**Abstract.** We propose the first distributed discrete-log key generation (DLKG) protocol from scratch which is adaptively-secure in the non-erasure model, and at the same time completely avoids the use of interactive zero-knowledge proofs. As a consequence, the protocol can be proven secure in a universally-composable (UC) like framework which prohibits rewinding. We prove the security in what we call the single-inconsistent-player (SIP) UC model, which guarantees arbitrary composition as long as all protocols are executed by the same players. As applications, we propose a fully UC threshold Schnorr signature scheme, a fully UC threshold DSS signature scheme, and a SIP UC threshold Cramer-Shoup cryptosystem.

Our results are based on a new adaptively-secure Feldman VSS scheme. Although adaptive security was already addressed by Feldman in the original paper, the scheme requires secure communication, secure erasure, and either a linear number of rounds or digital signatures to resolve disputes. Our scheme overcomes all of these shortcomings, but on the other hand requires some restriction on the corruption behavior of the adversary, which however disappears in some applications including our new DLKG protocol.

We also propose several new adaptively-secure protocols, which may find other applications, like a distributed trapdoor-key generation protocol for Pedersen's commitment scheme, an adaptively-secure Pedersen VSS scheme (as a *committed* VSS), or distributed-verifier proofs for proving relations among commitments or even any NP relations in general.

## 1 Introduction

A distributed key generation protocol is an essential component in threshold cryptography. It allows a set of  $n$  players to jointly generate a key pair,  $(pk, sk)$ , that follows the distribution defined by the target cryptosystem, without the need for a trusted party. While the public-key  $pk$  is output in clear, the corresponding secret-key  $sk$  remains hidden and is maintained in a shared manner among the players via a secret sharing scheme. This should allow the players to later use  $sk$  without explicitly having to reconstruct it. The distributed key-generation for discrete-log based schemes, DLKG in short, amounts to the joint generation of a random group element  $y$  as public-key and a sharing of its discrete-log (DL)  $x = \log_g(y)$  as secret-key with regard to some given base  $g$ . A DLKG protocol must remain secure in the presence of a malicious adversary who may corrupt up to a minority of the players and make them behave in an arbitrary way. Informally, it is required that, for any adversary,  $y$  must be uniformly distributed, and the adversary must learn nothing about  $x$  beyond  $y = g^x$ .

DLKG was first addressed by Pedersen in [18]. Gennaro *et al.* pointed out that Pedersen's scheme is not secure against a rushing adversary (and even against a non-rushing adversary) and proposed a new (statically) secure scheme [14]. Then Frankel *et al.* and Canetti *et al.*

introduced in [13] respectively [7] adaptively secure schemes in the erasure model, and Jarecki and Lysyanskaya improved the schemes to work in the non-erasure model and to remain secure under concurrent composition [16].

These DLKG protocols which are secure against an adaptive adversary rely heavily on the use of interactive zero-knowledge proofs. This poses the question whether this is an inherent phenomenon for adaptively secure DLKG. We answer this question in the negative. Concretely, we propose an adaptively-secure distributed key-generation protocol from scratch which completely avoids the use of interactive zero-knowledge proofs. As a consequence, the protocol can be and is proven secure in a relaxed version of Canetti’s universally-composable (UC) framework [4], which prohibits rewinding. We show the usefulness of our distributed key-generation protocol by showing how it gives rise to a *fully* UC threshold Schnorr signature scheme as well as a *fully* UC threshold DSS signature scheme. To the best of our knowledge, these are the first threshold schemes proven secure in the UC framework. We also point out how to combine our results with [16] to get a threshold Cramer-Shoup cryptosystem provably secure in the relaxed UC framework.

The relaxed UC framework, which we call the single-inconsistent-player (SIP) UC framework, coincides with the original UC framework, except that the simulator is allowed to fail in case the adversary corrupts some designated player  $P_{j^*}$ , which is chosen at random from the set of all players and announced to (and only to) the simulator. This relaxation still allows for a powerful composition theorem in that protocols may be arbitrary composed, as long as all subsidiary protocols involve the same set of players.

We stress once more that this relaxation only applies to the proposed distributed key-generation protocol but *not* to its application for the threshold signature schemes.

Our DLKG protocol is based on a new adaptively-secure version of Feldman’s famous (statically secure) VSS scheme. Although adaptive security was already addressed by Feldman in the original paper [12], and besides the well known standard Feldman VSS scheme he also proposed an adaptively-secure version, the proposed scheme has several shortcomings: (1) it requires the players to be able to reliably erase data, (2) it either proceeds over a linear number of rounds or otherwise needs to incorporate signatures as we will point, and (3) it requires secure communication channels (or expensive non-committing encryption schemes). We propose a new variant of Feldman’s VSS scheme which overcomes all of these limitations. Even though the proposed scheme is not fully adaptively secure but requires some restriction on the corruption behavior of the adversary, this restriction is acceptable in that it disappears in the above applications to threshold cryptography.

Furthermore, as building blocks for the above schemes or as related constructions, we also propose several adaptively-secure protocols of independent interest which may very well find other applications: a simple modification of Feldman’s adaptively-secure VSS scheme which overcomes (1) and (2) above, though not (3), but is *fully* adaptively-secure, a new adaptively-secure distributed trapdoor-key generation protocol for Pedersen’s commitment scheme, an adaptively secure version of Pedersen’s VSS scheme as a *committed* VSS, and (distributed-verifier) zero-knowledge proofs in the UC model.

The paper is organized as follows. Section 2 reviews the model we are considering. It includes an introduction to the UC framework of Canetti and the new SIP UC framework. In Sect. 3 we recall Feldman’s statically and adaptively secure VSS schemes, and we point out an obstacle in the dispute resolution phase of the adaptive scheme, before we construct our version in Sect. 4. Finally, Sect. 5 shows the applications to adaptively-secure DLKG and universally-composable threshold cryptography, and some related constructions are given in Sect. 6. For improved readability, some lengthy proofs have been moved to the appendix.

## 2 Preliminaries

### 2.1 Communication and Adversary

We consider a *synchronized authenticated-link model* where a message from  $P_s$  to  $P_r$  is delivered within a constant delay and accepted by  $P_r$  if and only if it is sent from  $P_s$  to  $P_r$ . Moreover, we assume a broadcast channel with which every player sends a message authentically and all players receives the same message.

We consider a central adversary  $\mathcal{A}$  which may corrupt players at will. Corrupting a player  $P_i$  allows  $\mathcal{A}$  to read  $P_i$ 's internal state and to act on  $P_i$ 's behalf from that point on. In the non-erasure model,  $\mathcal{A}$  additionally gains  $P_i$ 's complete history.  $\mathcal{A}$  is called *t-limited* if it corrupts at most  $t$  players. Furthermore,  $\mathcal{A}$  is called *static* if it corrupts the players *before* the protocol starts, and  $\mathcal{A}$  is called *adaptive* if it corrupts the players *during* the execution of the protocol, depending on what it has seen so far.

### 2.2 Canetti's Universally Composable Framework

In order to formally specify and prove the security of our protocols, we will use the universally composable (UC) framework of Canetti [4]. In this framework, a protocol  $\pi$  is compared with an *ideal functionality*  $\mathcal{F}$ . Such a functionality can be thought of as a trusted party with whom every player can communicate privately. There is a number of commands specified that  $\mathcal{F}$  will execute. Every player can privately send a command to  $\mathcal{F}$ , and  $\mathcal{F}$  will faithfully carry out the command according to its specification, and may send results back privately to (some of) the players and the adversary. For instance the assumed broadcast channel can be seen as a functionality, say  $\mathcal{F}_{\text{BB}}$ , such that on receiving  $(\text{send}, \text{sid}, P_j, m)$ , it sends  $(\text{sid}, P_j, m)$  to all players and the adversary in a synchronized way.

Many cryptographic constructions – including ours – actually aim at building a protocol  $\pi$  for the players only (without a trusted party) that does “the same thing” as some ideal functionality  $\mathcal{F}$ , even if the adversary  $\mathcal{A}$  can corrupt some of the players. The framework provides on one hand a precise definition of what it means that a protocol  $\pi$  securely realizes  $\mathcal{F}$ . On the other hand it provides the following composition theorem. For any protocol  $\rho$  that securely realizes functionality  $\mathcal{G}$  in the so-called  $\mathcal{F}$ -hybrid model, meaning that it may use  $\mathcal{F}$  as a subroutine, composed protocol  $\rho^\pi$  that replaces  $\mathcal{F}$  with a secure protocol  $\pi$  also securely realizes  $\mathcal{G}$  (in the real-life model).

To prove that a protocol  $\pi$  securely realizes  $\mathcal{F}$ , one has to construct, for every adversary  $\mathcal{A}$  attacking the protocol in question, an ideal-life adversary, or *simulator*  $\mathcal{S}$ , which gets to attack an ideal scenario where only the players and  $\mathcal{F}$  are present. The goal of  $\mathcal{S}$  is to achieve “the same” as  $\mathcal{A}$  could have achieved by an attack on the real protocol. In the framework, this is formalized by considering an *environment*  $\mathcal{Z}$  which provides inputs to and collects outputs from the honest players and can communicate in the real-life execution with  $\mathcal{A}$  and in the ideal-life execution with  $\mathcal{S}$ , and it is required that it cannot tell the difference.

Formally, let  $\text{REAL}_{\pi, \mathcal{A}, \mathcal{Z}}(\kappa, a)$  denote the binary distribution of the output of  $\mathcal{Z}$  with input  $a \in \{0, 1\}^*$  after observing the real-life computation with security parameter  $\kappa \in \mathbb{N}$  and uniformly chosen randomness for every player and  $\mathcal{A}$ . Let  $\text{REAL}_{\pi, \mathcal{A}, \mathcal{Z}}$  denote the ensemble of  $\text{REAL}_{\pi, \mathcal{A}, \mathcal{Z}}(\kappa, a)$  for all  $\kappa$  and  $a$ . Similarly, let  $\text{IDEAL}_{\mathcal{F}, \mathcal{S}, \mathcal{Z}}(\kappa, a)$  and  $\text{IDEAL}_{\mathcal{F}, \mathcal{S}, \mathcal{Z}}$  denote the binary distribution of the output of  $\mathcal{Z}$  and its ensemble, respectively, regarding the ideal-model computation. The protocol  $\pi$  is said to securely realize  $\mathcal{F}$  (in the real-life model), or simply to be secure, if for every adversary  $\mathcal{A}$  there exists a simulator  $\mathcal{S}$ , such that no environment  $\mathcal{Z}$  can tell if it is in the real-life or the ideal-life execution, more precisely,

such that  $\text{REAL}_{\pi, \mathcal{A}, \mathcal{Z}} \approx \text{IDEAL}_{\mathcal{F}, \mathcal{S}, \mathcal{Z}}$  for every environment  $\mathcal{Z}$ , where  $\approx$  denotes computational indistinguishability: for all positive constant  $c \in \mathbb{N}$  and for all sufficiently large  $\kappa$  and all  $a \in \{0, 1\}^*$ ,

$$|\Pr[\text{REAL}_{\pi, \mathcal{A}, \mathcal{Z}}(\kappa, a) = 1] - \Pr[\text{IDEAL}_{\mathcal{F}, \mathcal{S}, \mathcal{Z}}(\kappa, a)]| < \kappa^{-c}.$$

This extends to the security of protocols in the hybrid model. That is, protocol  $\rho$  in the  $\mathcal{F}$ -hybrid model securely realizes functionality  $\mathcal{G}$  if for every hybrid-model adversary  $\mathcal{A}$  there exists a simulator  $\mathcal{S}$  such that  $\text{HYB}_{\rho, \mathcal{A}, \mathcal{Z}}^{\mathcal{F}} \approx \text{IDEAL}_{\mathcal{G}, \mathcal{S}, \mathcal{Z}}$  for all environments  $\mathcal{Z}$ , where  $\text{HYB}_{\rho, \mathcal{A}, \mathcal{Z}}^{\mathcal{F}}$  is the ensemble of the output distribution of  $\mathcal{Z}$  interacting with parties running  $\rho$  in the  $\mathcal{F}$ -hybrid model. Then, the composition theorem guarantees that if protocol  $\pi$  securely realizes  $\mathcal{F}$  in the real-life model, then the composed protocol  $\rho^\pi$  securely realizes  $\mathcal{G}$  in the real-life model. For more details, see [4].

In proofs of this type of security, the simulator  $\mathcal{S}$ , which is running in the ideal-life execution with players  $\tilde{P}_1, \dots, \tilde{P}_n$ , typically works as follows.  $\mathcal{S}$  internally runs a copy of the adversary  $\mathcal{A}$  and, by impersonating the real-life players  $P_1, \dots, P_n$  (and functionality  $\mathcal{F}$  in the  $\mathcal{F}$ -hybrid model),  $\mathcal{S}$  simulates  $\mathcal{A}$ 's view of an execution of the protocol consistent with the in- and output(s) in the ideal-life execution. Any interaction between  $\mathcal{Z}$  and  $\mathcal{A}$  is passed back and forth with no change. If  $\mathcal{S}$  can simulate  $\mathcal{A}$ 's view such that together with the outputs of the honest  $\tilde{P}_i$ 's it is computationally indistinguishable from  $\mathcal{A}$ 's view and the honest  $P_i$ 's outputs in a real execution with the same inputs, then  $\mathcal{Z}$  will not be able to tell any difference.

### 2.3 Single-Inconsistent-Player UC Framework

The single-inconsistent-player (SIP) technique of [7] is often used to achieve both adaptive security and efficiency. A protocol in the SIP model is secure (i.e. securely simulatable in the classical model of computation) if the adversary does not corrupt a designated player which is chosen independently at random before the protocol starts. Using the terms of the UC framework, it means that the simulator  $\mathcal{S}$  is given as input the identity of a randomly chosen player  $P_{j^*}$ , and  $\mathcal{S}$  is required to work well as long as  $P_{j^*}$  is uncorrupt. In the case of  $t$ -limited adversary with  $t < n/2$ , this reduces  $\mathcal{S}$ 's success probability by a factor of  $1/2$ . This still guarantees security in that whatever  $\mathcal{A}$  can do in the real-life model,  $\mathcal{S}$  has a good chance in achieving the same in the ideal-life model. Indeed, in the classical sense, a simulator is considered successful if it works better than with negligible probability. However, with such a simulator  $\mathcal{S}$ , the composition theorem no longer works in its full generality. To minimize the effect of the SIP approach, we have to limit the set of players to be the same in all subsidiary protocols. This way,  $P_{j^*}$  can be sampled once and for all, and the condition that  $P_{j^*}$  remains uncorrupt applies to (and either holds or does not hold) simultaneously for all protocols. With this limitation, the composition theorem essentially works as before.

This is formalized as follows. We include the choice of  $j^*$  in the probability space and extend the notation  $\text{IDEAL}_{\mathcal{F}, \mathcal{S}, \mathcal{Z}}(\kappa, a)$  to represent the output distribution of  $\mathcal{Z}$  for such a  $\mathcal{S}$ . Let  $\text{corr}$  denote the event that  $P_{j^*}$  is corrupted. Suppose that protocol  $\pi$  securely realizes functionality  $\mathcal{F}$  in the SIP UC model in the sense that for any adversary  $\mathcal{A}$ , there exists  $\mathcal{S}_\pi$  such that for any environment  $\mathcal{Z}$

$$|\Pr[\text{REAL}_{\pi, \mathcal{A}, \mathcal{Z}}(\kappa, a) = 1 | \neg \text{corr}] - \Pr[\text{IDEAL}_{\mathcal{F}, \mathcal{S}_\pi, \mathcal{Z}}(\kappa, a) | \neg \text{corr}]| < \kappa^{-c},$$

for any constant  $c$  and sufficiently large  $\kappa$ . In short,  $\text{REAL}_{\pi, \mathcal{A}, \mathcal{Z} | \neg \text{corr}} \approx \text{IDEAL}_{\mathcal{F}, \mathcal{S}_\pi, \mathcal{Z} | \neg \text{corr}}$ . Also suppose that a  $\mathcal{F}$ -hybrid model protocol  $\rho$  securely realizes functionality  $\mathcal{G}$  in the SIP

UC model in that for every  $\mathcal{A}$  there exists  $\mathcal{S}_\rho$  such that  $\text{HYB}_{\rho, \mathcal{A}, \mathcal{Z}}^{\mathcal{F}} \approx \text{IDEAL}_{\mathcal{G}, \mathcal{S}_\rho, \mathcal{Z}} | \neg \text{corr}$  for all  $\mathcal{Z}$ . Then, the SIP universal composition theorem states that the composed protocol  $\rho^\pi$  securely realizes  $\mathcal{G}$  in the (real-life) SIP UC model, i.e., for every  $\mathcal{A}$  there exists  $\mathcal{S}_\rho$  such that  $\text{REAL}_{\rho^\pi, \mathcal{A}, \mathcal{Z}} | \neg \text{corr} \approx \text{IDEAL}_{\mathcal{G}, \mathcal{S}, \mathcal{Z}} | \neg \text{corr}$  for all  $\mathcal{Z}$ . This theorem can be proven essentially in the same way as for the original UC theorem with some minor adjustments.  $\mathcal{S}$  mainly behaves as  $\mathcal{S}_\rho$  does. For every invocation of sub-protocol  $\pi$  within  $\rho$ ,  $\mathcal{S}$  simulates the sub-protocol by invoking  $\mathcal{S}_\pi$  with the same  $j^*$  given to  $\mathcal{S}$ . In this way, all simulation is done with respect to the same SIP  $P_{j^*}$  and  $\text{corr}$  can be treated as a global condition that holds or fails in all invocation of sub-protocols at the same time. Since  $\neg \text{corr}$  happens with probability at least  $1/2$  for any  $n/2$ -limited adversary,  $\mathcal{S}$  achieves good quality of reduction for evaluating the security of composed protocol  $\rho^\pi$ .

## 2.4 Modeling Secure Message Transmission and Committed VSS

*Secure Message Transmission (SMT)*: Following [4], secure communication is modeled by the following functionality.

**Definition 1 (Secure Message Transmission Functionality:  $\mathcal{F}_{\text{SMT}}$ ).**

On receiving  $(\text{send}, \text{sid}, P_r, m)$  from  $P_s$ ,  $\mathcal{F}_{\text{SMT}}$  sends  $(\text{sid}, P_s, m)$  to  $P_r$  and  $(\text{sid}, P_s, P_r)$  to  $\mathcal{S}$ .

Note that it is required by definition of the hybrid-model that  $(\text{sid}, P_s, P_r)$  is sent to  $\mathcal{S}$ . If the length of  $m$  may vary, it is also given to  $\mathcal{S}$ .

This functionality, however, cannot be realized in the synchronized communication model where messages will never be blocked by the adversary. This is important for us since we assume the use of a broadcast channel which essentially results in assuming all communication be done in a synchronized way. It is known that such  $\mathcal{F}_{\text{SMT}}$  can be realized in the authenticated and asynchronous communication model where  $\mathcal{S}$  can block the message from  $\mathcal{F}_{\text{SMT}}$  to  $P_r$ . The realization, say  $\pi_{\text{SMT}}$ , requires the sender and the receiver to interact in order to complete the transmission. Now, when  $\mathcal{F}_{\text{SMT}}$  is considered in the synchronized communication model where  $\mathcal{S}$  cannot block the message from  $\mathcal{F}_{\text{SMT}}$  to the receiver, the message transmission in the ideal-process is *atomic* in such a sense that once it is invoked it is always completed. On the other hand, if  $\pi_{\text{SMT}}$  is first invoked by an honest sender and the sender is later corrupted by  $\mathcal{A}$  and ordered to halt or to lead the receiver to reject,  $\mathcal{S}$  cannot simulate such a situation in the ideal-process since the message once sent off from the honest sender has to be delivered to the receiver. So in the current model,  $\pi_{\text{SMT}}$  must be non-interactive to securely realize  $\mathcal{F}_{\text{SMT}}$  in the synchronized communication model in the presence of an adaptive adversary.<sup>3</sup> Although aborting the protocol is harmless as long as its aftermath can be treated in a correct way and the model should be changed to be able to handle this type of really ideal functionalities, we decided to ease the functionality to fit to the current model so that unexpected flaws caused by the change of the model can be avoided. Concretely, we consider *spooled* message transmission functionality, denoted by  $\mathcal{F}_{\text{SSMT}}$ , to capture the case where as a consequence of a corruption the sender changes its mind during the execution of the protocol.

<sup>3</sup> As pointed out by Nielsen [17], a similar problem also appears in the context of commitment schemes: the standard commitment functionality cannot be securely realized by an interactive protocol (in which the first message is not yet committing), *not even in the asynchronous communication model*. This uncovers a flaw in essentially all “proven-secure” UC commitments [6, 11].

**Definition 2 (Spooled SMT Functionality:  $\mathcal{F}_{\text{SSMT}}$ ).**

1. On receiving  $(\text{spool}, \text{sid}, P_r, m)$  from  $P_s$ , record  $m$  and send  $(\text{spooled}, \text{sid}, P_s, P_r)$  to  $\mathcal{S}$ .
2. On receiving  $(\text{send}, \text{sid})$  from  $P_s$ , send  $(\text{sid}, P_s, m)$  to  $P_r$  and  $(\text{received}, \text{sid})$  to  $\mathcal{S}$ ; or, on receiving  $(\text{send}, \text{sid}, m')$  from corrupted  $P_s$ , send  $(\text{sid}, P_s, m')$  to  $P_r$ .

In the definition of this functionality, we implicitly understand that each step is performed only once and in order. This rule applies to all functionalities defined in this paper, unless explicitly stated otherwise.

Finally, the following extended version of  $\mathcal{F}_{\text{SSMT}}$  allows the sender, in case of a dispute, to convince the other players of the message  $m$  sent to the receiver.

**Definition 3 (Spooled SMT Functionality with Opening:  $\mathcal{F}_{\text{SSMTwo}}$ ).**

1. On receiving  $(\text{spool}, \text{sid}, P_r, m)$  from  $P_s$ , send  $(\text{spooled}, \text{sid}, P_s, P_r)$  to  $\mathcal{S}$ .
2. On receiving  $(\text{send}, \text{sid})$  from  $P_s$ , send  $(\text{sid}, P_s, m)$  to  $P_r$  and  $(\text{received}, \text{sid})$  to  $\mathcal{S}$ ; or, on receiving  $(\text{send}, \text{sid}, m')$  from corrupted  $P_s$ , send  $(\text{sid}, P_s, m')$  to  $P_r$ , and set  $m := m'$ .
3. On receiving  $(\text{open}, \text{sid})$  from  $P_s$ , send  $(\text{sent}, \text{sid}, P_s, P_r, m)$  to all players and  $\mathcal{S}$ .

It is important to see that  $(\text{open}, \text{sid})$  is executed only if it is given from  $P_s$ . In some sense, the sender commits the message to the network and opens it when needed.

As one can imagine, such a functionality could be realized in the straightforward way in the secure-channel model by using digital signature functionality; the receiver signs the received message and returns the signature to the sender through a secure-channel.

*Committed VSS:* An advantage of using Feldman and Pedersen VSS in protocol design is that besides producing a (correct) sharing, they also commit the dealer to the shared secret. Often, this commitment can be and is used in upper-level protocols. However, in the definition of UC-secure VSS given in [4], such a commitment is hidden in the protocol and not part of the functionality, and thus not available for external protocols. We introduce the notion of *committed VSS* to overcome this inconvenience.

Let  $\text{com}_K : S_K \times R_K \rightarrow Y_K$  be a (efficiently computable) commitment function, indexed by a *commitment key*  $K$ . Typically,  $K$  is sampled by a poly-time generator (on input the security parameter  $\kappa$ ). A commitment for a secret  $s \in S_K$  is computed as  $y = \text{com}_K(s; r)$ , where we use the semicolon ';' to express that the second argument,  $r$ , is chosen randomly (from  $R_K$ ) unless it is explicitly given.

A committed VSS is a type of VSS where the dealer is committed to the shared secret  $s$  by  $\text{com}_K(s; r)$  as a result of the protocol execution. It is understood as a VSS whose sharing phase leaks nothing but  $\text{com}_K(s; r)$  with regard to secret  $s$ . We formally model this notion for a threshold access structure (with threshold  $t + 1$ ) by the following functionality.

**Definition 4 (Committed Verifiable Secret Sharing Functionality:  $\mathcal{F}_{\text{VSS}}^{\text{com}_K}$ ).**

1. On receiving  $(\text{share}, \text{sid}, (s, r))$  from dealer  $P_d$ , send  $(\text{shared}, \text{sid}, P_d, \text{com}_K(s; r))$  to all players and  $\mathcal{S}$ .
2. On receiving  $(\text{open}, \text{sid})$  from  $t + 1$  distinct players send  $(\text{opened}, \text{sid}, s)$  to all players and  $\mathcal{S}$ .

Optionally,  $\mathcal{F}_{\text{SVSS}}^{\text{com}_K}$  might also be instructed to additionally announce  $r$  in step 2. Because of the same reason as in the modeling of the secure message transmission, we need to allow an adaptively corrupted dealer to change his mind during the protocol execution. As above, this is done by incorporating spooling into the VSS functionality.

**Definition 5 (Committed Verifiable Secret Sharing with Spooling:  $\mathcal{F}_{SVSS}^{\text{com}_K}$ ).**

1. On receiving (spool, sid, (s, r)) from dealer  $P_d$ , send (spooled, sid,  $P_d, y$ ) to  $\mathcal{S}$  where  $y = \text{com}_K(s; r)$ .
2. On receiving (share, sid) from  $P_d$ , send (shared, sid,  $P_d, y$ ) to all players and  $\mathcal{S}$ ; or, on receiving (share, sid, (s', r')) from corrupt  $P_d$ , send (shared, sid,  $P_d, y'$ ) to all players where  $y' = \text{com}_K(s'; r')$  and set  $s := s'$ .
3. On receiving (open, sid) from  $t + 1$  distinct players, send (opened, sid, s) to all players and  $\mathcal{S}$ .

We stress that, in both definitions,  $y$  must be determined only from the input. This is because in the real world,  $y$  is chosen by the possibly corrupt dealer and may follow a distribution the simulator does not know. Hence it is too much demanding that  $r$  is generated inside the ideal functionality.<sup>4</sup>

We would like to mention that for certain candidate protocols  $\pi_{VSS}$  for committed VSS (with spooling), whose security relies on the commitment scheme  $\text{com}_K$ , the generation of the key  $K$  needs to be added to the VSS functionality in order to be able to prove  $\pi_{VSS}$  secure in the UC framework. This is for instance the case for Pedersen's VSS scheme as discussed in Section 6.2.

## 2.5 The Discrete-Log Setting

Let  $\kappa$  be a security parameter and  $q$  be a prime of size  $\kappa$ . Let  $G_q$  denote a group of order  $q$ , and let  $g$  be its generator. We use multiplicative notation for the group operation of  $G_q$ . Some of our constructions require  $G_q$  to be the order- $q$  multiplicative subgroup of  $\mathbb{Z}_p^*$  with prime  $p = 2q + 1$ . Unless otherwise noted, all arithmetics are done in  $\mathbb{Z}_q$  or  $G_q$  and should in each case be clear from the context.

Throughout, we assume that such  $(G_q, q, g)$  is given to all players, and that the Decision Diffie-Hellman problem for  $(G_q, q, g)$  is intractable, meaning that the respective uniform distributions over  $\text{DH} = \{(g^\alpha, g^\beta, g^\gamma) \in G_q^3 \mid \alpha \cdot \beta = \gamma\}$  and  $\text{RND} = G_q^3$  are computationally indistinguishable. This assumption implies the discrete-log assumption for  $(G_q, q, g)$ : given a random  $h = g^\omega$ , it is computationally infeasible to compute  $\omega$ .

## 3 The Original Feldman VSS

*The Basic Scheme:* Let  $\alpha_1, \dots, \alpha_n \in \mathbb{Z}_q$  be distinct and non-zero. In order to share a (random) secret  $s \in \mathbb{Z}_q$ , the dealer selects a Shamir sharing polynomial  $f(X) = s + a_1X + \dots + a_tX^t \in \mathbb{Z}_q[X]$  and sends  $s_j = f(\alpha_j)$  privately to  $P_j$ . Additionally, he broadcasts  $C_0 = g^s$  as well as  $C_k = g^{\alpha_k}$  for  $k = 1, \dots, t$ . Each player  $P_j$  now verifies whether

$$g^{s_j} = \prod_{k=0}^t C_k^{\alpha_j^k}. \quad (1)$$

If it does not hold for some  $j$ , then player  $P_j$  broadcasts an *accusation* against the dealer, who has to respond by broadcasting  $s_j$  such that (1) holds. If he fails, then the execution is

<sup>4</sup> This observation leads to an interesting consequence, namely that Pedersen VSS is not secure in the UC framework if  $y$  is considered as a part of its output despite the fact that the shared secret is perfectly independent of the joint view of any  $t$  corrupted players. This subject is discussed more extensively in Section 6.2.

rejected, while otherwise  $P_j$  uses the new  $s_j$  as his share. Correct reconstruction is achieved simply by filtering out shares that do not satisfy (1).

This scheme is proved secure against a *static* adversary: Assume that  $\mathcal{A}$  corrupts  $P_{j_1}, \dots, P_{j_t}$ . Given  $C_0 = g^s$ , the simulator  $\mathcal{S}$  simply chooses random shares  $s_{j_i} \in \mathbb{Z}_q$  ( $i = 1 \dots t$ ) for the corrupted players, and it computes  $C_1, \dots, C_t$  with the right distribution from  $g^s$  and  $g^{s_{j_1}}, \dots, g^{s_{j_t}}$ 's by applying appropriate Lagrange interpolation coefficients "in the exponent". Informally, this shows that  $\mathcal{A}$  learns nothing about  $s$  beyond  $g^s$ .

This simulation-based proof though fails completely if the adversary may corrupt players *adaptively*, i.e., during or even after the execution of the protocol. The problem is that given  $C_0 = g^s$ ,  $\mathcal{S}$  needs to come up with  $C_1, \dots, C_t$  such that if  $\mathcal{A}$  corrupts some player  $P_j$  at some later point,  $\mathcal{S}$  can serve  $\mathcal{A}$  with  $s_j$  such that (1) is satisfied. However, it is not known how to successfully provide such  $s_j$  for any dynamic choice of  $j$  without knowing  $s$ , unless  $\mathcal{A}$  corrupts the dealer to start with.

*Adaptive Security with Erasure:* Feldman addressed adaptive security by providing a set-up phase where the dealer assigns a *private* X-coordinate  $\alpha_j \in \{1, \dots, n\}$  to every  $P_j$ . Additionally, he needs to convince the players of the uniqueness of their  $\alpha_j$ . This is done in the following way. Let  $E$  be a semantically-secure public-key encryption function, with public-key chosen by the dealer.

1. The dealer computes an encryption  $A_j = E(j; r_j)$  (with random  $r_j$ ) for every  $j \in \{1, \dots, n\}$ , and he chooses  $\alpha_1, \dots, \alpha_n$  as a random permutation of  $1, \dots, n$ . Then, he broadcasts  $A_1, \dots, A_n$  ordered in such a way that  $A_j$  appears in  $\alpha_j$ -th position, and he privately sends  $(\alpha_j, r_j)$  to  $P_j$ .
2. Each  $P_j$  locates  $A_j$  in position  $\alpha_j$  and verifies whether  $A_j = E(j; r_j)$  and, if it holds, erases  $r_j$ . The dealer erases  $r_1, \dots, r_n$ , too.

After the erasure is completed, the dealer performs the basic Feldman VSS with X-coordinates  $\alpha_1, \dots, \alpha_n$ . We stress that it is important that the erasures of the  $r_j$ 's must be done before entering to the sharing phase. On reconstruction, each player broadcasts  $(\alpha_j, s_j)$ .

Since each  $A_j$  can be opened only to  $j$ , player  $P_j$  is convinced of the uniqueness of  $\alpha_j$ . Simulation against an adaptive adversary is argued separately for each phase. If a player gets corrupted in the set-up phase, the simulator  $\mathcal{S}$  just honestly gives the internal state of the corrupt player to the adversary. Nothing needs to be simulated. Then, the sharing phase is simulated similar as for the static adversary, except that, since  $\mathcal{S}$  does not know which players will be corrupted, it predetermines shares for a *random* subset of size  $t$  of the X-coordinates  $\{1, \dots, n\}$ , and whenever a player  $P_j$  gets corrupted one of these prepared X-coordinates is assigned to  $P_j$  as his  $\alpha_j$ . Since  $r_j$  has already been erased, it is computationally infeasible to determine whether  $A_i$  in position  $\alpha_j$  is an encryption of  $j$  or not.

*An Obstacle in Dispute Resolution:* We identify a problem in the dispute resolution of the above scheme.<sup>5</sup> Suppose that honest  $P_j$  accuses the dealer, and that instead of publishing correct  $(\alpha_j, s_j)$ , the corrupt dealer responds by publishing  $(\alpha_i, s_i)$  of another honest player  $P_i$ . Since  $r_j$  and  $r_i$  have been already erased, both  $P_j$  and  $P_i$  have no way to prove that the published  $\alpha_i$  is different from the original assignment.

---

<sup>5</sup> No dispute resolution procedure is shown in [12]. It is said that a player simply rejects the dealer when he receives an incorrect share (and the dealer is disqualified if more than  $t + 1$  players rejects). But this works only if  $t < n/3$ .

To efficiently settle such a dispute, digital signature scheme will be needed. That is, the dealer sends  $\alpha_j$  with his signature in the set-up phase. This allows  $P_j$  to publish the signature when he accuses the dealer in the sharing phase. Without using digital signatures,  $O(t)$  additional rounds are needed to settle the dispute: If  $P_i$  observes that his  $(\alpha_i, s_i)$  is published to respond to the accusation from  $P_i$ ,  $P_i$  also accuses the dealer and the dealer publishes the data for  $P_i$  this time. After repeating this accuse-then-publish process at most  $t + 1$  times, the dealer either gets stuck or exposes  $t + 1$  correct shares.

## 4 Adaptive Security without Overheads and Erasures

The goal of this section is an adaptively secure Feldman VSS that provides (1) security without the need for reliably erasing data, (2) efficient dispute resolution without digital signatures, and (3) efficient realization over a public network, i.e. without secure channels (or expensive non-committing encryptions).

The first two goals are achieved by a simple modification of the original Feldman VSS. The idea is to replace the encryption function  $E$  with instantiations of a trapdoor commitment scheme with certain properties whose commitment keys are provided separately from each player so that the trapdoors are not known to the dealer. We show this modified Feldman VSS and the security proof in Sect. 6.1. Since Pedersen's commitment scheme turns out to be good enough for this purpose, we have a scheme that meets (1) and (2) solely under the DL assumption. Furthermore, the modified scheme is more efficient in the number of communication rounds over the original adaptively-secure Feldman VSS.

Hence, what the secure-channels model is concerned, we are done. Unfortunately, we do not know how to efficiently implement the above scheme efficiently over a public network, even when limiting the power of the adversary as we do in Sect. 4.2 below. Therefore, we design a new scheme which allows to seamlessly install our efficient components for public communication presented later.

### 4.1 Construction in a Hybrid Model

Our approach is to let each player  $P_j$  select a random non-zero X-coordinate  $\alpha_j \in \mathbb{Z}_q$  and send it privately to the dealer. When corrupted, a simulated player reveals a (fake) X-coordinate that has been prepared in advance to be consistent with the transcript, as in Feldman's approach. On the other hand, in case of a dispute, each player  $P_j$  should be able to convince the other players of his  $\alpha_j$ . This is achieved by initially sending  $\alpha_j$  to the dealer using secure message transmission *with opening*, as specified in Sect. 2.4 by functionality  $\mathcal{F}_{\text{SSMTwo}}$ . The scheme is detailed in Fig. 1 in the  $(\mathcal{F}_{\text{SSMTwo}}, \mathcal{F}_{\text{SSMT}})$ -hybrid model.

Consider Feldman's commitment scheme  $\text{fcom}_g$  with base  $g$ : a commitment for a secret  $s \in \mathbb{Z}_q$  is computed as  $\text{fcom}_g(s; r) = \text{fcom}_g(s) = g^s$  (without using  $r$ ).

**Proposition 1.** *Protocol  $\pi_{\text{XFVSS}}$  shown in Fig. 1 securely realizes functionality  $\mathcal{F}_{\text{SVSS}}^{\text{fcom}_g}$  in the  $(\mathcal{F}_{\text{SSMTwo}}, \mathcal{F}_{\text{SSMT}})$ -hybrid model against  $t$ -limited adaptive adversary for  $t < n/2$ .*

The proof is given in Appendix A. Essentially, it uses the same idea as Feldman's version: the simulator prepares (random) shares  $\tilde{s}_1, \dots, \tilde{s}_t$  for  $t$  X-coordinates  $\tilde{\alpha}_1, \dots, \tilde{\alpha}_t$  and assigns to every newly corrupt player  $P_j$  one of these X-coordinates as  $\alpha_j$  and the corresponding share as  $s_j$ .

**[Sharing Phase]**

- F-1. Each  $P_j$  selects  $\alpha_j \leftarrow \mathbb{Z}_q^*$  and sends  $\alpha_j$  to the dealer via  $\mathcal{F}_{\text{SSMTwo}}$ . The dealer replaces any  $\alpha_j$  that happens to be 0 by  $\alpha_j = 1$ .
- F-2. The dealer selects  $f(X) = a_0 + a_1X + \dots + a_tX^t \leftarrow \mathbb{Z}_q[X]$  where  $a_0 = s$  and computes  $C_k = g^{\alpha_k}$  for  $k = 0, \dots, t$  and broadcasts  $(C_0, \dots, C_t)$ . For every  $P_i$  he sends  $s_i = f(\alpha_i)$  by using  $\mathcal{F}_{\text{SSMT}}$ .
- F-3. Each  $P_j$  verifies  $g^{s_j} = \prod_{k=0}^t C_k^{\alpha_k^j}$  and broadcasts *verified* if it holds. Otherwise,  $P_j$  broadcasts *accuse dealer*. For every accusation, the following sub-protocol is executed in parallel.
- (a)  $P_j$  sends *(open, sid)* to  $\mathcal{F}_{\text{SSMTwo}}$  and every player receives  $\alpha_j$ . If  $\alpha_j = 0$ , then it is replaced by  $\alpha_j = 1$ .
  - (b) The dealer broadcasts the corresponding  $s_j$ .
  - (c) If  $(\alpha_j, s_j)$  satisfies the verification predicate, then  $P_j$  accepts  $(\alpha_j, s_j)$  as his share, otherwise the players output a default sharing of  $s = 0$ . (Note that the players have agreement on the published values  $\alpha_j$  and  $s_j$ ).

**[Reconstruction Phase]**

Each  $P_j$  broadcasts  $(\alpha_j, s_j)$ , identifies  $\mathcal{Q} \subseteq \{1, \dots, n\}$ ,  $|\mathcal{Q}| \geq t+1$ , so that  $(\alpha_i, s_i)$  satisfies the verification predicate for all  $i \in \mathcal{Q}$ , reconstructs secret  $s$  by Lagrange interpolation with regard to  $\mathcal{Q}$ , and then outputs  $s$ .

**Fig. 1.** Adaptively secure Feldman-VSS  $\pi_{\text{XFVSS}}$  in  $(\mathcal{F}_{\text{SSMTwo}}, \mathcal{F}_{\text{SSMT}})$ -hybrid model.

## 4.2 Efficient Composition to the Real-life Protocol

This section provides protocols that realize  $\mathcal{F}_{\text{SSMT}}$  and  $\mathcal{F}_{\text{SSMTwo}}$  over the public network with broadcast, i.e., without secure channels. Then, by applying the composition theorem, one can have adaptively secure Feldman VSS as a real-life protocol. As we shall see, these realizations are efficient but have some limitation on the adversary, which though can be successfully overcome in our applications.

Our constructions require an efficient bidirectional mapping between  $\mathbb{Z}_q$  and  $G_q$  while the DDH problem should be hard to solve. This is the case when  $G_q$  is the order- $q$  multiplicative subgroup of  $\mathbb{Z}_p^*$  with prime  $p = 2q + 1$ . Indeed, encoding  $\mathbb{Z}_q \rightarrow G_q$  can be done by  $m \mapsto M = m^2 \bmod p$ , where  $m \in \mathbb{Z}_q$  is identified with its representant in  $\{1, \dots, q\}$ . This encoder is denoted by  $M = \text{Encode}(m)$  and the corresponding decoder by  $m = \text{Decode}(M)$ .

*Receiver Non-committing Message Transmission:* By  $\pi_{\text{RNC}}$ , we denote a protocol that realizes  $\mathcal{F}_{\text{SMT}}$  (or  $\mathcal{F}_{\text{SSMT}}$ ) with receiver non-committing feature. That is, remains secure even if the receiver is adaptively corrupted (in the non-erasure model), while the sender may only be statically corrupted. Note that with such a restriction on the sender,  $\mathcal{F}_{\text{SMT}}$  can be realized (without spooling). We review the construction by [16] (adapted to accept messages  $m \in \mathbb{Z}_q$ ), which is originally designed in a classical model but can fit to the UC model. A proof is given in Appendix B.

- A-0. (Initial step) Sender  $P_s$  chooses  $h \leftarrow G_q$  and sends it to receiver  $P_r$ .
- A-1.  $P_r$  selects  $z_1, z_2 \leftarrow \mathbb{Z}_q$ , computes  $y = g^{z_1} h^{z_2}$ , and sends  $y$  to  $P_s$ .
- A-2.  $P_s$  computes  $u = g^r$ ,  $v = h^r$  and  $c = \text{Encode}(m) y^r$ , where  $r \leftarrow \mathbb{Z}_q$ , and sends  $(u, v, c)$  to  $P_r$ .
- A-3.  $P_r$  computes  $m = \text{Decode}(cu^{-z_1} v^{-z_2})$ .

**Fig. 2.** Protocol  $\pi_{\text{RNC}}$  for receiver non-committing transmission.

**Lemma 1.** *Under the DDH assumption, protocol  $\pi_{\text{RNC}}$  securely realizes  $\mathcal{F}_{\text{SMT}}$  (or  $\mathcal{F}_{\text{SSMT}}$ ) against an adaptive adversary if the sender is only statically corrupt and  $\mathcal{S}$  is aware of  $\varpi$  with  $\text{Encode}(m) = g^\varpi$ .*

The assumption that the ideal-life adversary  $\mathcal{S}$  is aware of the DL of  $\text{Encode}(m)$  seems quite restrictive for  $\pi_{\text{RNC}}$  to be a general stand-alone tool. It is however acceptable for our purpose as  $m$  will be chosen by  $\mathcal{S}$  in an upper-level protocol (playing the role of the to-be-corrupted sender) such that it knows the DL of  $\text{Encode}(m)$ . We stress that this assumption does not mean at all that  $\mathcal{S}$  is given any kind of power to solve the DL problem.

*Sender Non-committing Message Transmission with Opening:* A protocol  $\pi_{\text{SNC}}$  that realizes  $\mathcal{F}_{\text{SSMT}}$  with sender non-committing feature follows easily from  $\pi_{\text{RNC}}$ . The receiver  $P_r$  simply uses  $\pi_{\text{RNC}}$  to securely send a randomly chosen  $k \in G_q$  to the sender  $P_s$  (precisely,  $P_r$  sends the message  $\text{Decode}(k) \in \mathbb{Z}_q$ ), and then  $P_s$  sends  $e = k\text{Encode}(m)$  to  $P_r$ , who computes  $m$  as  $m = \text{Decode}(ek^{-1})$ . We also consider the following variant of  $\pi_{\text{SNC}}$ , which we denote by  $\pi_{\text{SNCwo}}$ . All communication is done over the broadcast channel, and in an additional phase, the *opening phase*, the sender  $P_s$  publishes  $z_1$  and  $z_2$ , privately sampled for the secure transmission of  $m$ , and every player verifies whether  $g^{z_1}h^{z_2} = y$  and computes  $k = cu^{-z_1}v^{-z_2}$  and  $m = \text{Decode}(ek^{-1})$ . A full description is given in Figure 11 in Appendix C.

**Lemma 2.** *Under the DDH assumption, protocol  $\pi_{\text{SNC}}$  securely realizes  $\mathcal{F}_{\text{SSMT}}$  and  $\pi_{\text{SNCwo}}$  securely realizes  $\mathcal{F}_{\text{SSMTwo}}$  against an adaptive adversary if the receiver is only statically corrupt and  $\mathcal{S}$  is aware of  $\varpi$  with  $\text{Encode}(m) = g^\varpi$ .*

The proof of Lemma 2 is similar to that of Lemma 1, although slightly more involved. For completeness, it is given in Appendix C.

*Composition with the Efficient Realizations:* We now show that when the functionalities  $\mathcal{F}_{\text{SSMTwo}}$  and  $\mathcal{F}_{\text{SSMT}}$  in the hybrid-protocol  $\pi_{\text{XFVSS}}$  are implemented by  $\pi_{\text{SNCwo}}$  and  $\pi_{\text{RNC}}$ , respectively, then the composed protocol securely realizes  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$  (or  $\mathcal{F}_{\text{SVSS}}^{\text{fcom}_g}$ ) in some weakened sense as stated below.

**Theorem 1.** *Implementing the functionality  $\mathcal{F}_{\text{SSMTwo}}$  in step F-1 of the hybrid-protocol  $\pi_{\text{XFVSS}}$  from Fig. 1. by  $\pi_{\text{SNCwo}}$  and  $\mathcal{F}_{\text{SSMT}}$  in step F-2 by  $\pi_{\text{RNC}}$  results in a secure realization of  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$  (or  $\mathcal{F}_{\text{SVSS}}^{\text{fcom}_g}$ ) in the real-life model, assumed that (1) the adversary corrupts the dealer only statically, and (2) the adversary corrupts players only before the reconstruction phase.*

*Proof.* The claim follows essentially from Proposition 1, Lemma 1 and 2, and the composition theorem. It remains to show that the assumptions for Lemma 1 and 2 are satisfied. By assumption (1) it is guaranteed that the receiver in  $\pi_{\text{SNC}}$  and the sender in  $\pi_{\text{RNC}}$  (which in both cases is the dealer) is only statically corrupt. Furthermore, by (2) and the way  $\mathcal{S}$  works in the proof of Proposition 1, the messages, which are supposedly sent through  $\mathcal{F}_{\text{SSMTwo}}$  and  $\mathcal{F}_{\text{SSMT}}$  and for which  $\mathcal{S}$  has to convince  $\mathcal{A}$  as being the messages sent through  $\mathcal{F}_{\text{SSMTwo}}$  respectively  $\mathcal{F}_{\text{SSMT}}$  are the values  $\tilde{\alpha}_1, \dots, \tilde{\alpha}_t$  and  $\tilde{s}_1, \dots, \tilde{s}_t$ , all chosen randomly from  $\mathbb{Z}_q$  (respectively  $\mathbb{Z}_q^*$ ) by  $\mathcal{S}$ . Hence,  $\mathcal{S}$  could sample them just as well by choosing  $\varpi \leftarrow \mathbb{Z}_q$  and computing  $\text{Decode}(g^\varpi)$  such that the conditions for Lemma 1 and 2 are indeed satisfied. Finally, as the dealer may only be statically corrupted, we do not need to care about spooling. Thus  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$  and  $\mathcal{F}_{\text{SVSS}}^{\text{fcom}_g}$  are equivalent here.  $\square$

## 5 Applications to Threshold Cryptography

In this section, we propose several applications of the adaptively-secure Feldman VSS scheme from the previous section. Our main applications are a distributed DL-key generation protocol and UC threshold versions of the Schnorr and the DSS signature scheme, though we also propose some related applications which might be of independent interest like a trapdoor-key generation protocol for Pedersen’s commitment scheme, a common-random-string generator with applications to zero-knowledge in the UC model, and distributed-verifier UC proofs of knowledge. Interestingly, even though our Feldman VSS scheme has restricted adaptive security, the applications remain fully adaptively secure in the (SIP) UC model and do not underly restrictions as posed in Theorem 1.

To simplify terminology, from now on when referring to protocol  $\pi_{\text{XFVSS}}$ , we mean  $\pi_{\text{XFVSS}}$  from Fig. 1 with  $\mathcal{F}_{\text{SSMTwo}}$  and  $\mathcal{F}_{\text{SSMT}}$  replaced by  $\pi_{\text{SNCwo}}$  and  $\pi_{\text{RNC}}$  as specified in Theorem 1. Furthermore, it will at some point be convenient to use a different basis, say  $h$ , rather than the public parameter  $g$  in the core part of  $\pi_{\text{XFVSS}}$ , such that for instance  $h^s$  will be published as  $C$ . This will be denoted by  $\pi_{\text{XFVSS}}[h]$ , and obviously securely realizes  $\mathcal{F}_{\text{VSS}}^{\text{fcom}h}$ . We stress that this modification is not meant to affect the sub-protocols  $\pi_{\text{SNCwo}}$  and  $\pi_{\text{RNC}}$ .

### 5.1 How to Generate The First Trapdoor Commitment-Key

In many protocols, a trapdoor commitment-key is considered as given by some trusted party so that the trapdoor information is unknown to any player. In order to achieve security *from scratch*, the (trapdoor) commitment-key needs to be generated securely by the players, without a trusted party, and without the use of a common trapdoor commitment-key. In this section, we show such a protocol for Pedersen’s commitment scheme.

The protocol,  $\pi_{\text{HGEN}}$ , is illustrated in Fig. 3. We assume that it is triggered by a player  $P_i$  who sends *init* to all players. The protocol outputs a (trapdoor) commitment-key  $h \in G_q$  for Pedersen’s commitment scheme. Note that the corresponding trapdoor  $\log_g h = \sum_{j \in \mathcal{Q}} \chi_j$  is not shared among the players (in the usual way).

H-1. Every  $P_j$  chooses  $\chi_j \leftarrow \mathbb{Z}_q$  and sends  $(\text{share}, \text{sid}, \chi_j)$  to  $\mathcal{F}_{\text{VSS}}^{\text{fcom}g}$ . Let  $\mathcal{Q}$  be the set of players whose  $(\text{shared}, \text{sid}, P_j, Y_j)$  is published by  $\mathcal{F}_{\text{VSS}}^{\text{fcom}g}$ . Remember that  $Y_j = \text{fcom}_g(\chi_j) = g^{\chi_j}$ .  
H-2. Every player outputs  $h = \prod_{j \in \mathcal{Q}} Y_j$ .

**Fig. 3.** Commitment-key generation protocol  $\pi_{\text{HGEN}}$  in  $\mathcal{F}_{\text{VSS}}^{\text{fcom}g}$ -hybrid model.

Unfortunately, one cannot expect  $h$  to be random as a rushing party can affect its distribution. However, the protocol inherits the following two properties which are sufficient for our purpose. (1) A simulator that simulates  $\pi_{\text{HGEN}}$  can compute the DL of  $h$ , and (2) given  $Y \in G_q$ , a simulator can embed  $Y$  into  $h$  so that given  $\log_g h$ , the simulator can compute  $\log_g Y$ . The latter in particular implies that the adversary is not able to compute the trapdoor  $\log_g h$ .

Our idea for formally capturing such a notion is that the ideal functionality challenges the adversary  $\mathcal{S}$  by sending a random  $h' \in G_q$  and allows  $\mathcal{S}$  to randomize it so that  $h'$  is transformed into  $h$  such that  $\mathcal{S}$  knows the trapdoor for  $h$  if and only if it knows it for  $h'$ . This clearly captures (1) and (2) above.

**Definition 6 (Commitment-Key Generation Functionality:  $\mathcal{F}_{\text{HGEN}}$ ).**

1. On receiving  $(\text{generate}, \text{sid})$  from  $P_i$ , choose  $h' \leftarrow G_q$  and send  $(h', P_i)$  to  $\mathcal{S}$ .
2. On receiving  $\gamma \in \mathbb{Z}_q$  from  $\mathcal{S}$ , compute  $h = h'g^\gamma$  and send  $(\text{com-key}, \text{sid}, h)$  to all players and  $\mathcal{S}$ .

**Proposition 2.** *Protocol  $\pi_{\text{HGEN}}$  in Fig. 3 securely realizes  $\mathcal{F}_{\text{HGEN}}$  against  $t$ -limited adaptive adversary for  $t < n/2$  in the  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$ -hybrid SIP UC model.*

*Proof.* If  $\mathcal{A}$  corrupts a player,  $P_i$ , before starting  $\pi_{\text{HGEN}}$ ,  $\mathcal{S}$  corrupts  $\tilde{P}_i$  and gives its internal state to  $\mathcal{A}$ . If corrupted  $P_i$  initiates  $\pi_{\text{HGEN}}$ ,  $\mathcal{S}$  lets  $\tilde{P}_i$  do so by sending  $(\text{generate}, \text{sid})$  to  $\mathcal{F}_{\text{HGEN}}$ .

On receiving  $(h', P_i)$  from  $\mathcal{F}_{\text{HGEN}}$ ,  $\mathcal{S}$  lets honest  $P_i$  initiate the protocol. (If  $P_i$  has been already corrupted,  $\mathcal{S}$  can skip this step because the initial message should have been already broadcast by  $\mathcal{A}$ .) To simulate the SIP  $P_{j^*}$ ,  $\mathcal{S}$  simulates  $P_{j^*}$ 's invocation of the sharing phase of  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$  with output  $(\text{shared}, \text{sid}, h', P_{j^*})$  as if it has received corresponding input from  $P_{j^*}$ .  $\mathcal{S}$  also simulates all honest players and their invocation of  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$  as prescribed.  $\mathcal{S}$  obtains  $\chi_j$  for all  $j \in \mathcal{Q} \setminus \{j^*\}$  as inputs to  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$ .  $\mathcal{S}$  then sends  $\gamma = \sum_{j \in \mathcal{Q} \setminus \{j^*\}} \chi_j$  to  $\mathcal{F}_{\text{HGEN}}$ . This results in receiving  $(\text{com-key}, \text{sid}, h)$  from  $\mathcal{F}_{\text{HGEN}}$  where  $h = h'g^\gamma$ .  $\mathcal{S}$  delivers the message to all players.

It is straightforward to verify that this is a perfect simulation: the only difference to the real-life execution is that  $P_{j^*}$  does not provide his input for  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$ , which though is invisible to  $\mathcal{A}$  and  $\mathcal{Z}$ .  $\square$

We claim that  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$  in  $\pi_{\text{HGEN}}$  can be securely realized by the protocol  $\pi_{\text{XFVSS}}$  from Theorem 1. This may look contradictory since  $\pi_{\text{XFVSS}}$  is secure only against static corruption of the dealer as stated in Theorem 1, while in  $\pi_{\text{HGEN}}$  every player acts as a dealer and may be adaptively corrupted. However, looking at the proof, except for the run launched by the SIP  $P_{j^*}$ ,  $\mathcal{S}$  simulates all runs of  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$  honestly with true inputs. Hence, for these simulations, the situation is exactly as in the case where the dealer is statically corrupted and the secret is known to the simulator at the beginning. Furthermore, the reconstruction phase of  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$  is never invoked in  $\pi_{\text{HGEN}}$ . Thus, the following holds.

**Theorem 2.** *Implementing  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$  in  $\pi_{\text{HGEN}}$  of Fig. 3 by  $\pi_{\text{XFVSS}}$  results in a secure realization of  $\mathcal{F}_{\text{HGEN}}$  against  $t$ -limited adaptive adversary for  $t < n/2$  in the (real-life) SIP UC model.*

## 5.2 DL-Key Generation

This section constructs an adaptively secure protocol for DLKG, whose functionality is defined below. Clearly, from such a key-generation protocol (respectively functionality), one expects that it outputs a public-key  $y$  and in some hidden way produces the corresponding secret-key  $x$  (typically by having it shared among the players), such that  $x$  can be used to do some cryptographic task like signing or decrypting if enough of the players agree [21]. However, as we want to view our protocol as a generic building block for threshold schemes, we simply require that the secret-key  $x$  can be opened rather than be used for some specific task. In Sect. 5.3 and 5.5 we then show concrete example threshold schemes based on our DLKG protocol.

**Definition 7 (Threshold DL Key Generation Functionality:  $\mathcal{F}_{\text{DLKG}}$ ).**

1. On receiving  $(\text{generate}, \text{sid})$  from  $P_i$ , select  $x \leftarrow \mathbb{Z}_q$ , compute  $y = g^x$ , and send  $(\text{key}, \text{sid}, y)$  to all players and  $\mathcal{S}$ .
2. On receiving  $(\text{open}, \text{sid})$  from  $t + 1$  players, send  $(\text{private}, \text{sid}, x)$  to all players and  $\mathcal{S}$ .

Our realization of  $\mathcal{F}_{\text{DLKG}}$  is illustrated in Fig. 5 below, and makes use of (ordinary) Pedersen's VSS scheme given in Fig. 4. We do not prove Pedersen's VSS secure in the UC framework, and in fact it is not (as a committed VSS against an adaptive adversary). The only security requirement we need is covered by the following well-known fact.

**Lemma 3.** *Except with negligible probability, after the sharing phase of Pedersen's VSS, both the  $s_i$ 's and  $r_i$ 's of the uncorrupt players are correct sharings of  $s$  and  $r$  such that  $g^s h^r = C$  and such that  $s$  is reconstructed in the reconstruction phase (and  $s$  and  $r$  coincide with the dealer's choice in case he remains honest), or otherwise  $\log_g h$  can be efficiently extracted from the adversary.*

**[Sharing Phase]**

P-1. The dealer selects  $f(X) = a_0 + a_1X + \dots + a_tX^t \leftarrow \mathbb{Z}_q[X]$  and  $f'(X) = b_0 + b_1X + \dots + b_tX^t \leftarrow \mathbb{Z}_q[X]$  where  $a_0 = s$ . Let  $r = b_0$ . The dealer then computes and broadcasts  $C = C_0 = g^s h^r$  and  $C_k = g^{a_k} h^{b_k}$  for  $k = 1, \dots, t$ , and he sends  $s_i = f(i)$  and  $r_i = f'(i)$  to  $P_i$  using  $\mathcal{F}_{\text{SSMT}}$ .

P-2. Each  $P_i$  verifies whether  $g^{s_i} h^{r_i} = E_i$  where  $E_i = \prod_{k=0}^t C_k^{i^k}$ .  $P_i$  broadcasts *verified* if it holds and else initiates the accusation sub-protocol which is the same as that of Feldman VSS with obvious modification.

**[Reconstruction Phase]**

Every player  $P_i$  publicly opens  $E_i$  to  $s_i$ . The secret  $s$  is reconstructed using Lagrange interpolation from the correctly opened  $s_i$ 's.

**Fig. 4.** Pedersen's VSS scheme:  $\text{PedVSS}_{g,h}(s) \rightarrow (s_1, \dots, s_n, r, C, E_1, \dots, E_n)$

We write  $\text{PedVSS}_{g,h}^j(s) \rightarrow (s_1, \dots, s_n, r, C, E_1, \dots, E_n)$  to denote an execution of the sharing phase of Pedersen's VSS with secret  $s$  and player  $P_j$  acting as dealer, and with values  $s_1, \dots, s_n, r, C, E_1, \dots, E_n$  generated as described in Fig. 4.

Note that in  $\pi_{\text{DLKG}}$  the *additive* shares  $x_j$  are used to reconstruct the secret-key  $x$ , rather than the threshold-shares implicitly given by  $\xi_j = \sum_i x_{ij}$ . The reason is that even though using the threshold shares can be proven secure in the hybrid-model, it resists a security proof when the ideal functionality  $\mathcal{F}_{\text{SSMT}}$  in Pedersen's VSS is replaced by  $\pi_{\text{RNC}}$  as we do (due to the DL condition from Lemma 1). In Sect. 5.4 we show how to modify the scheme in order to be able to use the threshold-shares as secret-key shares. Also note that using the terminology introduced in [2], based on the results in [1], step K-3 can be seen as a *distributed-verifier zero-knowledge proof* of knowledge of  $x_j$  and  $r_j$  such that  $g^{x_j} = C'_j$  and  $h^{r_j} = C''_j$ .

**Theorem 3.** *Implementing in the DLKG protocol  $\pi_{\text{DLKG}}$  from Fig. 5 the functionalities  $\mathcal{F}_{\text{HGEN}}$ ,  $\mathcal{F}_{\text{SSMT}}$ ,  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$  and  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_h}$  by  $\pi_{\text{HGEN}}$ ,  $\pi_{\text{RNC}}$ ,  $\pi_{\text{XFVSS}}[g]$  and  $\pi_{\text{XFVSS}}[h]$ , respectively, results in a secure realization of  $\mathcal{F}_{\text{DLKG}}$  against adaptive  $t$ -limited adversary for  $t < n/2$  in the SIP UC model.*

**[Key-Generation Phase]**

- K-1. A player,  $P_i$ , sends (*generate*,  $sid$ ) to  $\mathcal{F}_{\text{HGEN}}$ , and commitment-key  $h$  is obtained.
- K-2. Each player  $P_j$  chooses  $x_j \leftarrow \mathbb{Z}_q$  and executes the sharing phase of Pedersen's VSS with secret  $x_j$  and commitment-key  $h$ :  $\text{PedVSS}_{g,h}^j(x_j) \rightarrow (x_{j1}, \dots, x_{jn}, r_j, C_j, E_{j1}, \dots, E_{jn})$ . If a player  $P_j$  refuses then a default Pedersen sharing of  $x_j = 0$  is taken instead.
- K-3. Each  $P_j$  sends (*share*,  $sid_j, x_j$ ) to  $\mathcal{F}_{\text{VSS}}^{\text{com } g}$  and (*share*,  $sid'_j, r_j$ ) to  $\mathcal{F}_{\text{VSS}}^{\text{com } h}$ .
- K-4. If  $P_i$  receives (*shared*,  $sid_j, P_j, C'_j$ ) and (*shared*,  $sid'_j, P_j, C''_j$ ), he verifies that  $C_j = C'_j C''_j$  holds. (Note that  $C'_j = g^{x_j}$  and  $C''_j = h^{r_j}$ .) If either of such messages has not been received or the relation does not hold, then  $x_j$  is reconstructed from its Pedersen sharing, and every  $P_i$  sets  $C'_j = g^{x_j}$ . Output of this phase is the public-key  $y = \prod_{j=1}^n C'_j$ , while each  $P_j$  stores  $x_j$  as his (additive) secret-key share, to which he is committed by  $C_j$ .

**[Opening Phase]**

Every player  $P_j$  publicly opens  $C_j$  by broadcasting  $x_j$  and  $r_j$ . If a player  $P_j$  fails to do so,  $x_j$  is reconstructed from its Pedersen sharing. Secret-key  $x$  is then computed as  $x = \sum_{j=1}^n x_j$ .

**Fig. 5.** Threshold DLKG protocol  $\pi_{\text{DLKG}}$  in  $(\mathcal{F}_{\text{HGEN}}, \mathcal{F}_{\text{VSS}}^{\text{com } g}, \mathcal{F}_{\text{VSS}}^{\text{com } h}, \mathcal{F}_{\text{SMT}})$ -hybrid model.

Using the UC with joint state framework [8], one can prove using similar arguments that the commitment-key  $h$  can be generated once and for all invocations of  $\pi_{\text{DLKG}}$ . Furthermore, concerning efficiency, the communication complexity of the key-generation phase is comparable to that of the schemes by [16]: it requires  $O(n^2\kappa)$  bits to be sent over the bilateral public channels and another  $O(n^2\kappa)$  bits to be broadcast.

The full proof of Theorem 3 is given in Appendix D. We simply sketch its idea here. First, the simulator  $\mathcal{S}$  simulates the generation of  $h$  such that it knows the DL of  $h$ , while step K-2 is executed as prescribed. Then, it reconstructs the  $x_i$ 's of the corrupt players, and it computes  $C'_{j^*}$  and  $C''_{j^*}$  for the SIP  $P_{j^*}$  such that  $C'_{j^*} \cdot \prod_{j \neq j^*} g^{x_j} = y$  and  $C_{j^*} = C'_{j^*} C''_{j^*}$ , where  $y$  is the value provided by  $\mathcal{F}_{\text{DLKG}}$ . Then it simulates the two Feldman VSSes with  $P_{j^*}$  as dealer, while the other executions are followed as prescribed (with inputs  $x_j$  respectively  $r_j$ ). As a result, the output of the key-generation phase is  $y$ . In the opening phase, having received  $x = \log_g(y)$  from  $\mathcal{F}_{\text{DLKG}}$ ,  $\mathcal{S}$  simply adapts  $P_{j^*}$ 's initial  $x_{j^*}$  such that  $\sum_j x_j = x$ , and it uses the DL of  $h$  to open  $C_{j^*}$  to (the new)  $x_{j^*}$ . The only difference in the adversary's and thus the environment's view between the simulation and a real execution lies in the encrypted Pedersen shares of (the initial)  $x_{j^*}$  given to the uncorrupt players. By the property of  $\pi_{\text{RNC}}$ , this cannot be distinguished by the environment.

From now on, when referring to protocol  $\pi_{\text{DLKG}}$ , we mean  $\pi_{\text{DLKG}}$  from Fig. 5 with the functionalities replaced by real-life protocols as specified in Theorem 3.

### 5.3 Universally-Composable Threshold Schnorr-Signatures

As an example application of our DL-key generation protocol, we propose a threshold variant of Schnorr's signature scheme [19], provable secure in the UC framework. The scheme is illustrated in Fig. 6. Recall, a Schnorr signature for message  $m$  under public-key  $y = g^x$  consists of  $(c, s)$  such that  $r = g^s/y^c$  satisfies  $H(m, r) = c$ , where  $H$  is a cryptographic hash-function. Such a signature is computed by the signer (in the single-signer variant), who knows the secret-key  $x$ , by choosing  $k \leftarrow \mathbb{Z}_q$  and computing  $r = g^k$ ,  $c = H(m, r)$  and  $s = k + cx$ . Schnorr's signature scheme can be proven secure, in the sense of existential unforgeability against chosen message attacks, in the *random oracle* model.

**[Key-Generation Phase]**

The players execute the key-generation phase of  $\pi_{\text{DLKG}}$ , resulting in a public-key  $y$ , private (additive) secret-key shares  $x_1, \dots, x_n$  with corresponding commitments  $C_1, \dots, C_n$ , and commitment-key  $h$ .

**[Signing Phase]**

In order to sign a message  $m$ , the following steps are executed.

- S-1. The players once more invoke the key-generation phase of  $\pi_{\text{DLKG}}$ , but skipping the generation of  $h$  and taking  $h$  from the generation of  $y$ . Denote the output by  $r$ , the corresponding additive secret-key shares by  $k_1, \dots, k_n$ , and the corresponding commitments by  $K_1, \dots, K_n$ .
- S-2. Each player  $P_j$  computes  $c = H(m, r)$  and publicly opens  $K_j C_j^c$  to  $s_j = k_j + cx_j$ . If a player  $P_j$  fails to do so,  $s_j$  is reconstructed from its Pedersen sharing (which is implicitly given by the Pedersen sharings of  $x_j$  and  $k_j$ ). Signature  $(c, s)$  is completed by  $s = \sum_j s_j$ .

**Fig. 6.** Threshold Schnorr-signature scheme  $\pi_{\text{TSIG}}^{\text{SCHNORR}}$

Consider the ideal threshold signature functionality  $\mathcal{F}_{\text{TSIG}}$  by adapting the (single-signer) signature functionality  $\mathcal{F}_{\text{SIG}}$  from [5] in the obvious way, as illustrated in Definition 8 below.

**Definition 8 (Threshold Signature Functionality:  $\mathcal{F}_{\text{TSIG}}$ ).**

1. On receiving (generate,  $sid$ ) from  $t+1$  players, hand (key,  $sid$ ) to  $\mathcal{S}$ . On receiving (key,  $sid$ ,  $pk$ ) from  $\mathcal{S}$  send (key,  $sid$ ,  $pk$ ) to all players.
2. On receiving (sign,  $sid$ ,  $m$ ) from  $t + 1$  players, hand (sign,  $sid$ ,  $m$ ) to  $\mathcal{S}$ . On receiving (signature,  $sid$ ,  $m$ ,  $\sigma$ ) from  $\mathcal{S}$  send (signature,  $sid$ ,  $m$ ,  $\sigma$ ) to all players and record  $(m, \sigma)$ .
3. On receiving (verify,  $sid$ ,  $m$ ,  $\sigma$ ,  $pk'$ ) from some player  $P_j$ , send (verified,  $sid$ ,  $m$ ,  $v$ ) to  $P_j$  and  $\mathcal{S}$ , where  $v$  is determined as follows. If  $pk = pk'$  and the pair  $(m, \sigma)$  is recorded, then  $v = 1$ . If  $pk = pk'$  and no pair  $(m, \sigma')$  for any  $\sigma'$  is recorded, then  $v = 0$ . Otherwise (i.e. if  $pk \neq pk'$  or if  $(m, \sigma')$  is recorded for  $\sigma' \neq \sigma$ ) let  $\mathcal{S}$  decide on the value of  $v$ .

After the execution of the first step, the second and third step may be performed an unbounded number of times, and in an arbitrary order.

**Theorem 4.** Protocol  $\pi_{\text{TSIG}}^{\text{SCHNORR}}$  securely realizes  $\mathcal{F}_{\text{TSIG}}$  against adaptive  $t$ -limited adversary for  $t < n/2$  in the UC model, under the DDH assumption and under the assumption that the standard Schnorr signature scheme is secure.

We stress that interestingly  $\pi_{\text{TSIG}}^{\text{SCHNORR}}$  securely realizes  $\mathcal{F}_{\text{TSIG}}$  in the *standard* rather than the SIP UC model.

*Proof. (Sketch)* The simulator  $\mathcal{S}$  simply executes *honestly*  $\pi_{\text{TSIG}}^{\text{SCHNORR}}$ . Note that the public-key  $y$  is not dictated by  $\mathcal{F}_{\text{TSIG}}$ , but rather  $\mathcal{F}_{\text{TSIG}}$  asks  $\mathcal{S}$  to provide it. Accordingly,  $\mathcal{S}$  knows the private key  $x$  and can use it in the signing phase of the real-life protocol. In order to prove that this is a good simulation, we argue as follows. The only way  $\mathcal{Z}$  may see a difference is when  $\mathcal{A}$  breaks the signature scheme, i.e., when a player provides at some point a valid signature on a message that has not been signed. However, if there exist  $\mathcal{Z}$  and  $\mathcal{A}$  that can enforce such an event with non-negligible probability, then there exists a forger  $F$  that breaks the existential unforgeability against chosen message attacks of the standard (single-signer) Schnorr signature scheme.  $F$  works as follows.  $F$  runs  $\mathcal{Z}$  and  $\mathcal{A}$ , and it simulates the action of  $\mathcal{S}$ , i.e. the execution of  $\pi_{\text{TSIG}}^{\text{SCHNORR}}$ , as follows. It uses the SIP simulator for the key-generation phase of  $\pi_{\text{DLKG}}$  to force the output of the key-generation to be the given public-key  $y$ . Furthermore, to sign a message  $m$ , it asks the signing oracle for

a signatures  $(c, s)$  on  $m$ , it forces as above the outcome of S-1 to be  $r = g^s/y^c$ , and it uses a straightforward modification of the SIP simulator for the opening phase of  $\pi_{\text{DLKG}}$  to simulate the signing phase: the simulated  $P_{j^*}$  opens  $K_{j^*}C_{j^*}^c$  to  $s - \sum_{j \neq j^*} s_j$  in step S-2 (rather than to  $k_{j^*} + cx_{j^*}$ ), forcing the output of the signing phase to be the given signature  $(c, s)$ . Additionally, whenever a message-signature pair  $(m, \sigma)$  is asked to be verified,  $F$  first checks whether  $m$  was never signed before and if  $\sigma$  is a valid signature on  $m$ . Once such a pair  $(m, \sigma)$  is found,  $F$  outputs that pair and halts. Similar to the proof of Theorem 3, one can show that if  $\mathcal{A}$  does not corrupt the SIP then  $\mathcal{Z}$  cannot distinguish between the real execution of  $\pi_{\text{T\SIG}}^{\text{SCHNORR}}$  (executed by the simulator  $\mathcal{S}$ ) and the SIP simulation (executed by the forger  $F$ ). Hence, by assumption on  $\mathcal{Z}$  and  $\mathcal{A}$ ,  $F$  outputs a signature on a message not signed by the signing oracle with non-negligible probability.  $\square$

#### 5.4 A DL-Key Generation Variant with Threshold Shares

The protocol  $\pi_{\text{DLKG}}$  from Fig. 5 remains secure in the  $(\mathcal{F}_{\text{HGEN}}, \mathcal{F}_{\text{VSS}}^{\text{fcom}_g}, \mathcal{F}_{\text{VSS}}^{\text{fcom}_h}, \mathcal{F}_{\text{SSMT}})$ -hybrid model if the threshold shares  $\xi_j = \sum_i x_{ij}$  of  $x$  are used in the opening phase rather than the additive shares  $x_j$ . Indeed, on receiving  $(\text{private}, \text{sid}, x)$ , the simulator  $\mathcal{S}$  may simply adapt the secret-key shares  $\xi_i$  of the uncorrupt players such that the new  $\xi_i$ 's form a sharing of  $x$ , hereby using the non-committing property of  $\mathcal{F}_{\text{SSMT}}$ . However, this attempt fails short when replacing  $\mathcal{F}_{\text{SSMT}}$  in the execution of Pedersen's VSS by the (weakly secure) protocol  $\pi_{\text{RNC}}$  as we do, due to the DL condition in Lemma 1. Indeed, in order to adapt the  $\xi_i$ 's,  $\mathcal{S}$  needs to correspondingly adapt  $P_{j^*}$ 's sharing of  $x_{j^*}$ , such that it results in a sharing of  $x - \sum_{j \neq j^*} x_j$ . However,  $\mathcal{S}$  does not know the DL of (the encodings of) the adapted  $x_{j^*}$ 's (which are sent over  $\mathcal{F}_{\text{SMT}}$ ). In contrast, in the simulation of the original  $\pi_{\text{DLKG}}$ ,  $\mathcal{S}$  only needed to adapt  $x_{j^*}$ , but not its sharing.

This problem, though, can be overcome by *randomizing* the secret-key shares  $\xi_i$  before publishing them in the opening phase. Concretely, every player  $P_j$  Pedersen VSSes 0, and then for every sharing of 0 every  $P_j$  adds the share he receives to  $\xi_j$ , resulting in a new share,  $\tilde{\xi}_j$ , of  $x$ . The opening phase is given in detail in Fig. 7. In the simulation, this randomization gives  $\mathcal{S}$  the opportunity to make  $\tilde{\xi}_1, \dots, \tilde{\xi}_n$  a sharing of  $x$  without adapting the  $\xi_i$ 's by letting  $P_{j^*}$  share  $x - x'$  rather than 0. This can be done since the simulator knows the trapdoor to the commitment-key. Furthermore, by the way the private shares are communicated, this cannot be detected by the adversary  $\mathcal{A}$  and thus by the environment  $\mathcal{Z}$ .

##### [Key-Generation Phase]

The key-generation phase is identical to that of  $\pi_{\text{DLKG}}$  from Fig. 5, except that each  $P_i$  stores  $\xi_i = \sum_{j=1}^n x_{ji}$  as his secret-key share (rather than  $x_i$ ), to which he is committed by  $E_i = \prod_{j=1}^n E_{ji}$ .

##### [Opening Phase]

- O'-1. Each player  $P_j$  executes Pedersen VSS for secret 0 and default commitment 1 with regard to  $g$  and  $h$ :  $\text{PedVSS}_{g,h}^j(0) \rightarrow (o_{j1}, \dots, o_{jn}, 0, 1, O_{j1}, \dots, O_{jn})$ . If a player  $P_j$  refuses then a default sharing of 0 is taken instead. Every  $P_j$  sets  $o_j = \sum_{i=1}^n o_{ij}$ . Write  $O_j = \prod_{i=1}^n O_{ij}$ .
- O'-2. Each  $P_j$  opens publicly the commitment  $E_j O_j$  to  $\tilde{\xi} = \xi_j + o_j$ . Secret-key  $x$  is reconstructed by Lagrange interpolation from the correctly opened  $\tilde{\xi}$ 's.

**Fig. 7.** Threshold DLKG protocol  $\pi'_{\text{DLKG}}$  with threshold shares in hybrid model.

**Theorem 5.** *Implementing in the DLKG protocol  $\pi'_{\text{DLKG}}$  from Fig. 7 the functionalities  $\mathcal{F}_{\text{HGEN}}$ ,  $\mathcal{F}_{\text{SSMT}}$ ,  $\mathcal{F}_{\text{VSS}}^{\text{com}_g}$  and  $\mathcal{F}_{\text{VSS}}^{\text{com}_h}$  by  $\pi_{\text{HGEN}}$ ,  $\pi_{\text{RNC}}$ ,  $\pi_{\text{XFVSS}}[g]$  and  $\pi_{\text{XFVSS}}[h]$ , respectively, results in a secure realization of  $\mathcal{F}_{\text{DLKG}}$  against adaptive  $t$ -limited adversary for  $t < n/2$  in the SIP UC model.*

From now on, when referring to protocol  $\pi'_{\text{DLKG}}$ , we mean  $\pi'_{\text{DLKG}}$  from Fig. 7 with the functionalities replaced by real-life protocols as specified in Theorem 5.

We also fix the following terminology. We say that the players “jointly generate a (degree- $t$ ) Pedersen sharing of 0” if they execute step O'-1 of protocol  $\pi'_{\text{DLKG}}$  (for a given commitment-key  $h$ ). Similarly, we say that the players “jointly generate a (degree- $t$ ) Pedersen sharing of a random number” if they execute step O'-1 of protocol  $\pi'_{\text{DLKG}}$  modified in that every  $P_j$  shares a random  $\rho_j \in \mathbb{Z}_q$  (rather than 0) so that the resulting sharing is a sharing of  $\rho = \sum_j \rho_j$  (rather than of 0). We also consider the joint generation of degree- $2t$  Pedersen sharings, which can be achieved as above with obvious modifications.

## 5.5 Universally-Composable Threshold DSS-Signatures

In this section, we propose a threshold variant of the DSS signature scheme [20], provable secure in the UC framework. The scheme is illustrated in Fig. 8, and it uses the DLKG-variant  $\pi'_{\text{DLKG}}$  from Sect. 5.4.

In DSS,  $G_q$  is specified to be an order- $q$  subgroup of  $\mathbb{Z}_p^*$ . Let  $[\cdot] : G_q \rightarrow \mathbb{Z}_q$  denote a mapping defined by  $[h] = h \bmod q$ . A DSS signature for message  $m$  under public-key  $y = g^x$  consists of  $(r, s)$  such that  $r = [g^{H(m)/s} y^{r/s}]$ , where  $H$  is a cryptographic hash-function (SHA-1 according to the DSS's specification). Such a signature is computed by the signer (in the single-signer variant), who knows the secret-key  $x$ , by choosing  $k \leftarrow \mathbb{Z}_q$  and computing  $r = [g^k]$  and  $s = (H(m) + xr)/k$ . The DSS signature scheme is believed to be secure (in the sense of existential unforgeability against chosen message attacks). For our threshold DSS signature scheme it is important to note that it does not harm the security of the standard DSS signature scheme when  $R = g^k$  is made available, as it can anyway be computed as  $R = g^{H(m)/s} y^{r/s}$ .

Concerning the multiplication protocol in step S-2 (b), instead of sharing the local product  $k_j u_j$ , as required by Rabin's multiplication protocol [15], every player  $P_j$  shares  $p_j = k_j u_j + o_j$  instead, where  $o_1, \dots, o_n$  is a degree- $2t$  (!) Pedersen sharing of 0, jointly generated by the players.<sup>6</sup> Furthermore, the shares of the  $p_j$ 's (and the randomness for the corresponding commitments) are distributed using  $\pi_{\text{RNC}}$ . Finally, the proofs for the correctness of the  $p_j$ 's (based on the commitments for  $k_j$ ,  $u_j$ ,  $o_j$  and  $p_j$ ) are done in parallel among every two players by using an off-the-shelf *witness-indistinguishable* honest-verifier (!) zero-knowledge proof, and  $p_j$  is globally accepted as being correct if at least  $t + 1$  players broadcast a confirmation that they accept  $P_j$ 's (bilateral) proof. The corresponding applies to the multiplication protocol in step S-2 (d). The reason for the randomization of the local products is that in the security proof, for all messages (shares) distributed using  $\pi_{\text{RNC}}$ , we can only argue for those sent by the SIP  $P_{j^*}$  that  $\mathcal{A}$  has no information about them. Therefore, without the randomization,  $\mathcal{A}$  might get information about the local products  $k_j u_j$  (of the honest players) and thus about the  $k_j$ 's, and therefore  $\mathcal{Z}$  might be able to

<sup>6</sup> We implicitly assume that every player  $P_j$  shares  $p_j$  correctly. The easiest (though maybe not the most efficient) way to deal with a (corrupt) player  $P_j$  that refuses to share  $p_j$ , or whose correctness proof is not globally accepted (see below), is to restart the signing phase but without  $P_j$  taking part (and to have  $P_j$  excluded from any further invocations of the signing phase).

**[Key-Generation Phase]**

The players execute the key-generation phase of  $\pi'_{\text{DLKG}}$ , resulting in a public-key  $y$ , private *threshold* secret-key shares  $\xi_1, \dots, \xi_n$  with corresponding commitments  $E_1, \dots, E_n$ , and commitment-key  $h$ .

**[Signing Phase]**

In order to sign a message  $m$ , the following steps are executed.

- S-1. The players once more invoke the key-generation phase of  $\pi'_{\text{DLKG}}$ , but skipping the generation of  $h$  and taking  $h$  from the generation of  $y$ . Denote the output by  $R = g^k$ , and the corresponding (committed) threshold secret-key shares by  $k_1, \dots, k_n$ .  $r = [R]$  is the first part of the signature.
- S-2. The players compute a sharing  $s_1, \dots, s_n$  of  $s = (H(m) + xr)/k$  as follows.
  - (a) The players jointly generate a degree- $t$  Pedersen sharing  $u_1, \dots, u_n$  of a random element  $u$ .
  - (b) The players jointly compute a (degree- $t$ ) sharing of  $v = ku$  using (a variant of) Rabin's multiplication protocol [15] (see comment in text), and reconstruct  $v$ .
  - (c) Every player  $P_j$  puts  $k_j^{\text{inv}} = u_j v^{-1}$  as his share of  $k^{-1}$ .
  - (d) The players jointly compute a sharing  $s_1, \dots, s_n$  of  $s = (H(m) + xr)k^{-1}$  again using (a variant of) Rabin's multiplication protocol. Let  $S_1, \dots, S_n$  denote the corresponding commitments.
- S-3. The players jointly generate a degree- $t$  Pedersen sharing  $o_1, \dots, o_n$  of 0 with commitments  $O_1, \dots, O_n$ , as in step O'-1 of  $\pi'_{\text{DLKG}}$  in Fig. 7.
- S-4. Each  $P_j$  opens publicly the commitment  $O_j S_j$  to  $\tilde{s}_j = s_j + o_j$ . The second part of the signature,  $s$ , is reconstructed by Lagrange interpolation from the correctly opened  $\tilde{s}_j$ 's.

**Fig. 8.** Threshold DSS-Signature Scheme  $\pi_{\text{TSIG}}^{\text{DSS}}$

recognize the simulation, in which the  $k_j$ 's do not reconstruct to the intended value  $\log_g R$ . As a side remark, due to this randomization of the (degree- $2t$ ) sharing of  $s$  in step S-2 (d), the randomization of the final (degree- $t$ ) shares of  $s$  in step S-3 is in fact unnecessary (see the proof below). Finally, the reason why we do not need to incorporate (fully) zero-knowledge correctness proofs is that the SIP simulator does not need to simulate any proof as it knows a witness for every instance. The only security requirement needed from the proofs (besides soundness) is that it should remain (information-theoretically) hidden that the SIP simulator uses *different* witnesses (as in a real-life execution), which is covered by the witness-indistinguishability property.

**Theorem 6.** *Protocol  $\pi_{\text{TSIG}}^{\text{DSS}}$  securely realizes  $\mathcal{F}_{\text{TSIG}}$  against adaptive  $t$ -limited adversary for  $t < n/2$  in the UC model, under the DDH assumption and under the assumption that the standard DSS signature scheme is secure.*

*Proof. (Sketch)* The simulator  $\mathcal{S}$  simply executes *honestly*  $\pi_{\text{TSIG}}^{\text{DSS}}$ . In order to prove that this is a good simulation, we argue as in the proof of Theorem 4: The only way  $\mathcal{Z}$  may see a difference is when  $\mathcal{A}$  breaks the signature scheme, i.e., when a player provides at some point a valid signature on a message that has not been signed. However, if there exist  $\mathcal{Z}$  and  $\mathcal{A}$  that can enforce such an event with non-negligible probability, then there exists a forger  $F$  that breaks the existential unforgeability against chosen message attacks of the standard (single-signer) DSS signature scheme.  $F$  works as follows.  $F$  runs  $\mathcal{Z}$  and  $\mathcal{A}$ , and it simulates the action of  $\mathcal{S}$ , i.e. the execution of  $\pi_{\text{TSIG}}^{\text{DSS}}$ , as follows. It uses the SIP simulator for the key-generation phase of  $\pi'_{\text{DLKG}}$  to force the output of the key-generation to be the given public-key  $y$ . Furthermore, to sign a message  $m$ , it asks the signing oracle for a signatures  $(r, s)$  on  $m$ , it forces  $R$  in S-1 to be  $R = g^{H(m)/s} y^{r/s}$  (such that  $[R] = r$ ), and it honestly follows S-2, except that in (sub)step (d), in the joint generation of the Pedersen sharing of 0 (within the multiplication protocol), the SIP  $P_{j^*}$  deviates from the protocol and shares a value (probably different than 0) such that the output of step S-2,  $s_1, \dots, s_n$ , is in fact a

sharing of  $s$ .  $P_{j^*}$  can do this as it knows the DL of  $h$ . Additionally, whenever a message-signature pair  $(m, \sigma)$  is asked to be verified,  $F$  first checks whether  $m$  was never signed before and if  $\sigma$  is a valid signature on  $m$ . Once such a pair  $(m, \sigma)$  is found,  $F$  outputs that pair and halts.

It remains to show that  $\mathcal{Z}$  cannot distinguish the real execution of  $\pi_{\text{TSIG}}^{\text{DSS}}$  (executed by  $\mathcal{S}$ ) from the SIP simulation (executed by  $F$ ), of course assuming that the SIP remains uncorrupt. It is rather straightforward to verify that the difference between the two only lies in the shares (and the randomness for the corresponding commitments) sent from the SIP  $P_{j^*}$  to the (finally) uncorrupt players. Also,  $\pi_{\text{TSIG}}^{\text{DSS}}$  is constructed such that uncorrupt players release no information about these shares (see comments before Theorem 6). It follows that the real execution and the SIP simulation are statistically indistinguishable for  $\mathcal{Z}$  in the hybrid-model where the SIP  $P_{j^*}$ , and only  $P_{j^*}$ , uses  $\mathcal{F}_{\text{SSMT}}$  to send out messages (shares and randomness) in all executions of Pedersen’s VSS where  $P_{j^*}$  acts as dealer. Finally, similar to the proof of Theorem 3, when replacing  $\mathcal{F}_{\text{SSMT}}$  by  $\pi_{\text{RNC}}$  one can argue that  $\mathcal{Z}$  still cannot distinguish the real execution from the SIP simulation unless it can break DDH.  $\square$

## 5.6 Threshold Cramer-Shoup Cryptosystem

We would like to point out that the concurrent (erasure-free) threshold Cramer-Shoup scheme from [16], which *assumes* a correctly generated trapdoor commitment-key  $h$ , in combination with our protocol  $\pi_{\text{HGEN}}$  for generating  $h$  results in a threshold version of the Cramer-Shoup cryptosystem [10] which can be proven secure in the *SIP* UC model. Unfortunately, the techniques for achieving *fully* UC signatures (as in Sect. 5.3 and 5.5) do not translate to the threshold Cramer-Shoup (or any other) cryptosystem. The reason is the following. Because the simulator  $\mathcal{S}$  has to produce an encryption of a default message in order to simulate the encryption phase (as it does not know the corresponding message),  $\mathcal{S}$  has to “cheat” in the simulation of the decryption of such a ciphertext in order to enforce the outcome to be the correct message (rather than the default message). Such cheating however, seems to require a SIP (or expensive fully non-committing encryptions). Note that such a problem does not occur for the signature schemes, where  $\mathcal{S}$  can simply honestly follow the protocol, and the SIP is only needed to prove that this results in a “good” simulation.

## 6 Related Constructions

### 6.1 Adaptively-Secure Feldman VSS in Secure Channel Model

Here we present another adaptively secure Feldman VSS without erasure in  $\mathcal{F}_{\text{SSMT}}$ -hybrid model. This scheme is more efficient than the one in Fig. 1, but does not fit to the efficient realization of  $\mathcal{F}_{\text{SSMT}}$  shown in Fig. 2 (essentially due to the DL condition of Lemma 1). Accordingly, the scheme is useful only in the secure channel model where  $\mathcal{F}_{\text{SSMT}}$  is realized by a (possibly physical) secure channel.

Our construction is based on a special kind of commitment scheme, called *trapdoor claw-free commitment scheme*. The claw-freeness means that for independently generated commitment keys  $K$  and  $K'$ , it is infeasible to compute  $(s, r)$  and  $(s', r')$  such that  $\text{com}_K(s; r) = \text{com}_{K'}(s'; r')$ . And the trapdoor property means that besides the commitment key  $K$  the key-generation algorithm also outputs a trapdoor  $\tau$  such that given  $\tau, \tau', s, r, s'$ , one can efficiently compute  $r'$  such that  $\text{com}_K(s; r) = \text{com}_{K'}(s'; r')$ .

The well-known Pedersen commitment scheme  $\text{pcom}_{g,h}(s; r) = g^s h^r$  satisfies all of the above conditions, where the trapdoor  $\tau$  is given by  $\tau = \log_g(h)$ : If there exists an algorithm

$\mathcal{A}$  that outputs  $(s, r)$  and  $(s', r')$  such that  $g^s h^r = g^{s'} h'^{r'}$  for randomly chosen  $h$  and  $h'$ , one can use  $\mathcal{A}$  to solve  $\log_g Y$  for random  $Y$  by embedding it into  $h$  and  $h'$  as  $h = Y$  and  $h' = Yg^\rho$  with random  $\rho$ . On the other hand, given  $\tau = \log_g(h)$  and  $\tau' = \log_g(h')$ , it is easy to compute  $r'$  for any  $s, r$  and  $s'$  such that  $s + \tau r = s' + \tau' r'$ .

Our modification to (the original) Feldman's adaptively-secure VSS scheme simply replaces the encryption  $E$  in the set-up phase by a trapdoor claw-free commitment scheme  $\text{com}_K$  as above, whose commitment keys are given from each player. This is illustrated in Fig. 9.

- X-1. Every  $P_j$  generates a commitment-key  $K_j$  and broadcasts it.
- X-2. The dealer computes a commitment  $A_j = \text{com}_{K_j}(j; r_j)$  (with random  $r_j$ ) for every  $j \in \{1, \dots, n\}$ , and he chooses  $\alpha_1, \dots, \alpha_n$  as a random permutation over  $1, \dots, n$ . Then, he broadcasts  $A_1, \dots, A_n$  ordered in such a way that  $A_j$  appears in  $\alpha_j$ -th position, and he privately sends  $(\alpha_j, r_j)$  to  $P_j$ . Simultaneously, the dealer starts to execute the basic Feldman VSS, taking  $\alpha_j$  as  $P_j$ 's X-coordinate.
- X-3. Each  $P_j$  identifies  $A_j$  in  $\alpha_j$ -th position and accepts the assignment if  $A_j = \text{com}_{K_j}(j; r_j)$ , and he accepts his share  $s_j$  if it satisfies the verification predicate (1) for the received  $\alpha_j$ . Otherwise, he accuses the dealer who in turn has to publicly open  $A_j$  (to  $j$ ) and announce  $s_j$ .

**Fig. 9.** Protocol  $\pi_{\text{CFVSS}}$  for adaptively secure Feldman-VSS in  $\mathcal{F}_{\text{SMT}}$ -hybrid model.

The sharing phase is unchanged except that, on receiving an accusation from  $P_j$ , the dealer broadcasts  $(s_j, \alpha_j, r_j)$ . Unlike to the original Feldman VSS, where the set-up phase, i.e. the distribution of the  $\alpha_j$ 's, needs to be strictly separated from the actual sharing phase where the secret is shared, these phases may interleave in this new variant. This saves one round of communication compared to the original scheme even if no accusation happens. The reconstruction phase remains unchanged. We denote this modified and parallelized Feldman VSS protocol by  $\pi_{\text{CFVSS}}$ . The security of  $\pi_{\text{CFVSS}}$  in the UC framework can be stated as follows.

**Theorem 7.** *Protocol  $\pi_{\text{CFVSS}}$  securely realizes  $\mathcal{F}_{\text{SVSS}}^{\text{fcom}_g}$  in the  $\mathcal{F}_{\text{SSMT}}$ -hybrid model (without erasures) against  $t$ -limited adaptive adversary for  $t < n/2$ .*

The proof is omitted since it can be done using essentially the same reasoning as for Proposition 1, except for the uniqueness of the assignments among honest players as claimed below.

*Claim.* For every honest  $P_i$  and  $P_j$ ,  $\alpha_i \neq \alpha_j$  holds with overwhelming probability.

*Proof.* The dealer who successfully assigns duplicate  $\alpha_j$  to different honest players can be reduced to the following adversary  $\mathcal{A}$ : Adversary  $\mathcal{A}$  is given  $K_1, \dots, K_n$  generated by players.  $\mathcal{A}$  is allowed to corrupt up to  $t < n/2$  players and obtains corresponding trapdoor key  $\tau_j$  on corruption. Then  $\mathcal{A}$  specifies  $K_i$  and  $K_j$  and outputs  $(s, r)$ ,  $(s', r')$  that satisfy  $\text{com}_{K_i}(s; r) = \text{com}_{K_j}(s'; r')$ .

Now we show a reduction from  $\mathcal{A}$  to breaking claw-free property as follows. Given  $K$  and  $K'$  for which we want to find a claw, guess  $i^*$  and  $j^*$  randomly from  $\{1, \dots, n\}$  and set  $K_{i^*} = K$  and  $K_{j^*} = K'$ . Generate  $(K_i, \tau_i)$  for all other players. Then run  $\mathcal{A}$  with  $K_1, \dots, K_n$ . Whenever  $\mathcal{A}$  corrupts a player  $P_i$ , give  $\tau_i$ . If  $\mathcal{A}$  corrupts either  $P_{i^*}$  or  $P_{j^*}$ , abort. If  $\mathcal{A}$  happens to choose  $K_{i^*}$  and  $K_{j^*}$  and outputs correct  $(s, r)$ ,  $(s', r')$ , output  $(s, r)$ ,  $(s', r')$  as a claw. This reduction works only when the initial guess comes true. Accordingly, we

have  $\epsilon_{dup} < n^2 \epsilon_{claw}$  where  $\epsilon_{dup}$  is the probability that duplicated  $\alpha_j$  is successfully assigned and  $\epsilon_{claw}$  the probability of finding a claw, respectively. Since  $\epsilon_{claw}$  is assumed negligible, this proves the claim.  $\square$

Instantiating com by Pedersen’s commitment scheme pcom, one can improve the reduction to be tight by exploiting the following facts. (1)  $K$  can be generated without knowing  $\tau$ . Thus, it is not necessary to give  $\tau$  to  $\mathcal{A}$  on corruption. And (2) one can embed  $K$  and  $K'$  to all  $K_1, \dots, K_n$  thanks to the random self-reducibility. By embedding  $K$  and  $K'$  respectively to the first and last  $n/2$  keys,  $\mathcal{A}$  eventually specifies  $K_i$  and  $K_j$  that embed  $K$  and  $K'$  with probability better than  $1/2$ . This yields a claw. If either  $K$  or  $K'$  is embedded in both specified keys, it results in breaking the ordinary binding property of pcom, which is assumed to be successful only with negligible probability.

## 6.2 Pedersen’s VSS as Committed VSS

Pedersen VSS is a twin-base version of Feldman VSS. Instead of committing to secret  $s$  by  $g^s$  it uses so-called Pedersen commitment  $\text{pcom}_{g,h}(s; r) = g^s h^r$  with random  $r$ . As a result, the shared secret is statistically independent of the joint view of any  $t$  players if the shares are delivered in an unconditionally secure way. Accordingly, it seems that if the shares are delivered in a non-committing way, the scheme is in fact secure against adaptive adversaries: the simulator simply shares *some* secret, and then uses the trapdoor for the commitment scheme (the DL of  $h$ ) in order to open the shares in an appropriate way in the reconstruction phase. This intuition, however, is correct only in a restricted sense. That is, if the output of the VSS functionality is limited to the reconstructed secret, while its commitment  $C$  and all other variables possibly chosen by the corrupt dealer are never observed by  $\mathcal{Z}$  (except for the ones read from the output of  $\mathcal{A}$ , which can also be output by  $\mathcal{S}$ ). Thus, the original Pedersen VSS is secure as a non-committing VSS. On the other hand, if  $C$  is used in external protocols and thus is part of the output of the VSS functionality, then the original Pedersen VSS is not secure against adaptive adversaries. The reason is that the corrupted dealer might choose  $C$  according to a strange and secret distribution that is unknown to the simulator, hence the simulator has to perform the simulation with given  $C$  to adjust to its distribution. Now the simulator encounters the same difficulty observed in the original Feldman’s VSS.

Adaptively secure Pedersen VSS,  $\pi_{\text{XPVSS}}$ , as a committing VSS can be obtained by simply applying the randomized X-coordinate technique used for Feldman’s VSS to the original Pedersen’s VSS. As pointed out in Sect. 2.4, a technical subtlety is that the key  $h$  needs to be generated as part of the scheme (rather than considering it as given) in order to describe and prove secure the scheme correctly in the UC framework. (Even in the classical model, it is an important issue though often overlooked.) Optimally,  $h$  is uniformly distributed, which could for instance be achieved by the key-generation phase of  $\mathcal{F}_{\text{DLKG}}$  (respectively  $\pi_{\text{DLKG}}$ ). However, we claim that imposing uniform  $h$  is an overkill for the security of Pedersen’s VSS. Indeed, Pedersen’s VSS only requires that the dealer is not aware of  $\log_g h$  while on the other hand the simulator is, which is exactly the property specified by  $\mathcal{F}_{\text{HGEN}}$ . Since  $\mathcal{F}_{\text{HGEN}}$  is much less expensive than  $\mathcal{F}_{\text{DLKG}}$  with our respective realizations, using  $\mathcal{F}_{\text{HGEN}}$  is a more practical choice. Reflecting this argument, we introduce the functionality  $\mathcal{F}_{\text{HGEN}+\text{SVSS}}^{\text{pcom}_{g,h}^?}$  that captures Pedersen VSS in the UC framework.  $\mathcal{F}_{\text{HGEN}+\text{SVSS}}^{\text{pcom}_{g,h}^?}$  first generates key  $h$  simply by following the specification of  $\mathcal{F}_{\text{HGEN}}$  and then executes the sharing and reconstruction phases of  $\mathcal{F}_{\text{SVSS}}^{\text{pcom}_{g,h}}$ . We illustrate the scheme in Fig. 10 for completeness.

**[Key Generation Phase]**

The dealer invokes  $\mathcal{F}_{\text{HGEN}}$  and every player obtains  $h$ .

**[Sharing Phase]**

P-1. The dealer initiates the protocol by sending *sharing* to every player.

P-2. Each  $P_j$  selects  $\alpha_j \leftarrow \mathbb{Z}_q^*$  and send it to the dealer by using  $\mathcal{F}_{\text{SMT}_{\text{wO}}}$ . Let  $\mathcal{Q} \subseteq \{1, \dots, n\}$  be the set of players whose  $\alpha_j \neq 0$  is received by the dealer. If  $|\mathcal{Q}| < t + 1$ , the dealer aborts the protocol.

P-3. The dealer selects  $f(X) = a_0 + a_1X + \dots + a_tX^t \leftarrow \mathbb{Z}_q[X]$  and  $f'(X) = b_0 + b_1X + \dots + b_tX^t \leftarrow \mathbb{Z}_q[X]$  where  $a_0 = s$ . Let  $r = b_0$ . The dealer then computes and broadcasts  $C = C_0 = g^s h^r$  and  $C_k = g^{a_k} h^{b_k}$  for  $k = 1, \dots, t$ , and he sends  $s_j = f(\alpha_j)$  and  $r_i = f'(\alpha_j)$  to  $P_i$  by  $\mathcal{F}_{\text{SMT}}$ .

P-4. Each  $P_j$  verifies  $g^{s_j} h^{r_j} = \prod_{k=0}^t C_k^{\alpha_j^k}$  and broadcasts *verified* if it holds. Otherwise,  $P_j$  initiates the accusation sub-protocol which is the same as that of Feldman VSS with obvious modification.

**[Reconstruction Phase]**

Each  $P_j$  broadcasts  $(\alpha_j, s_j, r_j)$  and identifies  $\mathcal{Q} \subseteq \{1, \dots, n\}$  so that, for all  $j \in \mathcal{Q}$ ,  $g^{s_j} h^{r_j} = \prod_{k=0}^t C_k^{\alpha_j^k}$  holds. Then  $P_j$  reconstructs secret  $s$  by Lagrange interpolation with regard to  $\mathcal{Q}$ , and outputs  $s$ .

**Fig. 10.** Adaptively secure Pedersen VSS  $\pi_{\text{XPVSS}}$  in  $(\mathcal{F}_{\text{SMT}_{\text{wO}}}, \mathcal{F}_{\text{HGEN}}, \mathcal{F}_{\text{SMT}})$ -hybrid model.

**Proposition 3.** *Under the DL assumption, Protocol  $\pi_{\text{XPVSS}}$  in Fig. 10 securely realizes functionality  $\mathcal{F}_{\text{HGEN}+\text{SVSS}}^{\text{pccom}_{g,?}}$  in the  $(\mathcal{F}_{\text{SMT}_{\text{wO}}}, \mathcal{F}_{\text{HGEN}}, \mathcal{F}_{\text{SMT}})$ -hybrid model against  $t$ -limited adaptive adversary for  $t < n/2$ .*

Using similar arguments as for Theorem 1,  $\pi_{\text{XPVSS}}$  gives rise to an efficient real-life version secure under the conditions (1) and (2) from Theorem 1.

The proof of Proposition 3 essentially follows the lines of the security proof for adaptive Feldman VSS (proof of Proposition 1) with obvious modifications. The main difference is that for the proof of Proposition 3 we need to argue that under the assumed hardness of computing DLs, the shares  $s_j$  provided by the corrupted players  $P_j$  during the reconstruction phase are consistent with the shares of the honest players (except with negligible probability). But this follows from the fact that if not, then the simulator can compute the DL of the generated key  $h$  and thus of any DL instance by embedding it into  $h$ .

### 6.3 Common-Random-String Generator

Note that if in  $\pi_{\text{DLKG}}$  the opening phase is invoked right after step K-2 (and steps K-3 and K-4 are skipped) then this modified protocol realizes a common-random-string (CRS) generator, which produces a random element from  $\mathbb{Z}_q$ . Name our modified protocol by  $\pi_{\text{CRS}}$  and the obvious CRS generator functionality by  $\mathcal{F}_{\text{CRS}}$ . We have:

**Theorem 8.** *Protocol  $\pi_{\text{CRS}}$  securely realizes  $\mathcal{F}_{\text{CRS}}$  against adaptive  $t$ -limited adversary for  $t < n/2$  in the SIP UC model.*

Similar protocols were used in [7, 16], though with the difference that the generation of  $h$  either required secure channels, or could not be proven secure without rewinding the adversary and thus disallows a UC-like security proof.

As shown in [7, 16], such a CRS generator allows the following application. Consider an execution of a standard three-move public-coin honest-verifier zero-knowledge proof protocol with challenge-space  $\mathbb{Z}_q$  (like Schnorr's protocol for proving the knowledge of a DL or the Chaum-Pedersen protocol [9] for proving the equality of two DLs) where the first message

and the answer are broadcast (by the prover) and the random challenge is generated jointly by an invocation of  $\mathcal{F}_{\text{CRS}}$ . Such an execution still guarantees soundness, while it can be simulated without rewinding the possibly corrupt verifier. In [7, 16], this property holds under the assumption of a correctly generated  $h$ , while with our protocol  $\pi_{\text{HGEN}}$  it holds from scratch. The simulator can simply first produce an accepting transcript of the proof protocol using the honest-verifier zero-knowledge simulator, and then enforce the outcome of  $\pi_{\text{CRS}}$  to be the chosen challenge. This proof protocol can be useful in the construction of UC secure protocols; however, we stress that it is *not* a secure realization of the zero-knowledge functionality  $\mathcal{F}_{\text{ZK}}$  (modified to multiple verifiers). Secure realizations of  $\mathcal{F}_{\text{ZK}}$  in a distributed-verifier setting are sketched in Sect. 6.4.

## 6.4 Adaptively Secure Distributed-Verifier Proofs

In designing threshold cryptography, it is quite common to prove some relation (or knowledge) about committed witnesses in zero-knowledge manner. In the UC framework, however, zero-knowledge proofs are extremely expensive components: they are realized by combining a generic non-interactive zero-knowledge proof with a common-reference string generator, or UC-secure commitment scheme (which anyway needs common reference string) with generic zero-knowledge proof system for an NP-complete language such as Hamiltonian. They are generic and powerful, but cannot be directly used for practical subjects such as showing equality of discrete-logs or knowledge of a representation.

Combining our results with techniques developed in [1, 2], one can construct adaptively secure efficient distributed-verifier zero-knowledge proofs in universally composable way for many practical subjects. We illustrate a concrete example. Suppose that a prover needs to show that a triple,  $(g^\alpha, g^\beta, g^\gamma)$  is in multiplicative relation  $\alpha \cdot \beta = \gamma$ , which is equivalent to showing that the triple is in DH. This can be done as follows. A prover shares  $\alpha$  twice: once using the sharing phase of  $\pi_{\text{XFVSS}}[g]$  and once using that of  $\pi_{\text{XFVSS}}[g^\beta]$  with base  $g^\beta$ . Furthermore, in the second execution, the same sharing polynomial and X-coordinates as in the first execution are used. Hence the second execution is completed only by broadcasting a new commitment of the sharing polynomial, which is verified by the players by using the same share and X-coordinate received in the first execution. This guarantees that indeed the same secret,  $\alpha$ , has been shared. Note that  $(g^\beta)^\alpha$ , supposed to be  $g^\gamma$ , is published in the second execution. Finally, the prover shares  $\beta$  (or  $\gamma$ ) using the sharing phase of  $\pi_{\text{XFVSS}}[g]$  with base  $g$ . If all sharing phases are accepted, the proof is accepted. Given  $(g^\alpha, g^\beta, g^\gamma)$ ,  $\mathcal{S}$  can simulate the prover by simulating the dealer in each execution of  $\pi_{\text{XFVSS}}$ . In the case of corrupt prover who completes the proof,  $\mathcal{S}$  can extract  $\alpha$  and  $\beta$  from the set of uncorrupt players. Hence the simulator can extract a witness  $(\alpha, \beta)$  needed to invoke ideal zero-knowledge functionality.

The techniques of [1, 2] also apply to other commitment schemes that Feldman's, and allow to prove other relations as well like equality and additive and inverse relations among committed values. From these building blocks, one can even construct an adaptive distributed verifier proof for any NP relation by following the construction in [2].

## Acknowledgements

We thank Jesper Buus Nielsen for helpful discussions concerning the UC framework and for suggesting to use spooling to overcome the problem addressed in Sect. 2.4. Also thanks to the Crypto 04 program committee for helpful comments.

## A Proof of Proposition 1

First, we consider a statically corrupted dealer, i.e.,  $P_d$  is corrupted by  $\mathcal{A}$  before  $\pi_{\text{XFVSS}}$  starts. In this case,  $\mathcal{S}$  corrupts  $\tilde{P}_d$  to give its internal state to  $\mathcal{A}$  and then follows all subsequent instructions from  $\mathcal{A}$ . If  $\mathcal{A}$  initiates the sharing phase on behalf of corrupted dealer  $P_d$ ,  $\mathcal{S}$  simulates all the honest players as prescribed. Once the sharing phase is accepted by more than  $t$  honest players, each of these players holds  $(\alpha_j, s_j)$  that satisfies the verification predicate and each independently chosen  $\alpha_j$  is different from others with overwhelming probability  $> 1 - n^2/q$ .  $\mathcal{S}$  reconstructs secret  $s$  by interpolation, and then sends  $(\text{spool}, \text{sid}, s)$  and  $(\text{share}, \text{sid})$  to  $\mathcal{F}_{\text{SVSS}}^{\text{fcom}_g}$  under the name of  $\tilde{P}_d$ , and delivers the outputs to their intended players. If the sharing phase is rejected,  $\mathcal{S}$  does nothing in the ideal-process.  $\mathcal{S}$  is successful with overwhelming probability in this way.

Next, we assume that the dealer remains uncorrupt forever. On receiving  $(\text{spooled}, \text{sid}, P_d, Y)$  from  $\mathcal{F}_{\text{SVSS}}^{\text{fcom}_g}$ , the simulator  $\mathcal{S}$  works as follows. The item numbers correspond to those in Fig. 1.

- F'-1. If  $\mathcal{A}$  corrupts some players at the beginning, corrupt corresponding dummy players and give  $\mathcal{A}$  their internal states. Then simulate  $P_d$  and initiate the protocol by sending *init* to every player.
- F'-2. Simulate each honest player and  $\mathcal{F}_{\text{SNC}}$  by following their prescription. If  $\mathcal{A}$  corrupts a player,  $P_i$ , corrupt  $\tilde{P}_i$  and give its internal state with  $\alpha_i$  used in this step. Let  $\{j_1, \dots, j_k\}$  be set of identities of the players corrupted by the end of this step.
- F'-3. Simulate dealer  $P_d$  as follows. Set  $\tilde{\alpha}_i = \alpha_{j_i}$  for  $1 \leq i \leq k$ , and  $\tilde{\alpha}_i \leftarrow \mathbb{Z}_q^*$  for  $k+1 \leq i \leq t$ . Then select  $\tilde{s}_i \leftarrow \mathbb{Z}_q$  and compute  $E_i = g^{\tilde{s}_i}$  for  $i = 1, \dots, t$ . Let  $C_0 = Y$  and broadcast  $(C_0, C_1, \dots, C_t)$  that satisfies the following system of equations.

$$\begin{pmatrix} E_1 \\ \vdots \\ E_t \end{pmatrix} = \begin{pmatrix} 1 & \tilde{\alpha}_1^1 & \dots & \tilde{\alpha}_1^t \\ \vdots & \vdots & \ddots & \vdots \\ 1 & \tilde{\alpha}_t^1 & \dots & \tilde{\alpha}_t^t \end{pmatrix} \star \begin{pmatrix} Y \\ C_1 \\ \vdots \\ C_t \end{pmatrix} \quad (2)$$

Operator ' $\star$ ' is a usual matrix multiplication but replacing addition/multiplication with multiplication/exponentiation. For instance,  $E_1 = Y^1 C_1^{\tilde{\alpha}_1^1} \dots C_t^{\tilde{\alpha}_1^t}$ . From the inverse of the above Vandermonde matrix,  $(C_1, \dots, C_t)$  can be computed easily without solving discrete logarithms. Now, send  $s_{j_i} = \tilde{s}_i$  to each corrupt  $P_{j_i}$ , and  $s_j \leftarrow \mathbb{Z}_q$  to each honest  $P_j$  via  $\mathcal{F}_{\text{SSMT}}$ .  $P_j$  is simulated to broadcast *verified* whatever it receives.

If  $\mathcal{A}$  corrupts a player,  $P_j$ , at this moment, assign  $(\alpha_j, s_j) = (\tilde{\alpha}_{k+1}, \tilde{s}_{k+1})$ . Then corrupt  $\tilde{P}_j$  and give its internal state and  $(\alpha_j, s_j)$  to  $\mathcal{A}$ . Then let  $k := k + 1$ .

For accusation to  $P_d$ , simulate dealer  $P_d$  and all honest players as prescribed. Note that honest player will never accuse the dealer.

- F'-4. Since there are at least  $t + 1$  honest players and they have broadcast *verified*, honest players outputs *accept* and stop. If  $\mathcal{A}$  corrupts a player, build the internal state of the player in the same way as done in the previous step.

Observe that  $\tilde{\alpha}_1, \dots, \tilde{\alpha}_t$  distributes as it should be (some follow the choice of corrupt players and others are chosen uniformly.) Also, all  $\tilde{s}_1, \dots, \tilde{s}_t$  are chosen uniformly and other variables are in correct relation. Although  $\alpha_j$  and/or  $s_j$  given to  $\mathcal{A}$  as a part of internal state of  $P_j$  corrupted after the initial step are different from those really sent and received by  $P_j$ , it does not matter to this hybrid protocol due to the non-committing property of  $\mathcal{F}_{\text{SSMT}}$ .

Accordingly, all data observed by  $\mathcal{A}$  and hence  $\mathcal{Z}$  within  $\pi_{\text{XFVSS}}$  and  $\mathcal{F}_{\text{SVSS}}^{\text{fcom}_g}$  with regard to the sharing phase distributes identically.

Considering the reconstruction phase, when  $\mathcal{S}$  receives  $(\text{open}, \text{sid}, s)$  from  $\mathcal{F}_{\text{SVSS}}^{\text{fcom}_h}$ , it recovers the sharing polynomial, say  $f(X)$ , defined by points  $(0, s), (\tilde{\alpha}_1, \tilde{s}_1), \dots, (\tilde{\alpha}_t, \tilde{s}_t)$ . Then  $\mathcal{S}$  computes  $(\tilde{\alpha}_{t+1}, \tilde{s}_{t+1}), \dots, (\tilde{\alpha}_n, \tilde{s}_n)$  where  $\tilde{\alpha}_j \leftarrow \mathbb{Z}_q^*$  and  $\tilde{s}_j = f(\tilde{\alpha}_j)$ , and it assigns each of these newly computed points to each honest player so that they cast the points as their shares. If a player,  $P_j$ , is post-corrupted,  $\mathcal{S}$  corrupts  $\tilde{P}_j$  and hands its internal state together with the assigned point to  $\mathcal{A}$ .

As in the sharing phase, this simulated reconstruction phase provides  $\mathcal{Z}$  a view that is perfectly indistinguishable from that in real-life model.

Finally, suppose that the dealer is corrupted during (of after) the execution of the protocol. To start with, on receiving  $(\text{spooled}, \text{sid}, P_d, Y)$  from  $\mathcal{F}_{\text{SVSS}}^{\text{fcom}_g}$ , the simulator  $\mathcal{S}$  follows the above description (for the case of an uncorrupt dealer). If the dealer in this simulation is corrupted before step F-3,  $\mathcal{S}$  corrupts the dealer in the ideal-process and obtains the secret  $s$ . Then  $\mathcal{S}$  hands it to  $\mathcal{A}$  and follows the instructions concerning corrupted  $P_d$  to the end of the protocol, while honestly simulating the uncorrupt players. If the sharing phase is completed with acceptance,  $\mathcal{S}$  recovers  $(s', r')$  from the joint view of the honest majority and sends  $(\text{share}, \text{sid}, (s', r'))$  to  $\mathcal{F}_{\text{SVSS}}^{\text{fcom}_g}$ . If the dealer is corrupted after step F-3 but before the reconstruction took place,  $\mathcal{S}$  obtains  $s$  by corrupting the dealer in the ideal-process. Then, as above in the reconstruction phase,  $\mathcal{S}$  reconstructs the sharing polynomial  $f(X)$  from the  $t + 1$  points,  $(0, s), (\tilde{\alpha}_1, \tilde{s}_1), \dots, (\tilde{\alpha}_t, \tilde{s}_t)$ , computes the remaining points  $(\tilde{\alpha}_{t+1}, \tilde{s}_{t+1}), \dots, (\tilde{\alpha}_n, \tilde{s}_n)$  that are consistent with the polynomial, and from now on pretends as if those points are assigned to the players. If the sharing phase is completed with acceptance,  $\mathcal{S}$  sends  $(\text{share}, \text{sid}, (s, r))$  to  $\mathcal{F}_{\text{SVSS}}^{\text{fcom}_g}$ . In both cases, the reconstruction phase is simulated by letting every uncorrupt player  $P_j$  honestly follow the protocol, using his assigned point. Again, this simulation provides  $\mathcal{Z}$  a view that is perfectly indistinguishable from that in the real-life model.  $\square$

## B Proof of Lemma 1

*Construction of  $\mathcal{S}$ :* Hereafter, whenever element  $X$  is drawn from  $G_q$ ,  $\mathcal{S}$  first picks  $x \leftarrow \mathbb{Z}_q$  and then computes  $X = g^x$  so that all DLs are known. To remember this random choice with witness, we denote it by  $X \stackrel{w}{\leftarrow} G_q$ .

We distinguish between the following cases. In case (1), the sender is (statically) corrupt, and in case (2), the sender remains uncorrupt.

Case (1):  $\mathcal{S}$  corrupts  $\tilde{P}_s$  statically, gives its internal state to  $\mathcal{A}$ , and follows subsequent instructions about  $P_s$  from  $\mathcal{A}$ . If corrupt  $P_s$  later initiates  $\pi_{\text{RNC}}$ ,  $\mathcal{S}$  simulates  $P_r$  honestly. If at some point during the execution of  $\pi_{\text{RNC}}$   $\mathcal{A}$  corrupts  $P_r$ ,  $\mathcal{S}$  corrupts  $\tilde{P}_r$  and follows subsequent instruction about  $P_r$  from  $\mathcal{A}$ . On the other hand, if  $P_r$  remains uncorrupt and outputs a message  $m$  on completion of  $\pi_{\text{RNC}}$  (which might differ from the message  $\mathcal{Z}$  sent to  $\tilde{P}_s$ ),  $\mathcal{S}$  sends  $(\text{send}, \text{sid}, \tilde{P}_r, m)$  to  $\mathcal{F}_{\text{SMT}}$  (respectively  $(\text{spool}, \text{sid}, \tilde{P}_r, m)$  and  $(\text{send}, \text{sid})$  to  $\mathcal{F}_{\text{SSMT}}$ ) under the name of  $\tilde{P}_s$  and delivers the output of  $\mathcal{F}_{\text{SMT}}$  (respectively  $\mathcal{F}_{\text{SSMT}}$ ) to its destination. This simulation is clearly perfect.

Case (2): On receiving  $(\text{sid}, \tilde{P}_s, \tilde{P}_r)$  from  $\mathcal{F}_{\text{SMT}}$ ,  $\mathcal{S}$  starts  $\pi_{\text{SNC}}$ . Subsequent behavior of  $\mathcal{S}$  depends on the timing that  $\mathcal{A}$  corrupts receiver  $P_r$  as follows.

SA-0. In the initial step,  $\mathcal{S}$  chooses  $h \stackrel{w}{\leftarrow} G_q$  for  $P_s$  and sends it to  $P_r$ .

- SA-1. (Pre-corruption) If  $P_r$  is corrupted before  $y$  is sent off,  $\mathcal{S}$  corrupts  $\tilde{P}_r$  and gives  $\mathcal{A}$  the internal state of  $\tilde{P}_r$ . On receiving  $(\tilde{P}_s, m)$ ,  $\mathcal{S}$  continues the simulation by simulating  $P_s$  honestly in the execution of  $\pi_{\text{RNC}}$  with message  $m$ .
- SA-2. If pre-corruption does not happen,  $\mathcal{S}$  honestly follows step A-1. Then it samples  $u, v, c \xleftarrow{w} G_q$  for  $P_s$  and sends  $(u, v, c)$  to  $P_r$ . (As a result,  $(h, u, v)$  distributes differently from the real execution.)
- SA-3. (Post-corruption) If  $P_r$  is corrupted after the transmission phase is completed,  $\mathcal{S}$  gives  $\mathcal{A}$  the internal state of  $\tilde{P}_r$  as above.  $\mathcal{S}$  also gives  $(z_1, z_2)$  that satisfies  $y = g^{z_1} h^{z_2}$  and  $c = \text{Encode}(m) u^{z_1} v^{z_2}$  where  $m$  is the message observed in the internal state of  $\tilde{P}_s$ . Such  $(z_1, z_2)$  can be computed easily (except with negligible probability  $1/q$ ) since all the discrete-logs of  $h, y, u, v, c$  are known to  $\mathcal{S}$  by construction, and that of  $\text{Encode}(m)$  by assumption.

*Reduction to DDH:* We show that if there exists an adversary  $\mathcal{A}$  and an environment  $\mathcal{Z}$  such that  $\text{REAL}_{\pi_{\text{SNC}}, \mathcal{A}, \mathcal{Z}} \not\approx \text{IDEAL}_{\mathcal{F}_{\text{SMTwo}}, \mathcal{S}, \mathcal{Z}}$  for the above simulator  $\mathcal{S}$ , then the DDH assumption does not hold. Precisely, we construct a distinguisher  $\mathcal{D}$ , which uses such  $\mathcal{Z}$  and  $\mathcal{A}$ , and whose output distribution is given by  $\text{REAL}_{\pi_{\text{RNC}}, \mathcal{A}, \mathcal{Z}}$  if  $\mathcal{D}$ 's input is chosen uniformly in DH and by  $\text{IDEAL}_{\mathcal{F}_{\text{SMTwo}}, \mathcal{S}, \mathcal{Z}}$  if it is chosen uniformly in RND. Since the simulation differs from the real run only in step SA-2, we only consider case (2) in the following.

Let  $(g^\alpha, g^\beta, g^\gamma)$  be a DDH instance chosen at random either from DH or from RND. On input  $(g^\alpha, g^\beta, g^\gamma)$ ,  $\mathcal{D}$  runs  $\mathcal{Z}$  and  $\mathcal{A}$  as well as (ideal-life) players  $\tilde{P}_1, \dots, \tilde{P}_n$  and the functionality  $\mathcal{F}_{\text{SMT}}$ , and it simulates an execution of  $\pi_{\text{RNC}}$  during an ideal-life execution of  $\mathcal{F}_{\text{SMT}}$  exactly as  $\mathcal{S}$  does above, except for the following modifications. In step SA-0,  $\mathcal{D}$  sets  $h = g^\alpha$ , and in step SA-2,  $\mathcal{D}$  sets  $u = g^\beta$ ,  $v = g^\gamma$  and  $c = \text{Encode}(m) u^{z_1} v^{z_2}$ , where  $m$  is the message  $\tilde{P}_s$  received from  $\mathcal{Z}$ . Finally,  $\mathcal{D}$  outputs the output bit of  $\mathcal{Z}$ .

First, consider the case  $(g^\alpha, g^\beta, g^\gamma) \in \text{DH}$ , i.e.,  $\gamma = \alpha\beta$ . Observe that for  $r = \beta$ , it holds that  $u = g^r$ ,  $v = h^r$  and  $c = \text{Encode}(m) u^{z_1} v^{z_2} = \text{Encode}(m) y^r$ . Thus,  $\mathcal{D}$  simulates the players perfectly as in  $\pi_{\text{RNC}}$  and hence the output distribution of  $\mathcal{Z}$  is identical to  $\text{REAL}_{\pi_{\text{SNC}}, \mathcal{A}, \mathcal{Z}}$ . Next, consider the case where  $(g^\alpha, g^\beta, g^\gamma)$  is random in RND. Clearly,  $\mathcal{D}$  produces the same simulation as  $\mathcal{S}$ , except if  $(h, u, v) \in \text{DH}$ , which happens with probability  $1/q$  and in which case  $\mathcal{S}$  fails to handle a post-corruption. Accordingly,  $\mathcal{D}$ 's output distribution is statistically close to  $\text{IDEAL}_{\mathcal{F}_{\text{SMT}}, \mathcal{S}, \mathcal{Z}}$ . So, if  $\mathcal{Z}$  distinguishes  $\text{REAL}_{\pi_{\text{RNC}}, \mathcal{A}, \mathcal{Z}}$  and  $\text{IDEAL}_{\mathcal{F}_{\text{SMT}}, \mathcal{S}, \mathcal{Z}}$ , then  $\mathcal{D}$  distinguishes the respective uniform distributions over DH and RND with almost the same advantage.  $\square$

## C Proof of Lemma 2

We focus on the claim concerning  $\pi_{\text{SNCwo}}$  and  $\mathcal{F}_{\text{SMTwo}}$ . The proof of the security of  $\pi_{\text{SNC}}$  as a realization of  $\pi_{\text{SMT}}$  can easily be extracted. For completeness, we illustrate protocol  $\pi_{\text{SNCwo}}$  in Fig. 11. Steps B-0 to B-3 are exactly the same as  $\pi_{\text{RNC}}$  except that all communication is done via broadcast (although we keep the terminology “send”) and that the role of the sender and the receiver is reversed.

*Construction of  $\mathcal{S}$ :* As in the proof of Lemma 1, whenever an element  $X$  is drawn from  $G_q$ ,  $\mathcal{S}$  first picks  $x \leftarrow \mathbb{Z}_q$  and then computes  $X = g^x$  so that all DLs are known. To remember this random choice with witness, we denote it by  $X \xleftarrow{w} G_q$ .

We distinguish between the following cases:

- (1) The receiver is statically corrupted (and the sender is statically or adaptively corrupted).

**[Transmission Phase]**

- B-0. Receiver  $P_r$  chooses  $h \leftarrow G_q$  and sends it to sender  $P_s$ .
- B-1.  $P_s$  selects  $z_1, z_2 \leftarrow \mathbb{Z}_q$ , computes  $y = g^{z_1} h^{z_2}$ , and sends  $y$  to  $P_r$ .
- B-2.  $P_r$  computes  $u = g^r, v = h^r$  and  $c = k y^r$ , where  $k \leftarrow G_q, r \leftarrow \mathbb{Z}_q$ , and sends  $(u, v, c)$  to  $P_s$ .
- B-3.  $P_s$  recovers  $k = c u^{-z_1} v^{-z_2}$  and sends  $e = k \text{Encode}(m)$  to  $P_r$ .
- B-4.  $P_r$  outputs  $m = \text{Decode}(e k^{-1})$ .

**[Opening Phase]**

- C-1.  $P_s$  publishes  $z_1, z_2$  and  $m$ .
- C-2. Every player outputs  $m$  if  $y = g^{z_1} h^{z_2}$  and  $m = \text{Decode}(e k^{-1})$  holds for  $k = c u^{-z_1} v^{-z_2}$ . Otherwise output nothing.

**Fig. 11.** Protocol  $\pi_{\text{SNCWO}}$  for sender non-committing transmission with opening.

- (2) The receiver is never corrupted and the sender is statically corrupted.
- (3) The receiver is never corrupted and the sender is adaptively corrupted.

Case (1):  $\mathcal{S}$  corrupts receiver  $\tilde{P}_r$  at the beginning and gives its internal state to  $\mathcal{A}$ . On receiving  $(\text{spooled}, \text{sid}, \tilde{P}_s, \tilde{P}_r)$  from  $\mathcal{F}_{\text{SSMTWO}}$ ,  $\mathcal{S}$  invokes  $\pi_{\text{SNCWO}}$  and simulates  $P_s$  honestly. If  $\mathcal{A}$  corrupts  $P_s$  before  $e$  is sent off,  $\mathcal{S}$  corrupts  $\tilde{P}_s$  and gives  $\mathcal{A}$   $\tilde{P}_s$ 's internal state and all random choices used in the simulation of  $P_s$  so far. On the other hand, if  $P_s$  is not corrupted at step B-3,  $\mathcal{S}$  gets back to the ideal-process and waits for message  $(\text{received}, \text{sid}, \tilde{P}_s, m)$  sent to the corrupt  $\tilde{P}_r$ . Once received,  $\mathcal{S}$  continues the simulation by computing  $e$  correctly with this  $m$ . If  $P_s$  is corrupted at any further point,  $\mathcal{S}$  corrupts  $\tilde{P}_s$  and gives  $\mathcal{A}$   $\tilde{P}_s$ 's internal state and all random choices of  $P_s$ . If  $P_s$  does not get corrupted in the transmission phase and  $\mathcal{S}$  receives  $(\text{sent}, \text{sid}, \tilde{P}_s, \tilde{P}_r, m)$  from  $\mathcal{F}_{\text{SSMTWO}}$ ,  $\mathcal{S}$  publishes  $(r_1, r_2)$  chosen by  $P_s$  so that message  $m$  is recovered by following the protocol. Since there is no make-believe,  $\mathcal{S}$  works perfectly like  $\mathcal{A}$  from the viewpoint of  $\mathcal{Z}$ .

Case (2):  $\mathcal{S}$  corrupts  $\tilde{P}_s$ , gives its internal state to  $\mathcal{A}$ , and follows subsequent instruction about  $P_s$  from  $\mathcal{A}$ . If corrupt  $P_s$  later initiates  $\pi_{\text{SNCWO}}$ ,  $\mathcal{S}$  simulates  $P_r$  honestly. If the transmission phase of  $\pi_{\text{SNCWO}}$  is completed and  $P_r$  outputs a message  $m$  (which might differ from the message  $\mathcal{Z}$  sent to  $\tilde{P}_s$ ,  $\mathcal{S}$  sends  $(\text{spool}, \text{sid}, \tilde{P}_r, m)$  and  $(\text{send}, \text{sid})$  to  $\mathcal{F}_{\text{SSMTWO}}$  under the name of  $\tilde{P}_s$  and delivers the output of  $\mathcal{F}_{\text{SSMTWO}}$  to its destination. In the opening phase, if corrupt  $P_s$  publishes correct  $(z'_1, z'_2, m')$ ,  $\mathcal{S}$  simulates all players to output  $m'$  in the simulating real-life protocol and sends  $(\text{open}, \text{sid})$  to  $\mathcal{F}_{\text{SSMTWO}}$  on behalf of corrupt  $P_s$  and  $\mathcal{F}_{\text{SSMTWO}}$  publishes  $m$ . Note that  $y = g^{z_1} h^{z_2}$  and thus  $m' = e c^{-1} u^{z'_1} v^{z'_2} = e c^{-1} (g^r)^{z'_1} (h^r)^{z'_2} = e c^{-1} y^r = m$ . Therefore, as in the above cases,  $\mathcal{S}$  works perfectly.

Case (3): On receiving  $(\text{spool}, \text{sid}, \tilde{P}_s, \tilde{P}_r)$  from  $\mathcal{F}_{\text{SSMTWO}}$ ,  $\mathcal{S}$  starts  $\pi_{\text{SNCWO}}$ . Subsequent behavior of  $\mathcal{S}$  depends on the timing that  $\mathcal{A}$  corrupts sender  $P_s$  as follows.

- SB-1. In the initial step, choose  $h \leftarrow G_q$  for  $P_r$ .
- SB-2. (Pre-corruption) If  $P_s$  is corrupted before  $(u, v, c)$  is sent off from  $P_r$ ,  $\mathcal{S}$  behaves as in Case (2) up to the end of the protocol execution.
- SB-3. If pre-corruption does not happen,  $\mathcal{S}$  continues simulation up to B-2 and select  $(u, v, c) \leftarrow G_q^3$  for  $P_r$ . (As a result,  $(h, u, v)$  distributes differently than in the real-life execution.)
- SB-4. (Mid-corruption) If  $P_s$  is corrupted before  $e$  is sent off,  $\mathcal{S}$  gives  $\mathcal{A}$  the internal state of  $\tilde{P}_s$ . If  $P_r$  further receives  $e \in G_q$  from corrupt  $P_s$ ,  $\mathcal{S}$  sets  $m = \text{Decode}(e c^{-1} u^{z_1} v^{z_2})$  in step B-4, and sends  $(\text{send}, \text{sid}, \tilde{P}_r, m)$  to  $\mathcal{F}_{\text{SSMTWO}}$  so that  $\tilde{P}_r$  outputs  $m$ .

- SB-5. If mid-corruption does not happen,  $\mathcal{S}$  continues simulation by selecting  $e \stackrel{w}{\leftarrow} G_q$  for  $P_s$  in B-3. Once the transmission phase is done,  $\mathcal{S}$  resumes the ideal-process and completes the transmission phase by handling the rest of messages from  $\mathcal{F}_{\text{SSMT}_{wO}}$  as specified.
- SB-6. (Post-corruption) If  $P_s$  is corrupted after the transmission phase is completed,  $\mathcal{S}$  corrupts  $\tilde{P}_s$ . It then computes  $(z_1, z_2)$  that satisfies  $y = g^{z_1} h^{z_2}$  and  $c = e \text{Encode}(m)^{-1} u^{z_1} v^{z_2}$  where  $m$  is the message observed in the internal state of  $\tilde{P}_s$ . Such  $(z_1, z_2)$  exists (unless  $(h, u, v) \in \text{DH}$ , which happens with negligible probability  $1/q$ ) and can be computed easily since all the discrete-logs of  $h, u, v, c, y, e$  are known to  $\mathcal{S}$  by construction, and that of  $\text{Encode}(m)$  by assumption.  $\mathcal{S}$  gives such  $(z_1, z_2, m)$  to  $\mathcal{A}$  with the internal state of  $\tilde{P}_s$ .

Finally, if corrupted  $P_s$  publishes correct  $(z'_1, z'_2, m')$  in the opening phase,  $\mathcal{S}$  simulates all players to output  $m'$  and sends  $(\text{open}, \text{sid})$  to  $\mathcal{F}_{\text{SSMT}_{wO}}$ . On the other hand, if  $P_s$  is not yet corrupted and  $(\text{sent}, \text{sid}, P_s, P_r, m)$  is sent from  $\mathcal{F}_{\text{SSMT}_{wO}}$ ,  $\mathcal{S}$  computes  $(z_1, z_2)$  adjusted to this  $m$  in the same way as shown in SB-6 and publishes  $(z_1, z_2, m)$ .

Concerning the question whether  $m = m'$ , we only need to look at the case of mid- or post-corruption, as in case of pre-corruption equality follows as in Case (2). We argue that (in case of mid- or post-corruption)  $m \neq m'$  can happen only with negligible probability, under the DL assumption. Note that by construction  $y = g^{z_1} h^{z_2}$  and  $c = e \text{Encode}(m')^{-1} u^{z_1} v^{z_2}$ , and by the correctness  $y = g^{z'_1} h^{z'_2}$  and  $c = e \text{Encode}(m')^{-1} u^{z'_1} v^{z'_2}$ . Therefore, if  $m \neq m'$  then  $(z_1, z_2) \neq (z'_1, z'_2)$  and thus the two representations  $g^{z_1} h^{z_2} = y = g^{z'_1} h^{z'_2}$  allow to compute the DL of  $h$ . It follows that the existence of  $\mathcal{A}$  and  $\mathcal{Z}$  that achieve  $m \neq m'$  with non-negligible probability implies the existence of an algorithm that contradicts the DL assumption: simply adapt  $\mathcal{S}$  in that it embeds a DL problem into  $h$  and, up to the point  $P_s$  gets corrupted, computes  $y, c$  and  $e$  as  $y = g^{z_1} h^{z_2}$ ,  $c = k u^{z_1} v^{z_2}$  and  $e = \text{Encode}(m) k$ , where  $m$  is the message sent from  $\mathcal{Z}$  to  $P_j$ . Note that this modification does not affect  $\mathcal{Z}$ 's view, except if  $(h, u, v) \in \text{DH}$  which happens with negligible probability  $1/q$ .

*Reduction to DDH:* Assuming that the unique opening is achieved as above, we now show that if there exists an adversary  $\mathcal{A}$  and an environment  $\mathcal{Z}$  such that  $\text{REAL}_{\pi_{\text{SNC}}, \mathcal{A}, \mathcal{Z}} \not\approx \text{IDEAL}_{\mathcal{F}_{\text{SSMT}_{wO}}, \mathcal{S}, \mathcal{Z}}$  for the above simulator  $\mathcal{S}$ , then the DDH assumption does not hold. Precisely, we construct a distinguisher  $\mathcal{D}$ , which uses such  $\mathcal{Z}$  and  $\mathcal{A}$ , and whose output distribution is given by  $\text{REAL}_{\pi_{\text{SNC}}, \mathcal{A}, \mathcal{Z}}$  if  $\mathcal{D}$ 's input is chosen uniformly in DH and by  $\text{IDEAL}_{\mathcal{F}_{\text{SSMT}_{wO}}, \mathcal{S}, \mathcal{Z}}$  if it is chosen uniformly in RND. Since the simulation differs from the real run only in step SB-3, we only consider Case (3) with Mid- or Post-corruption hereafter.

Let  $(g^\alpha, g^\beta, g^\gamma)$  be an DDH instance chosen at random either from DH or from RND. Given  $(p, q, g)$  and  $(g^\alpha, g^\beta, g^\gamma)$ ,  $\mathcal{D}$  runs  $\mathcal{Z}$  and  $\mathcal{A}$  as well as (ideal-life) players  $\tilde{P}_1, \dots, \tilde{P}_n$  and the functionality  $\mathcal{F}_{\text{SSMT}_{wO}}$ , and it simulates an execution of  $\pi_{\text{SNC}}$  during an ideal-life execution of  $\mathcal{F}_{\text{SSMT}_{wO}}$  exactly as  $\mathcal{S}$  does above, except for the following modifications. That is,  $\mathcal{D}$  sets  $h = g^\alpha$  in SB-1,  $u = g^\beta$ ,  $v = g^\gamma$  and  $c = k u^{z_1} v^{z_2}$  in SB-3, and  $e = m k$  in SB-5. Here,  $k$  is chosen randomly as  $k \stackrel{w}{\leftarrow} G_q$  and  $m$  is the message  $\tilde{P}_s$  received from  $\mathcal{Z}$ . Finally,  $\mathcal{D}$  outputs the output bit of  $\mathcal{Z}$ .

Now, consider the case  $(g^\alpha, g^\beta, g^\gamma) \in \text{DH}$ , i.e.,  $\gamma = \alpha\beta$ . Observe that for  $r = \beta$ , it holds that  $u = g^r$ ,  $v = h^r$  and  $c = k u^{z_1} v^{z_2} = k y^r$ . Thus,  $\mathcal{D}$  simulates the players perfectly as in  $\pi_{\text{SNC}}$  and hence the output distribution of  $\mathcal{Z}$  is identical to  $\text{REAL}_{\pi_{\text{SNC}}, \mathcal{A}, \mathcal{Z}}$ . Next, consider the case  $(g^\alpha, g^\beta, g^\gamma) \in \text{RND}$ , where  $\gamma$  is independent of  $\alpha$  and  $\beta$ . In this case,  $(y, u, v, c, e)$  distributes uniformly over  $G_q^5$  and  $\mathcal{D}$  simulates the players in the same way as done by  $\mathcal{S}$  (unless  $(h, u, v) \in \text{DH}$ , which happens with negligible probability  $1/q$ ) and the ensemble of

the output distribution of  $\mathcal{Z}$  is statistically close to  $\text{IDEAL}_{\mathcal{F}_{\text{SMT}_{\text{wO}}, \mathcal{S}, \mathcal{Z}}}$ . Since  $\mathcal{Z}$  distinguishes  $\text{REAL}_{\pi_{\text{RNC}}, \mathcal{A}, \mathcal{Z}}$  and  $\text{IDEAL}_{\mathcal{F}_{\text{SMT}_{\text{wO}}, \mathcal{S}, \mathcal{Z}}}$ ,  $\mathcal{S}$  results in distinguishing DH and RND with almost the same advantage.  $\square$

## D Proof of Theorem 3

We start by proving  $\pi_{\text{DLKG}}$  from Fig. 5 secure in the  $(\mathcal{F}_{\text{HGEN}}, \mathcal{F}_{\text{SMT}}, \mathcal{F}_{\text{VSS}}^{\text{fcom}_g}, \mathcal{F}_{\text{VSS}}^{\text{fcom}_h})$ -hybrid model.

On receiving  $(\text{key}, \text{sid}, y)$  from  $\mathcal{F}_{\text{DLKG}}$ ,  $\mathcal{S}$  simulates the generation phase by honestly following the protocol except that it simulates  $\mathcal{F}_{\text{HGEN}}$  in step K-1 such that it knows the DL of  $h$  as well as for the following modification. After step K-2,  $\mathcal{S}$  reconstructs  $x_j$  and  $r_j$  of any corrupt player  $P_j$  from the corresponding shares of the uncorrupt players and sets  $C'_{j^*} = y / \prod_{j \neq j^*} g^{x_j}$  and  $C''_{j^*} = C_{j^*} / C'_{j^*}$ . We show later the uniqueness of  $x_j$  and  $r_j$ . Then, instead of  $P_{j^*}$  sending  $x_{j^*}$  and  $r_{j^*}$  to the ideal functionalities  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$  and  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_h}$ ,  $\mathcal{S}$  simply makes them output  $(\text{shared}, \text{sid}_{j^*}, P_{j^*}, C'_{j^*})$  and  $(\text{shared}, \text{sid}'_{j^*}, P_{j^*}, C''_{j^*})$ , respectively, as if they have received corresponding inputs from  $P_{j^*}$ .

On receiving  $(\text{private}, \text{sid}, x)$  from  $\mathcal{F}_{\text{DLKG}}$ ,  $\mathcal{S}$  simulates the opening phase honestly as prescribed, except that it makes  $P_{j^*}$  open  $C_{j^*}$  to  $x - \sum_{j \neq j^*} x_j$ . This can be done as  $\mathcal{S}$  knows the trapdoor to the commitment scheme.

We show the following properties of the simulation, of which each holds except with negligible probability under the DL assumption: (1) the uncorrupt players hold correct sharings of values  $x_j$  and  $r_j$  such that  $g^{x_j} h^{r_j} = C_j$  for every player  $P_j$ , (2) the  $x_j$ 's used to compute  $x$  in the opening phase coincide with the  $x_j$ 's held by  $\mathcal{S}$  (except for  $P_{j^*}$ ), and (3) the output of the simulated generation phase equals the  $y$  provided by  $\mathcal{F}_{\text{DLKG}}$ .

Property (2) implies that the output of the simulated opening phase is indeed  $x = \log_g y$ ; hence, the output behavior of the simulated protocol is as dictated by  $\mathcal{F}_{\text{DLKG}}$ . Furthermore, it follows by inspection that the adversary  $\mathcal{A}$ 's view of the simulation is (statistically) indistinguishable from its view of a real protocol execution. Indeed, the difference only lies in  $x_{j^*}$ 's (Pedersen) shares, of which  $\mathcal{A}$  sees at most  $t$ . This then completes the security proof of  $\mathcal{F}_{\text{DLKG}}$  in the  $(\mathcal{F}_{\text{HGEN}}, \mathcal{F}_{\text{SMT}}, \mathcal{F}_{\text{VSS}}^{\text{fcom}_g}, \mathcal{F}_{\text{VSS}}^{\text{fcom}_h})$ -hybrid-model.

Before showing the security of  $\mathcal{F}_{\text{DLKG}}$  in the real-life model when replacing the ideal functionalities by protocols as specified, we prove the claimed properties. (1) and (2) clearly hold with respect to any uncorrupt player  $P_j$ . With respect to corrupt  $P_j$ , (1) and (2) essentially follow from Lemma 3. If either of them does not hold, then one can use  $\mathcal{A}$  (and  $\mathcal{Z}$ ) to solve the discrete logarithm problem by embedding an instance  $h'$  of the discrete logarithm problem into  $h$  in the course of the simulation of  $\mathcal{F}_{\text{HGEN}}$  as shown in Section 5.1 and computing the DL of  $h$  (and thus of  $h'$ ) using Lemma 3. Concerning (3), if the output is not  $y$  then at least for one corrupt player  $P_j$  (for which  $x_j$  is not reconstructed in step K-4), the values  $x'_j$  and  $r'_j$  sent to  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$  and  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_h}$ , respectively, differ from  $x_j$  and  $r_j$  reconstructed by  $\mathcal{S}$ . However, as  $g^{x_j} h^{r_j} = C_j = g^{x'_j} h^{r'_j}$ , this allows to compute the DL of  $h$  and we can conclude as above.

Next, we show that we may safely replace  $\mathcal{F}_{\text{SMT}}$  by  $\pi_{\text{RNC}}$  in the subprotocols  $\text{PedVSS}_{g,h}^j$  in  $\pi_{\text{DLKG}}$ . Consider the following simulator  $\mathcal{S}'$  in the  $(\mathcal{F}_{\text{HGEN}}, \mathcal{F}_{\text{VSS}}^{\text{com}})$ -hybrid model.  $\mathcal{S}'$  follows the specification of  $\mathcal{S}$  above but executes protocol  $\pi_{\text{RNC}}$  whenever  $\mathcal{S}$  calls for  $\mathcal{F}_{\text{SMT}}$ . Every instance of  $\pi_{\text{RNC}}$  is honestly executed except if the sender is  $P_{j^*}$  and the receiver, say  $P_i$ , is still uncorrupt when  $P_{j^*}$  comes to step A-2 of  $\pi_{\text{RNC}}$ . In that case,  $P_{j^*}$  computes  $u, v$  and  $c$  in step A-2 as  $u, v \leftarrow G_q$  and  $c = \text{Encode}(m)u^{z_1}v^{z_2}$ , where  $m$  is the input to  $\pi_{\text{RNC}}$  (which is a share of either  $x - \sum_{j \neq j^*} x_j$  or an independent random element) and  $z_1$  and  $z_2$  are the values

chosen by the simulated player  $P_i$  in step A-1. This way, uncorrupt  $P_i$  still receives the correct message  $m$  while the communication reveals no information on  $m$ . In order to show that this is a good simulation, we consider an artificial execution of  $\pi_{\text{DLKG}}$  with  $\mathcal{F}_{\text{SMT}}$  replaced by  $\pi_{\text{RNC}}$ , with the same modification as above: if the sender of a message  $m$  is  $P_{j^*}$  and the receiver  $P_i$  is still uncorrupt when  $P_{j^*}$  comes to step A-2 of  $\pi_{\text{RNC}}$ , then  $P_{j^*}$  computes  $u, v$  and  $c$  in step A-2 as  $u, v \leftarrow G_q$  and  $c = \text{Encode}(m)u^{z_1}v^{z_2}$ , where we assume that  $P_i$  privately told  $P_{j^*}$  the values  $z_1, z_2$  chosen in step A-1. By earlier observations that the difference between  $\pi_{\text{DLKG}}$  and its simulation only lies in the Pedersen shares of the uncorrupt players, it follows that  $\mathcal{Z}$  cannot distinguish between the simulation provided by  $\mathcal{S}'$  and the above artificial execution, as the communication of the shares of the uncorrupt players reveals no information. On the other hand, it is straightforward to show that if  $\mathcal{Z}$  can distinguish the artificial execution from the real execution of  $\pi_{\text{DLKG}}$ , then (together with  $\mathcal{A}$ )  $\mathcal{Z}$  can be used to solve the DDH problem: one simply embeds a (randomized) DDH-problem instance  $(g^\alpha, g^\beta, g^\gamma)$  into  $(h, u, v)$  of  $\pi_{\text{RNC}}$  and observes  $\mathcal{Z}$ 's output, similar as in the proof of Lemma 1 and 2.

Finally, using similar observations as for Theorem 2, it follows that  $\pi_{\text{DLKG}}$  securely realizes  $\mathcal{F}_{\text{DLKG}}$  in the real-life model when replacing  $\mathcal{F}_{\text{HGEN}}, \mathcal{F}_{\text{VSS}}^{\text{fcom}_g}$  and  $\mathcal{F}_{\text{VSS}}^{\text{fcom}_h}$  by  $\pi_{\text{HGEN}}, \pi_{\text{XFVSS}}[g]$  and  $\pi_{\text{XFVSS}}[h]$ , respectively. This concludes the proof.  $\square$
