  $e_j$  such that  $2^{k_2}(1 + (j - 1)/T) \leq e_j < 2^{k_2}(1 + j/T)$ .
4. Compute the public value  $v = 1/s^{e_1 \cdots e_T} \bmod n$ .
5. Compute the first period share  $s_{i1} = s_i^{e_2 \cdots e_T} \bmod n$  and  $t_{i1} = s_i^{e_1} \bmod n$  for each player  $P_i$ .
6. Send the secret share  $SK_{i1} = (1, T, n, s_{i1}, t_{i1}, e_1)$  to each player  $P_i$  at time period 1 and publish the public key  $PK = (n, v, T)$ .

### Updating Keys

*Input:*  $SK_{ij} = (j, T, n, s_{ij}, t_{ij}, e_j)$  for each player  $P_i$ .

Each player  $P_i$  updates his share from time period  $j$  to  $j + 1$ .

1. Each player regenerates  $e_{j+1}, \dots, e_T$ .
2. Each player  $P_i$  updates his share by computing:

$$s_{i(j+1)} = t_{ij}^{e_j + 2e_{j+1} + \dots + e_T} \bmod n; \quad t_{i(j+1)} = t_{ij}^{e_{j+1}} \bmod n$$

3. The new secret share of player  $P_i$  at time period  $j + 1$  is  $SK_{i(j+1)} = (j + 1, T, n, s_{i(j+1)}, t_{i(j+1)}, e_{j+1})$ .

Figure 4: TH-FS-GQ - Generating and Updating Keys

signing share  $s_{i(j+1)} = t_{ij}^{e_j + 2e_{j+1} + \dots + e_T} \bmod n$  and key evolving secret  $t_{i(j+1)} = t_{ij}^{e_{j+1}} \bmod n$ . Thus,  $P_i$ 's signing share in the  $j+1$ th period is

$$SK_{i(j+1)} = (j + 1, T, n, s_{i(j+1)}, t_{i(j+1)}, e_{j+1}).$$

### 4.3 Signing messages

The signing protocol, in Figure 5, is quite similar to TH-GQ-Sig except that we need time parameters and replace the values  $e$  and  $s_i$  with  $e_j$  and  $s_{ij}$  for time period  $j$ . Note that the time period  $j$  and the exponent  $e_j$  are put into the hash function in computing  $\sigma$ . Since the verifier doesn't know  $e_j$  exactly, the hashing ensures that the signer can't choose  $e_j$  arbitrarily after seeing the challenge  $\sigma$ . Finally, the signature for the message  $M$  is  $(z, \sigma, j, e_j)$ .

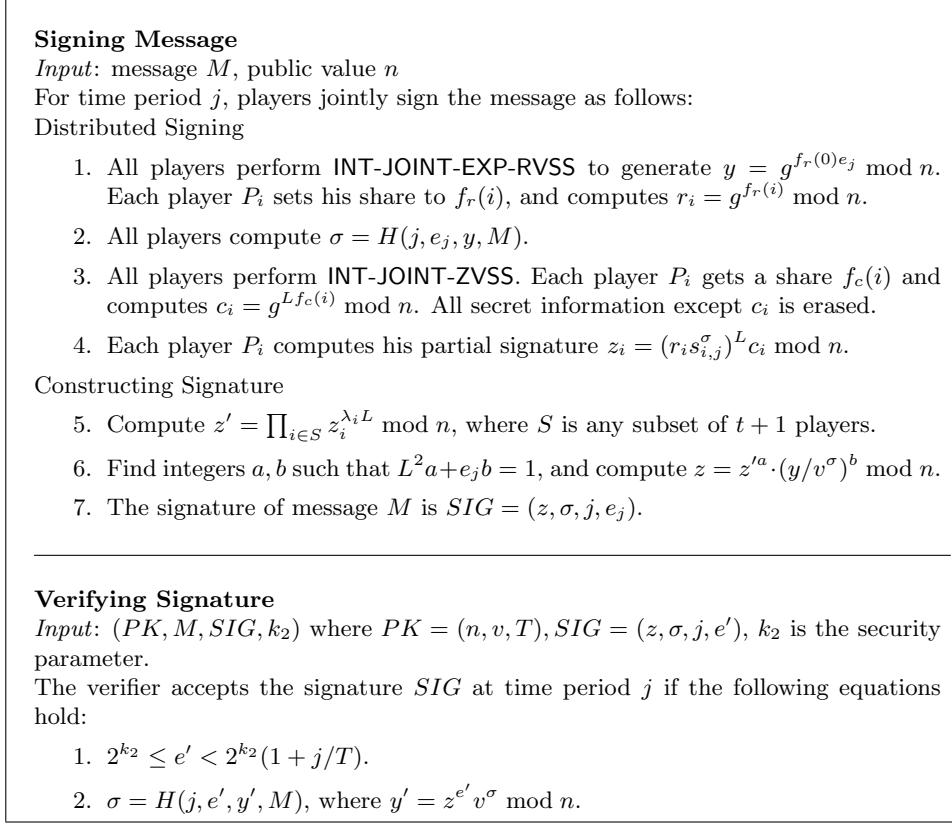

Figure 5: TH-FS-GQ - Signing and Verifying

#### 4.4 Signature verification

In order to have a constant size for the public key, the time period exponents  $e_1, e_2, \dots, e_T$  are computed when necessary. They are not part of the public key. Since the verifier gets  $e'$  from the signature, it need make sure that it is in between  $2^{k_2}(1 + (j - 1)/T)$  and  $2^{k_2}(1 + j/T)$ . Once  $e'$  is verified, the remaining verification is the same as that in TH-GQ-Sig.

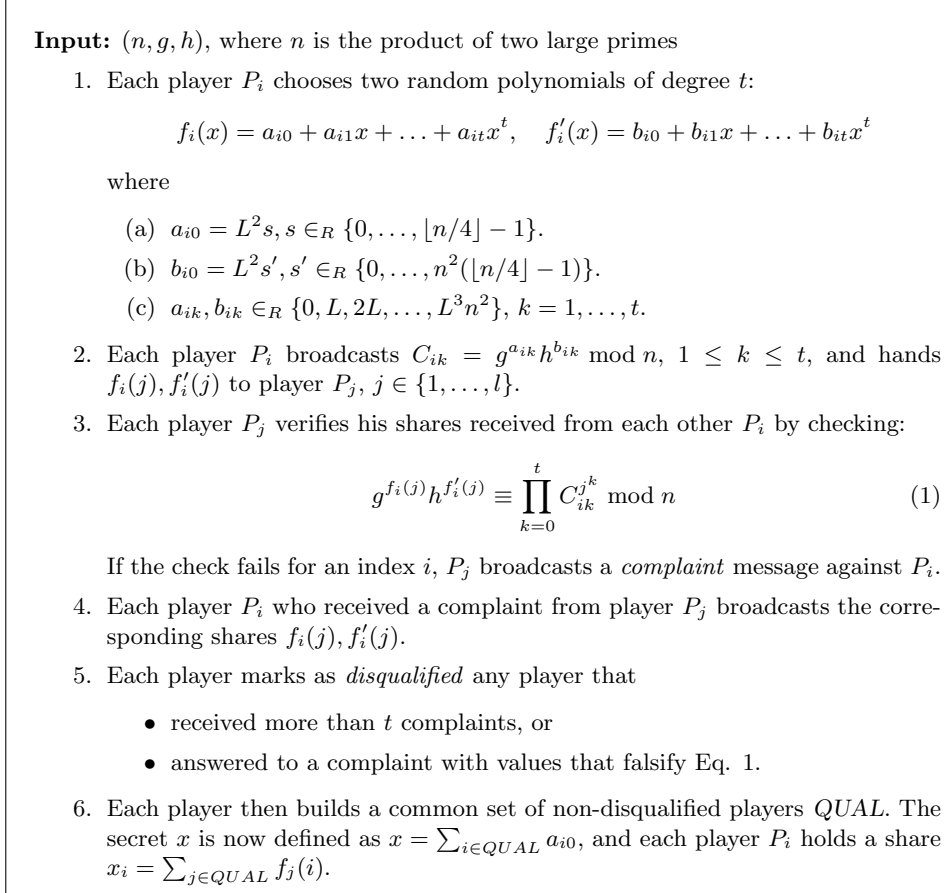

Figure 6: INT-JOINT-RVSS

## A INT-JOINT-RVSS protocol

The INT-JOINT-RVSS protocol is similar to the JOINT-RVSS protocol, except that we use unconditionally-secure VSS over integers [FGMY97, FMY98, FMY99] instead.

## B INT-JOINT-EXP-RVSS protocol

In addition to INT-JOINT-RVSS, players also need to share a random value on the exponent in some applications. For example, the distributed key generation for discrete-log based cryptosystem [Ped91, GJKR99, CGJ<sup>+</sup>99] shares the secret key  $x$  and outputs the public key  $y = g^x \bmod p$ . Our INT-JOINT-EXP-RVSS (Figure 7) is based on an adaptively-secure distributed key generation protocol [CGJ<sup>+</sup>99] except for the composite modulus and an additional constant exponent. In the protocol, players first jointly perform INT-JOINT-RVSS to share a random secret  $x$ . To compute  $y = g^{xe} \bmod n$ ,

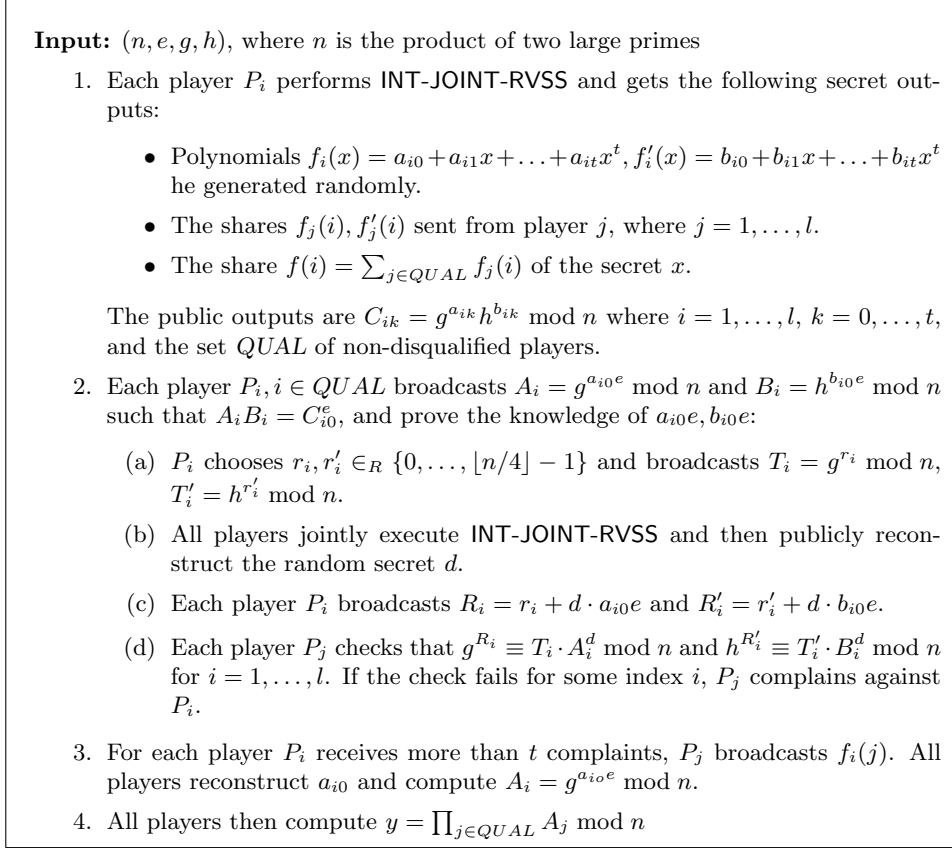

Figure 7: INT-JOINT-EXP-RVSS

each player  $P_i$  broadcasts  $A_i = g^{a_{i0}e}, B_i = h^{b_{i0}e}$  where  $\sum_{i \in QUAL} a_{i0} = x$ , and proves the knowledge of  $a_{i0}e, b_{i0}e$  by simultaneous proof technique [CGJ<sup>+</sup>99, Jar01].

We also provide a simulation for INT-JOINT-EXP-RVSS in Figure 8. On input  $y = g^{xe} \bmod n$ , the simulator constructs the same adversarial view as in the real protocol running. The simulator performs most steps on behalf of the un-corrupted players except for a random selected player  $P_u$ , which broadcasts  $A_u^*$  to fit the input  $y$  rather than computes  $A_u$  as others. For the later proof, the simulator chooses a challenge  $d^*$  and computes the appropriate commitment for  $P_u$  in advance. Then, let all players reconstruct the challenge  $d^*$ ,  $P_u$  will pass the verification. However, since the adaptive adversary corrupts players dynamically, if  $P_u$  is corrupted in the simulation, the simulator rewinds to the step 2 and executes all the following steps again.

**Input:** the result value  $y$  and parameters  $(n, e, g, h)$

1. Perform INT-JOINT-RVSS on behalf of honest players.
2. Choose an uncorrupted player  $P_u$ , and do the following computation:
  - Compute  $A_i = g^{a_{i0}e} \bmod n$  and  $B_i = h^{b_{i0}e} \bmod n$  for  $i \in QUAL \setminus \{u\}$ .
  - Set  $A_u^* = y \cdot \prod_{i \in QUAL \setminus \{u\}} A_i^{-1} \bmod n$  and  $B_u^* = C_{u0}^e / A_u^* \bmod n$ .
  - Choose  $d^*, R_u, R'_u \in_R \{0, \dots, \lfloor n/4 \rfloor - 1\}$  and set  $T_u^* = g^{R_u} \cdot (A_u^*)^{-d^*} \bmod n$ ,  $T'_u = g^{R'_u} \cdot (B_u^*)^{-d^*} \bmod n$ .
3. Broadcast  $A_i$  for player  $P_i, i \in QUAL \setminus \{u\}$  and  $A_u^*$  for player  $P_u$ .
4. Perform Step 2a in the protocol on behalf of each player  $P_i, i \in QUAL \setminus \{u\}$ , and broadcast  $T_u^*$  and  $T'_u$  for player  $P_u$ .
5. Perform INT-JOINT-RVSS on behalf of honest players as Step 2b in the protocol, and each  $P_i$  gets a share  $d_i$ . Pick a random  $t$ -degree polynomial  $f_d^*(x)$  over integers such that  $f_d^*(0) = d^*, f_d^*(i) = d_i$  for  $i \in \mathcal{B}$ . Erase all other secret information generated in INT-JOINT-RVSS.
6. Broadcast  $f_d^*(i)$  for each honest player  $P_i$ .
7. Broadcast  $R_i, R'_i$  computed as Step 2c for player  $P_i, i \in \mathcal{G} \setminus \{u\}$ . Broadcast  $R_u^*, R'_u$  for player  $P_u$ .
8. Verify the proof as in the protocol. If players in  $\mathcal{B}$  receive more than  $t$  complaints, all other players reconstruct their secrets.
9. Erase all secret information except  $f(i)$ .
