Abstract. Recent non-interactive timed-release encryption (TRE) schemes can be viewed as being supported by a certificateless encryption (CLE) mechanism. However, the security models of CLE and TRE differ and there is no generic transformation that turns a CLE into a TRE. In this paper, we give a generalized model for CLE that is also sufficient to fulfill the requirements of TRE.
Our model is secure against an adversary with adaptive trapdoor extraction capabilities for arbitrary identifiers (instead of selective identifiers), decryption capabilities for arbitrary public keys (as considered in strongly-secure CLE) and partial decryption capabilities (as considered in security-mediated certificateless encryption, or SMCLE). Our model also supports hierarchical identities, which have not been considered formally in paradigms of TRE and CLE.
We propose a concrete scheme under our generalized model and prove it secure without random oracles. Our proposal yields the first strongly-secure SMCLE and the first TRE in the standard model. In addition, our technique of partial decryption is different from the previous approach.

Key words: security-mediated certificateless encryption, timed-release encryption

1 Introduction

The distinguishing feature of identity-based encryption (IBE) (e.g. [7, 15, 16, 25–27, 42]) is that a public key can be derived from any arbitrary string that acts as an identifier (ID). There exists a trusted authority, called a key generation center (KGC), which is responsible for the generation of the ID-based private key on demand. Since the birth of practical IBE constructions, we see many cryptographic schemes borrowing the idea of IBE for other security goals (e.g. broadcast encryption [9], oblivious transfer [27], etc.). This paper studies two of them: certificateless encryption (CLE) [2, 3, 18, 20, 21, 33, 38, 40] and timed-release encryption (TRE) [6, 12–14, 17, 22, 28, 30]. Our main result provides a transformation from a generalized CLE to a TRE.

CLE is intermediate between IBE and traditional public key encryption (PKE). Traditional PKE requires a certification infrastructure but allows users to create their own public/private key pairs so that their private keys are truly private. Conversely, IBE avoids the need for certificates at the expense of adding a KGC that generates the private keys which means the KGC has the capability to decrypt all messages. CLE combines the advantages of both: no certificates are needed and messages can only be decrypted by the recipient. Generally, CLE is constructed by combining IBE and PKE. The existence of the PKE component means that the KGC cannot decrypt messages. Instantaneous revocation is difficult for typical CLE schemes. Security-mediated certificateless encryption (SMCLE) addresses this issue. Here we give the first strongly-secure SMCLE in the standard model. Our scheme also supports hierarchical identities.

In TRE, the sender encrypts the message under a public key and a time, so knowledge of both the matching secret key and a time-dependent trapdoor are necessary for decryption. A time-server is trusted to

⋆ This research is done while the author was a research intern of FX Palo Alto Laboratory.

keep a time-dependent trapdoor confidential until an appointed time, so that the recipient cannot decrypt prior to that time. A feature of modern TRE schemes is that the senders only need to retrieve the system parameters including the schedule for the release of trapdoors from the time-server, without any other interaction. Apart from the obvious application of delayed release of information, TRE supports many other applications which can be classified into two categories: rapid dissemination of information and commitment of confidential information. With TRE, one can send bulky ciphertexts ahead of time. When the information should be made public, a small trapdoor can be widely distributed. Because the size of the trapdoor is small compared with the ciphertext, this approach avoids the problem of any network impedance at the release time. Applications include release of stock market values, strategic business plans, news agencies timed publications, licensed software updates, scheduled payments, internet contests, etc. Some applications require also the commitment of confidential information, such as sealed-bid auction, electronic lotteries, legal will, certified e-mail [30] etc. Text encrypted using TRE can be viewed as a kind of commitment made by the sender; once the ciphertext is sent, the sender cannot change the message that will be received.

Our general CLE scheme, together with our security-preserving transformation converting a general CLE to a TRE, provides the first TRE proven secure in the standard model.

1.1 The difficulty of converting between CLE and TRE

A practical TRE requires the system parameter to be small relative to the number of supported time periods. This is where the relation with IBE comes into the play. By treating the identities as time periods, IBE gives rise to a time-based unlock mechanism (e.g. [7, 36, 37]). However, this approach only supports universal disclosure of encrypted documents since one trapdoor can decrypt all ciphertexts for a specific time. In other words, the inherent key-escrow property of IBE prohibits the encryption for a designated receiver.

Since CLE is an "escrow-free version" of IBE, and both TRE and CLE are a kind of double-encryption, it is natural to think CLE is what we are looking for to realize a TRE. While most recent TRE schemes can be seen as converted from a corresponding implicit CLE mechanism, a generic conversion is not known. Despite similarities in syntax and functionality, as has been pointed out in [12], a generic transformation from CLE to TRE is unlikely to be provable secure. Difficulty in reducing the confidentiality of TRE to that of CLE arises when the adversary is a "curious" time-server. In CLE, each user is determined by a pair-up of identity and public key such that an identity is only associated to a certain public key. A curious KGC is not allowed to replace the public key associated with an identifier arbitrarily (otherwise, decryption of the ciphertext is trivial since it holds both pieces of secrets). On the other hand, a time identifier is never bound to any public key in TRE, which means that the public key associated with a time identifier can be replaced. There is no way to simulate this implicit public key replacement when the CLE is viewed as a black box.

Differences among these two notions not only manifest in the time-server model, the subtle difference in the modelling of a "impatient" recipient is seemingly neglected. In a multi-user system, it is expected that the security of a user is preserved even if other users are compromised. In CLE, the user secret key is combined with the trapdoor given by the KGC to give a *full* private key. With the argument that the user secret key is generated locally and is assumed to be securely deleted afterward, most CLE models assume the adversary can only get the trapdoors from the KGC and the full private keys. For most CLE schemes under this kind of model (e.g. [21]), the user secret key cannot be computed even both the trapdoor and the full private key are known. Moreover, some CLE formulations [3, 32, 40] do not have the concept of user secret key at all. While in TRE, user secret keys are held by all users of the system. Without considering the user secret key in the security model makes reducing the security of TRE to that of CLE not possible.

1.2 Our Contributions

The generalized model for CLE given here overcomes the difficulties described in [12] and has sufficient power to fulfill the requirements of TRE. Our model is secure against an adversary with adaptive trapdoor extraction capabilities for arbitrary identifiers (instead of selective identifiers, e.g. [7, 38]), decryption capabilities for arbitrary public keys (as considered in strongly-secure CLE [21]) and partial decryption capabilities (as

considered in security-mediated certificateless encryption, or SMCLE [18]). Our model also supports hierarchical identities which have not been considered formally for CLE and TRE. Design choices behind our formulation are justified. We also discuss the subtleties involved in building CLE from TRE.

Our model is strong but achievable. We propose a concrete construction under our generalized model. All existing concrete TRE schemes [6, 12–14, 17, 19, 22, 28, 30] and the only concrete SMCLE scheme [18] are proven in the random oracle model. It is true that the generic construction of SMCLE [18] can be instantiated by an IBE and a PKE without random oracles, nevertheless, the resulting scheme is not strongly-secure. Our proposal yields the first strongly-secure SMCLE and the first TRE in the standard model.

Our technique of partial decryption is different from that in [18], which enriches the study of SMCLE. It also enriches the TRE such that a new business model for the operation of the time-server is supported. Finally, hierarchy of identifiers makes decryption of ciphertext for passed periods more manageable.

2 Related Work

2.1 Timed-Release Encryption

The concept of timed-release cryptographic protocols was suggested by May [35] in 1993, and further studied by many researchers including [5, 8, 23, 24]. Early TRE schemes require interaction with the time-server. Rivest *et al.*'s idea [39] requires senders to reveal their identities and the release-time of the messages in their interactions with the server. In Di Crescenzo *et al.*'s scheme [19], the job of interacting with the time-server is moved from the sender to the receiver since a "conditional oblivious transfer protocol" will be executed between the server and the receiver. Such a protocol ensures that if the release-time is greater than the current time (the condition), the receiver learns nothing (obliviousness). However, this protocol [19] is computationally intensive and thus the time-server is vulnerable to denial-of-service attacks.

The first attempt to construct a non-interactive and user-anonymous TRE was made in [6]. A concrete construction is provided, but not supported by a formal security model and security properties are only argued for heuristically. The formal security model of message confidentiality is later considered independently by Cheon *et al.* [17] and Cathalo, Libert and Quisquater [12]. The former focuses on authenticated TRE. The latter claims to have a stronger model than the implicit non-authenticated version of [17], and formalizes the release-time confidentiality. The recovery of past time-dependent trapdoors from a current trapdoor is studied in [14] and [37], which employs a hash chain and a tree structure [11] respectively.

A special class of TRE scheme supports pre-open capability: the sender can help the recipient to decrypt the ciphertext early by publishing a pre-open key. Since the pre-open key is held by the sender, by manipulating the pre-open key, the sender might be able to control somehow what message is decrypted. Using a TRE with pre-open capability as a way to commit confidential information requires the TRE scheme to be binding. The study of the pre-open capability was initiated in [30] and improved by [22].

Recently, Chalkias, Hristu-Varsakelis and Stephanides proposed an efficient TRE scheme [13]. They claim their scheme is the most computationally efficient one for unknown recipients. However, it can be shown that the confidentiality of their scheme can be broken by a curious time-server. A plausible fix makes the decryption algorithm of their scheme less efficient and lessens the purported comparative advantage.

The time-lock puzzle approach [39] provides a way to realize TRE without a trusted server: delayed release is obtained by requiring the recipient to invest significant computational effort to solve a difficult problem. However, not only is this approach time-consuming, but the release-time is not precisely controllable.

2.2 Certificateless Encryption

Certificateless cryptography was suggested by Al-Riyami and Paterson [2] in 2003. We need a basic understanding of the security model to understand the contribution of different proposals. An extensive survey of various CLE security models can be found in [20]. Two types of adversaries are considered in certificateless cryptography. A Type-I adversary models coalitions of rogue users without the master secret. Due to the lack of a certificate, the adversary is allowed to replace the public keys of users at will. A Type-II adversary

models a curious KGC who has the master key but cannot replace the public keys of any users. In Al-Riyami and Paterson's security model for the encryption [2], a Type-I adversary can ask for the decryption of a ciphertext under a replaced public key. Schemes secure against such attacks are called "strongly-secure" [21], and the oracle is termed a "strong decryption oracle". A weaker type of adversary, termed Type-I$^-$, can only obtain a correct plaintext if the ciphertext is submitted along with the corresponding user secret key.

The first CLE scheme by Al-Riyami and Paterson [2] is secure against both Type-I and Type-II adversary in the random oracle model. Many generic constructions of CLE from IBE and PKE exist, some later shown to be insecure (see attacks in [33, 38]), while others (e.g. [33]) rely on the random oracle heuristics. It is believed [32, 34, 38] that [34] gives the first CLE in the standard model. However, it is possible to instantiate a prior generic construction in [18] with a PKE and an IBE in the standard model to obtain a secure CLE without random oracles. Both [34] and the instantiation of [18] are only secure against Type-I$^-$ attacks. Based on [25], a selective-ID secure CLE is proposed in [38]. This scheme cannot be trivially extended to a TRE since the user's public key is dependent on the identity, but a public key is never coupled with a fixed time-identifier in TRE. Recently, the first strongly-secure CLE in the standard model is proposed in [21].

Al-Riyami and Paterson scheme is also the basis for the hierarchical CLE described in [2]. However, neither a security model nor a security proof are given for this hierarchical extension. We are not aware of any literature with formal work on hierarchical CLE, particularly none proven secure in the standard model.

A CLE that does not use pairings is proposed in [3]. However, the reduction used in the security proof does not hold up if the public key associated with the challenge ciphertext can be replaced. Another CLE proposal without pairing [32] uses similar ideas, but no formal evidence was provided to show it does not have the same weakness. This limitation was recently removed by [40]. To replace the pairing, these schemes make part of the user's public key dependent on the identity-specific trapdoor given by the KGC, which means TRE cannot be obtained trivially from these constructions.

Security-mediated certificateless encryption (SMCLE), introduced by Chow, Boyd and González Nieto [18], adds a security-mediator (SEM) who performs partial decryption for the user by request. This idea gives another variant for the decryption queries in the CLE paradigm: the adversary can ask for partial decryption results under either the SEM trapdoor generated by the KGC or the user secret key. Intuitively, the notion of SMCLE is more general than that of CLE since two partial decryption algorithms can always be combined into a single one, but the converse is not necessary true (see Section 3.4). A concrete construction in the random oracle model and a generic construction in the standard model are proposed in [18]. Prior to our work, no strongly-secure SMCLE existed that had been proven secure in the standard model.

3 General Security-Mediated Certificateless Encryption

We propose a new definition of the (security-mediated) certificateless encryption. We will also highlight the relationship between our definition and existing definitions.

3.1 Notation

We use an ID-vector $\overrightarrow{ID} = (\mathsf{ID}_1, \mathsf{ID}_2, \cdots, \mathsf{ID}_L)$ to denote a hierarchy of identifiers $(\mathsf{ID}_1, \mathsf{ID}_2, \cdots, \mathsf{ID}_L)$. The length of $\overrightarrow{ID}$ is denoted by $|\overrightarrow{ID}| = L$. Let $\overrightarrow{ID}||\mathsf{ID}_r$ denote the vector $(\mathsf{ID}_1, \mathsf{ID}_2, \cdots, \mathsf{ID}_L, \mathsf{ID}_r)$ of length $|\overrightarrow{ID}|+1$. We say that $\overrightarrow{ID}$ is a prefix of $\overrightarrow{ID'}$ if $|\overrightarrow{ID}| \leq |\overrightarrow{ID'}|$ and $\mathsf{ID}_i = \mathsf{ID}'_i$ for all $1 \leq i \leq |\overrightarrow{ID}|$. We use $\emptyset$ to denote an empty ID-vector where $|\emptyset| = 0$ and $\emptyset||\mathsf{ID}_r = \mathsf{ID}_r$. Finally, we use the notation $(\{0,1\}^n)^{\leq h}$ to denote the set of vectors of length less than or equal to h, where each component is a n-bit long bit-string.

3.2 Syntax

Extending the definition of a 1-level SMCLE scheme [18], we define an h-level SMCLE scheme as follows.

Definition 1. *An h-level SMCLE scheme for identifiers of length n (where h and n are polynomially-bounded functions) is defined by the following sextuple of* PPT *algorithms:*

– Setup *(run by the server) is a probabilistic algorithm which takes a security parameter* 1^λ*, outputs a master secret key* Msk*, which can also be denoted as* $d_\emptyset$*, and the global parameters* Pub*. We assume that* λ*,* $h = h(\lambda)$ *and* $n = n(\lambda)$ *are implicit in* Pub *and all other algorithms take* Pub *implicitly as an input.*
– $\mathsf{Extract}$ *(run by the server or any one who holds a trapdoor) is a possibly probabilistic algorithm which takes a trapdoor* $d_{\overrightarrow{ID}}$ *corresponding to an* h*-level identity* $\overrightarrow{ID} \in (\{0,1\}^n)^{\leq h}$ *, and a string* $\mathsf{ID}_r \in \{0,1\}^n$*, outputs a trapdoor key* $d_{\overrightarrow{ID}||\mathsf{ID}_r}$ *associated with the ID-vector* $\overrightarrow{ID}||\mathsf{ID}_r$*. The master secret key* Msk *is a trapdoor corresponding to a* 0*-level identity.*
– KGen *(run by a user) is a probabilistic algorithm which generates a public/private key pair* $(\mathsf{pk}_u, \mathsf{sk}_u)$*.*
– Enc *(run by a sender) is a probabilistic algorithm which takes a message* m *from some implicit message space, an identifier* $\overrightarrow{ID} \in (\{0,1\}^n)^{\leq h}$*, and the receiver's public key* pk_u *as input , returns a ciphertext* C*.*
– Dec^S *(run by any one who holds the trapdoor, either a SEM in SMCLE or a receiver in CLE) is a possibly probabilistic algorithm which takes a ciphertext* C *and the trapdoor key* $d_{\overrightarrow{ID}}$*, returns either a token* D *which can be seen as a partial decryption result, or an invalid flag* $\perp$ *(which is not in the message space).*
– Dec^U *(run by a receiver) is a possibly probabilistic algorithm which takes the ciphertext* C*, the receiver's secret key* sk_u *and a token* D *as input, returns either the plaintext, an invalid flag* $\perp_D$ *denoting* D *is an invalid token, or an invalid flag* $\perp_C$ *denoting the ciphertext is invalid.*

For correctness, we require that $\mathsf{Dec}^U(C, \mathsf{sk}, \mathsf{Dec}^S(C, \mathsf{Extract}(\mathsf{Msk}, \overrightarrow{ID}))) = m$ *for all* $\lambda \in \mathbb{N}$*, all* $(\mathsf{Pub}, \mathsf{Msk}) \xleftarrow{\$} \mathsf{Setup}(1^\lambda)$*, all* $(\mathsf{pk}, \mathsf{sk}) \xleftarrow{\$} \mathsf{KGen}$*, all message* m*, all ID-vector* $\overrightarrow{ID}$ *in* $(\{0,1\}^n)^{\leq h}$ *and all* $C \xleftarrow{\$} \mathsf{Enc}(m, \overrightarrow{ID}, \mathsf{pk})$*.*

3.3 Security

Each adversary has access to the following oracles:

1. An $\mathsf{ExtractO}$ oracle that takes an ID-vector $\overrightarrow{ID} \in (\{0,1\}^n)^{\leq h}$ as input and returns its trapdoor $d_{\overrightarrow{ID}}$.
2. An UskO oracle that takes a public key pk.as input and returns its corresponding private key sk.
3. A DecO^S oracle that takes a ciphertext C and an ID-vector $\overrightarrow{ID}$, and outputs $\mathsf{Dec}^S(C, d_{\overrightarrow{ID}})$. Note that C may or may not be encrypted under $\overrightarrow{ID}$.
4. A DecO^U oracle that takes a ciphertext C, a public key pk and a token D, and outputs $\mathsf{Dec}^U(C, \mathsf{sk}, D)$ where sk is the secret key that matches pk.
5. A DecO oracle that takes a ciphertext C, an ID-vector $\overrightarrow{ID}$, and a public key pk, and outputs $\mathsf{Dec}^U(C, \mathsf{sk}, D)$ where sk is the secret key that matches pk and $D = \mathsf{Dec}^S(C, d_{\overrightarrow{ID}})$. Note that C may or may not be encrypted under $\overrightarrow{ID}$ and pk.

Following common practice, we consider the two kinds of adversaries.

1. A Type-I adversary that models any coalition of rogue users, and who aims to break the confidentiality of another user's ciphertext.
2. A Type-II adversary that models a curious KGC, who aims to break the confidentiality of a user's ciphertext[3].

We use the common security model in which the adversary plays a two-phased game against a challenger. The game is modeled by the experiment below, $\mathsf{X} \in \{\mathrm{I}, \mathrm{II}\}$ denotes whether an PPT adversary $\mathcal{A} = (\mathcal{A}_{\mathsf{find}}, \mathcal{A}_{\mathsf{guess}})$ is of Type-I or II, and determines the allowed oracle queries $\mathcal{O}$ and the auxiliary data Aux.

Definition 2. Experiment $\mathbf{Exp}_{\mathcal{A}}^{\mathsf{CCA-X}}(\lambda)$

$(\mathsf{Pub}, \mathsf{Msk}) \xleftarrow{\$} \mathsf{Setup}(1^\lambda)$
$(m_0, m_1, \mathsf{pk}^*, \overrightarrow{ID}^*, \mathsf{state}) \xleftarrow{\$} \mathcal{A}_{\mathsf{find}}^{\mathcal{O}}(\mathsf{Pub}, \mathsf{Aux})$
$b \xleftarrow{\$} \{0,1\}$, $C^* \xleftarrow{\$} \mathsf{Enc}(m_b, \overrightarrow{ID}^*, \mathsf{pk}^*)$
$b' \xleftarrow{\$} \mathcal{A}_{\mathsf{guess}}^{\mathcal{O}}(C^*, \mathsf{state})$
If $(|m_0| \neq |m_1|) \vee (b \neq b')$ *then return 0 else return 1*

[3] We do not explicitly consider a rogue SEM since this type of adversary is weaker than the Type-II adversary.

where $\mathcal{O}$ refers to a set of five oracles $\mathsf{ExtractO}(\cdot), \mathsf{UskO}(\cdot), \mathsf{DecO}^S(\cdot,\cdot), \mathsf{DecO}^U(\cdot,\cdot,\cdot), \mathsf{DecO}(\cdot,\cdot,\cdot)$.

Those variables marked with * are basically about the challenge of the adversary. The adversary chooses a public key pk^* and an ID-vector $\overrightarrow{ID}^*$ to be challenged with, and the challenger returns C^* to the adversary as the challenge ciphertext. The two definitions below basically prohibit the adversary from trivially cheating by using the oracles to query for the answer to (parts of) the challenge.

Definition 3. *A hierarchical security-mediated certificateless encryption scheme is (t, q_E, q_D, ϵ) CCA-secure against a Type-I adversary if $|\Pr[\mathbf{Exp}_{\mathcal{A}}^{\mathsf{CCA-I}}(\lambda) = 1] - \frac{1}{2}| \leq \epsilon$ for all t-time adversary $\mathcal{A}$ making at most q_E extraction queries and q_D decryption queries (of any type), subjects to the following constraints:*

1. $\mathsf{Aux} = \emptyset$, *i.e. no auxiliary information is given to the adversary.*
2. *No* $\mathsf{ExtractO}(\overrightarrow{ID}')$ *query throughout the game, where $\overrightarrow{ID}'$ is a prefix of $\overrightarrow{ID}^*$.*
3. *No* $\mathsf{UskO}(\mathsf{pk})$ *query throughout the game for any* pk.
4. *No* $\mathsf{DecO}^S(C^*, \overrightarrow{ID}^*)$ *query throughout the game.*
5. *No* $\mathsf{DecO}(C^*, \overrightarrow{ID}^*, \mathsf{pk}^*)$ *query throughout the game.*

All public keys in the game are chosen by the adversary. It is natural to assume the adversary knows the corresponding secret keys; and it is also unrealistic to give the adversary a user secret key extraction oracle.

Definition 4. *A hierarchical security-mediated certificateless encryption scheme is (t, q_K, q_D, ϵ) CCA-secure against a Type-II adversary if $|\Pr[\mathbf{Exp}_{\mathcal{A}}^{\mathsf{CCA-II}}(\lambda) = 1] - \frac{1}{2}| \leq \epsilon$ for all t-time adversary $\mathcal{A}$ making at most q_D decryption queries (of any type), subjects to the following conditions:*

1. $\mathsf{Aux} = (\mathsf{Msk}, \{\mathsf{pk}_1^*, \cdots, \mathsf{pk}_{q_K}^*\})$, *i.e. $\mathcal{A}$ is given the master secret and a set of challenge public keys.*
2. $\mathsf{pk}^* \in \{\mathsf{pk}_1^*, \cdots, \mathsf{pk}_{q_K}^*\}$, *i.e. the challenge public key must be among the set given by the challenger.*
3. *No* $\mathsf{UskO}(\mathsf{pk})$ *query throughout the game if* $\mathsf{pk} \notin \{\mathsf{pk}_1^*, \cdots, \mathsf{pk}_{q_K}^*\}$ *or* $\mathsf{pk} = \mathsf{pk}^*$.
4. *No* $\mathsf{DecO}^U(C^*, \mathsf{pk}^*, D)$ *query throughout the game, where D is outputted by the algorithm* $\mathsf{Dec}^S(C^*, d_{\overrightarrow{ID}^*})$.
5. *No* $\mathsf{DecO}(C^*, \overrightarrow{ID}^*, \mathsf{pk}^*)$ *query throughout the game.*

Since Msk is given to the adversary, the challenge public key must be in the set given by the challenger.

3.4 Discussions on Our Choices for Definition

In addition to the formalisms, we explain the intuitions behind the choices made in formulating our definition.

User key generation. In order to support more general applications like TRE, we also need to generalize our syntax describing the interface of the algorithms. A subtle change in our definition of algorithm description is that the user key generation algorithm KGen only takes the system parameter as input but *not* the identifier. In particular, there exists CLE schemes [3, 32, 38, 40] which the inclusion of the identifier or the trapdoor for an identifier is *essential* for the generation of the user public key. In the latter case, KGen can only be executed after $\mathsf{Extract}$. A straightforward adaption of these classes of CLE results in inefficient TRE in which the size of the user public key grows linearly with the total number of supported time periods.

Simplification of Type-I adversary. In existing models for 1-level CLE like [2, 21], $\mathsf{ExtractO}$ query of $\overrightarrow{ID}^*$ is allowed; but if such a query is issued, the challenge public key pk^* can no longer be chosen by the adversary. In our discussion, we try to separate this from Type-I model and consider this type of adversarial behavior ($\mathsf{ExtractO}(\overrightarrow{ID}')$ where $\overrightarrow{ID}'$ is a prefix of $\overrightarrow{ID}^*$) as a weaker variant of, and hence covered by, a Type-II adversary. It is true that our resulting definition for Type-I adversary is weaker. However, the "missing part" is not omitted from the security requirement since it is unreasonable to define a CLE without considering Type-II adversary. Indeed, this simplification has already been justified and adopted [29, Section 2.3].

Existing models also allow full private key extraction for the public key prepared by the challenger. In our Type-I game, the challenger does not prepare any public key at all, so UskO query is prohibited. Nevertheless, it does not mean the adversary does not hold any of the user secret key. On the contrasty, our model offers more – the user secret key can be adversarially generated. The remaining scenario, in which the adversary intends to attack a public key given by the challenger, is again a weaker variant of our Type-II model. To conclude, we keep the essence of the existing models, and include UskO to make it matches with TRE.

Strong decryption oracle. In our definition, the decryption oracle works even if the public key is adversarially chosen but the secret key is not supplied. The original definition of CLE [2] does not allow strong decryption oracle for curious KGC adversary, but it is considered in recent work like [21]. It is easy to weaken the definition to one corresponding to the Type-II$^-$ attack by placing the below restriction in Definition 4.

5. *(Type-II$^-$) No* $\mathsf{DecO}(C, \overrightarrow{ID}, \mathsf{pk})$ *query throughout the game for any* C *if* $\mathsf{pk} \notin \{\mathsf{pk}_1^*, \cdots \mathsf{pk}_{q_K}^*\}$*, unless the corresponding secret key* sk *is supplied when the* DecO *query is made.*

Type-I$^-$ game can be obtained by adding $\mathsf{Aux} = \{\mathsf{pk}_1^*, \cdots \mathsf{pk}_{q_K}^*\}$ and the above restriction to Definition 3.

Implicit public key replacement. In our generalization of CLE, we "remove" (i.e. make implicit) the oracle for replacing the public key corresponding to an identifier. This may make a difference in the following.

1. The adversary's choice of the victim user it wishes to be challenged with,
2. The choice of user in decryption oracle queries.

However, there are other "interfaces" in our model such that the adversary can still make the above choices. Our model still allows the adversary to choose which identifier/public key it wants to attack. For decryption queries, the adversary can just supply different combination of identifier and public key to the DecO^S and DecO^U oracles. In this way, implicit replacement is done. In other words, when compared with the original model [2], the security model is not weakened, but generalized to cover applications of CLE such as TRE.

Reason for "removing" public key request and public key replacement oracles. In the traditional definition of CLE [2], oracles for retrieving and replacing public key are defined upon the fact that an identifier is always bound to a particular user. Replacing a particular user's public key means the public key associated with a particular identifier should be changed. In TRE, and other related paradigms such as cryptographic workflow [1], identifiers correspond to different policies governing the decryption. It is entirely possible that a single identifier is "shared" among more than one user. Hence we decide to remove these public key related oracles from the definition, resulting a model free from the concept of "user = identifier".

Alternative definition of public key replacement. It is possible to give another definition supporting TRE (and cryptographic workflow [1]) by allowing a "restricted" public key replacement, such that a public key "associated" with an identifier can be replaced by a public key associated with another identifier, but not an arbitrary one supplied by the adversary. Again, this definition makes the model still leads to the concept of an identifier is belonged to a single user. Moreover, this definition may make the treatment of strong decryption oracle more complicated. The idea of restricted replacement among a fixed set of public keys does not naturally correspond to decryption oracle under adversarially chosen public key.

SMCLE is more general than plain CLE. Having two separated decryption oracles in the SMCLE model gives a more general notion than CLE. This can be justified as follows:

1. Partial decryption result cannot be made available in the CLE model. There exists CLE schemes which are not CCA-secure when the adversary is given access to a partial decryption oracle [18].
2. Since the decryption oracle is separated in two, the SMCLE model does not have the notion of a "full" private key which is present in previous CLE models (a full private key is a single secret for the complete decryption of the ciphertext). On the ground that separated secrets can always be concatenated into a single full one, this simplification (of private key) has already been adopted in more recent models [29].

Difference with the previous SMCLE definition. In our user decryption oracle, different invalid flags will be returned by DecO^U to distinguish the case that the token from the SEM is invalid or the ciphertext is invalid. This is not captured by the original SMCLE model in [18].

User decryption oracle in SMCLE. One of the restrictions for excluding trivial attack in our Type-II adversary model disallows the challenge ciphertext C^* to be decrypted by the decryption oracle under the challenge public key and a token D outputted by the algorithm (not the oracle) $\mathsf{Dec}^S(C^*, \mathsf{ID}^*)$, where ID^* is the challenge identifier. This restriction requires the ability to check if a token D is a *valid* token corresponding to a ciphertext and an identifier, which is ensured by our new SMCLE definition.

From the first glance, our security definition is tightly coupled with the ability to check the token. However, we think that it is natural for the user to be able to perform such a test (which is especially important if the user need to pay for each SEM decryption). Even there is no explicit testing algorithm, it maybe possible that the challenger can setup the system in a way that it can do the test for the challenge ciphertext. It is stronger than a weaker definition such that no user decryption query is allowed for the challenge ciphertext under the challenge public key, no matter what the token is.

Justifications for our definition of hierarchical CLE. In the hierarchical scheme suggested (without a security definition) in [2], an entity at level k derives a trapdoor for its children at level $k+1$ using both its trapdoor and its secret key; while in our proposed model, a level k entity only uses its trapdoor obtained from its parent at level $k-1$ to derive keys for its children. However, we do not see any practical reason for requiring the secret key in the trapdoor derivation. On the other hand, the resulting scheme will be more complicated. For example, in the scheme of [2], the decryption requires the public keys of all the ancestors.

Note that we do allow the decryption of the ciphertext under $\overrightarrow{ID}'$ which is a prefix of $\overrightarrow{ID}^*$. This is stronger than the counterpart in some hierarchical IBE model [26].

Our definition is more general than plain CLE. The following theorem summarizes our discussion.

Theorem 1 *If there exists an* 1*-level SMCLE scheme which is secure under Definition 3 and 4, there exists a CLE scheme which is secure under the definition of [2].*

Proof. We describe how to build a simulator $\mathcal{B}$ which make use of an adversary of CLE $\mathcal{A}$ to break the security of our 1-level SMCLE scheme. The simulator basically forwards everything (the system parameters, the oracle queries and responses, and the guess) back and forth between its own SMCLE challenger and the CLE adversary. In the face of a Type-II adversary of CLE, the simulator will act as a Type-II security of 1-level SMCLE. However, for a Type-I adversary of CLE, $\mathcal{B}$ flips a fair coin to determine its guess whether $\mathcal{A}$ will issue an $\mathsf{ExtractO}$ query of $\overrightarrow{ID}^*$. If it guesses not, $\mathcal{B}$ just plays the Type-I game as usual. If it guesses so, $\mathcal{B}$ will try to use $\mathcal{A}$ to win the Type-II game of SMCLE instead. In particular, the above $\mathsf{ExtractO}$ query can be answered by $\mathcal{B}$ because it owns Msk now. The tightness of the reduction is reduced by a factor of 2. This simple trick is also used in the proof in [21, Appendix B, Game 4].

For most queries, the monotonic details are omitted. Important distinctions between these "two worlds" are about public key request and replacement. The simulator needs to maintain a table to store the binding between an identifier and a public key. Whenever a Type-I adversary issues a public key request query, $\mathcal{B}$ executes $(\mathsf{pk}, \mathsf{sk}) \stackrel{\$}{\leftarrow} \mathsf{KGen}$, stores sk (so $\mathcal{B}$ can answer if $\mathcal{A}$ asks for it later) and returns pk. For Type-II adversary, $\mathcal{B}$ picks a random public key from $\{\mathsf{pk}_1^*, \cdots, \mathsf{pk}_{q_K}^*\}$ in Aux and assigns it as the public key of queried ID. Whenever a key replacement query is made by $\mathcal{A}$, the simulator updates its own table. For every other requests regarding a particular identifier, the simulator retrieves the corresponding public key in its table and queries its own challenger accordingly. Finally, the complete decryption queries made by the CLE adversary can be entertained by combining the result of two partial decryption oracle queries issued by $\mathcal{B}$. □

4 Our Proposed Construction

4.1 Preliminaries

Let $\mathbb{G}$ be a multiplicative group of prime order p and $\mathbb{G}_T$ be a multiplicative group also of order p. We assume the existence of an efficiently computable bilinear map $\hat{e} : \mathbb{G} \times \mathbb{G} \to \mathbb{G}_T$ such that

1. *Bilinearity*: For all $u, v \in \mathbb{G}$ and $r, s \in \mathbb{Z}_p$, $\hat{e}(u^r, v^s) = \hat{e}(u, v)^{rs}$.
2. *Non-degeneracy*: $\hat{e}(u, v) \neq 1_{\mathbb{G}_T}$ for all $u, v \in \mathbb{G} \setminus \{1_{\mathbb{G}}\}$.

We also assume the following problems are intractable in such groups.

Definition 5. *The* Decision **3**-Party Diffie-Hellman Problem *(3-DDH) in* $\mathbb{G}$ *is to decide if* $T = g^{\beta\gamma\delta}$ *given* $(g, g^\beta, g^\gamma, g^\delta, T) \in \mathbb{G}^5$. *Formally, defining the advantage of a* PPT *algorithm* $\mathcal{D}$, $Adv_{\mathcal{D}}^{3-\mathrm{DDH}}(k)$, *as*

$$|\Pr[1 \xleftarrow{\$} \mathcal{D}(g, g^\beta, g^\gamma, g^\delta, T) | T \leftarrow g^{\beta\gamma\delta} \wedge \beta, \gamma, \delta \xleftarrow{\$} \mathbb{Z}_p^*] - \Pr[1 \xleftarrow{\$} \mathcal{D}(g, g^\beta, g^\gamma, g^\delta, T) | T \xleftarrow{\$} \mathbb{G} \wedge \beta, \gamma, \delta \xleftarrow{\$} \mathbb{Z}_p^*]|.$$

We say 3-DDH is intractable if the advantage is a negligible function for all PPT *algorithms* $\mathcal{D}$.

Compared with the Bilinear Diffie-Hellman (BDH) problem, the problem instance of 3-DDH is purely in $\mathbb{G}$ while that of BDH contains an element $\hat{t} \in \mathbb{G}_T$. If BDH problem is solvable, one can solve 3-DDH by feeding $(g, g^\beta, g^\gamma, g^\delta, \hat{e}(g, T))$ to a BDH oracle. Apart from CLE [21], the above assumption has been employed in other advanced pairing-based cryptographic schemes such as [9].

We introduce a variant of the weak Bilinear Diffie-Hellman Inversion (BDHI) assumption [7] below in the favor of 3-DDH. The original h-wBDHI problem in $(\mathbb{G}, \mathbb{G}_T)$ [7] is to decide whether $\hat{t} = \hat{e}(g, g^\gamma)^{\alpha^{h+1}}$. The naming of "inversion" comes from the equivalence to the problem of deciding whether $\hat{t} = \hat{e}(g, g^\gamma)^{1/\alpha}$.

Definition 6. *The* h-Weak Diffie-Hellman Inversion Problem *(h-wDHI) in* $\mathbb{G}$ *is to decide if* $T = g^{\gamma\alpha^{h+1}}$ *given* $(g, g^\gamma, g^\alpha, g^{\alpha^2}, \cdots, g^{\alpha^h}, T) \in \mathbb{G}^{h+3}$. *Formally, defining the advantage of a* PPT *algorithm* $\mathcal{D}$ *as*

$$\begin{aligned} Adv_{\mathcal{D}}^{h-\mathrm{wDHI}}(k) = |\Pr[1 \xleftarrow{\$} \mathcal{D}(g, g^\gamma, g^\alpha, g^{\alpha^2}, \cdots, g^{\alpha^h}, T) | T \leftarrow g^{\gamma\alpha^{h+1}} \wedge \alpha, \gamma \xleftarrow{\$} \mathbb{Z}_p^*] \\ - \Pr[1 \xleftarrow{\$} \mathcal{D}(g, g^\gamma, g^\alpha, g^{\alpha^2}, \cdots, g^{\alpha^h}, T) | T \xleftarrow{\$} \mathbb{G} \wedge \alpha, \gamma \xleftarrow{\$} \mathbb{Z}_p^*]|. \end{aligned}$$

We say h-wDHI is intractable if the advantage is a negligible function for all PPT *algorithms* $\mathcal{D}$.

We require a hash function H drawn from a family of collision resistant hash functions too.

Definition 7. *A hash function* $H \xleftarrow{\$} \mathcal{H}(k)$ *is* collision resistant *if for all* PPT *algorithms* $\mathcal{C}$ *the advantage*

$$Adv_{\mathcal{C}}^{\mathrm{CR}}(k) = \Pr[H(x) = H(y) \wedge x \neq y | (x, y) \xleftarrow{\$} \mathcal{C}(1^k, H) \wedge H \xleftarrow{\$} \mathcal{H}(k)]$$

is negligible as a function of the security parameter k.

4.2 Proposed Construction

Our construction is an h-level generalization of the concrete construction for 1-level in [21]. While [21] uses the technique of [10] to achieve strong decryption oracle, we use the same technique for a different purpose, which is a new way (other than the only known way in [18]) to support partial decryption oracle.

$\mathsf{Setup}(1^\lambda, n)$: Let $\mathbb{G}$, $\mathbb{G}_T$ be two multiplicative groups with a bilinear map $\hat{e}$ as defined before. They are of the same order p, which is a prime and $2^\lambda < p < 2^{\lambda+1}$.

- **Encryption key:** choose two generators $g, g_2 \in_R \mathbb{G}$.
- **Master public key:** choose an exponent $\alpha \in_R \mathbb{Z}_p$ and set $g_1 = g^\alpha$.
- **Hash key for identity-based public key derivation:** choose h many $(\ell+1)$-length vectors $\vec{U}_1, \cdots, \vec{U}_h \in_R \mathbb{G}^{\ell+1}$, where each $\vec{U}_j = (u'_j, u_{j,1}, \cdots, u_{j,\ell})$, $1 \leq j \leq h$. ℓ is a tunable parameter which is a factor of n and $1 \leq \ell \leq n$. Each vector $\vec{U}_j$ $(1 \leq j \leq h)$ corresponds to the j-th level of the hierarchy. We use the notation $\overrightarrow{ID} = (\mathsf{ID}_1, \cdots, \mathsf{ID}_j, \cdots, \mathsf{ID}_k)$ to denote a hierarchy of k n-bit string ID_j's. We write ID_j as ℓ blocks each of length n/ℓ bits $(\mathsf{ID}_{j,1}, \cdots, \mathsf{ID}_{j,\ell})$. We define $F_{\vec{U}_j}(\mathsf{ID}_j) = u'_j \prod_{i=1}^{\ell} u_{j,i}^{\mathsf{ID}_{j,i}}$.

– **Hash key for ciphertext validity:** choose an $(n+1)$-length vector $\vec{V} = (v', v_1, \cdots, v_n) \in_R \mathbb{G}^{n+1}$. This vector defines the hash function $F_{\vec{V}}(w) = v' \prod_{j=1}^{n} {v_j}^{b_j}$ where w is a n-bit string $b_1 b_2 \cdots b_n$.
– **Hash function:** pick a function $H : \{0,1\}^* \to \{0,1\}^n$ from a family of collision-resistant hash functions.

The public parameters Pub and the master secret key Msk are given by

$$\mathsf{Pub} = (\lambda, p, \mathbb{G}, \mathbb{G}_T, \hat{e}(\cdot,\cdot), n, \ell, g, g_1, g_2, \vec{U}_1, \cdots, \vec{U}_h, \vec{V}, H(\cdot)), \qquad \mathsf{Msk} = g_2^{\alpha}.$$

We require the discrete logarithms (with respect to g) of all $\mathbb{G}$ elements in Pub except g, g_1 to be unknown to the KGC. In practice, these elements can be generated from a pseudorandom function of a public seed.

$\mathsf{Extract}(d_{\overrightarrow{ID}}, \mathsf{ID}_r)$: For an identity $\overrightarrow{ID} = (\mathsf{ID}_1, \cdots, \mathsf{ID}_k)$ for $k \leq h$, the trapdoor is in the form of

$$d_{\overrightarrow{ID}} = (a_1, a_2, \vec{z}_{k+1}, \cdots, \vec{z}_h) = (g_2^{\alpha} \cdot (\prod_{j=1}^{k} F_{\vec{U}_j}(\mathsf{ID}_j))^r, g^r, (\vec{U}_{k+1})^r, \cdots, (\vec{U}_h)^r),$$

where $r \in_R \mathbb{Z}_p^*$ and $(\vec{U}_j)^r = ((u'_j)^r, (u_{j,1})^r, \cdots, (u_{j,\ell})^r)$.

Note that (a_1, a_2) is sufficient for decryption, while $\vec{z}_{k+1}, \cdots, \vec{z}_h$ can help the derivation of the trapdoor for $(\mathsf{ID}_1, \cdots, \mathsf{ID}_k, \mathsf{ID}_{k+1})$ for any n-bit string ID_{k+1} and $k+1 \leq h$. The exact algorithm is as follows.

To generate $d_{\overrightarrow{ID}||\mathsf{ID}_r}$ parse $d_{\overrightarrow{ID}} = (a_1, a_2, (z_{k+1}, z_{k+1,1}, \cdots, z_{k+1,\ell}), \cdots (z_h, z_{h,1}, \cdots, z_{h,\ell}))$ and parse ID_r as ℓ blocks each of length n/ℓ bits $(\mathsf{ID}_{r,1}, \cdots, \mathsf{ID}_{r,\ell})$ pick $t \in_R \mathbb{Z}_p^*$ and output

$$d_{\overrightarrow{ID}||\mathsf{ID}_r} = (a_1 \cdot z_{k+1} \prod_{i=1}^{\ell} (z_{k+1,i})^{\mathsf{ID}_{r,i}} \cdot (\prod_{j=1}^{k+1} F_{\vec{U}_j}(\mathsf{ID}_j))^t, a_2 \cdot g^t, \vec{z}_{k+2} \cdot (\vec{U}_{k+2})^t \cdots, \vec{z}_h \cdot (\vec{U}_h)^t$$

where the multiplication of two vectors are defined component-wise, i.e. $\vec{z}_j \cdot \vec{\nu}_j = (z_j \cdot \nu_j, z_{j,1} \cdot \nu_{j,1}, \cdots, z_{j,\ell} \cdot \nu_{j,\ell})$. $d_{\overrightarrow{ID}}$ becomes shorter as the length of $\overrightarrow{ID}$ increases.

$\mathsf{KGen}()$: Pick $\mathsf{sk} \in_R \mathbb{Z}_p^*$, return sk as the secret key and $\mathsf{pk} = (X, Y) = (g^{\mathsf{sk}}, g_1^{\mathsf{sk}})$ as the public key.

$\mathsf{Enc}(m, \overrightarrow{ID}, \mathsf{pk})$: To encrypt $m \in \mathbb{G}_T$ for $\overrightarrow{ID} = (\mathsf{ID}_1, \cdots, \mathsf{ID}_k)$ where $k \leq h$, parse pk as (X, Y), then check that it is a valid public key by verifying that $\hat{e}(X, g_1) = \hat{e}(g, Y)$[4]. If equality holds, pick $s \in_R \mathbb{Z}_p^*$ and compute

$$C = (C_1, C_2, \tau, \sigma) = (m \cdot \hat{e}(Y, g_2)^s, \prod_{j=1}^{k} F_{\vec{U}_j}(\mathsf{ID}_j)^s, g^s, F_{\vec{V}}(w)^s)$$

where $w = H(C_1, C_2, \tau, \overrightarrow{ID}, \mathsf{pk})$.

$\mathsf{Dec}^S(C, d_{\overrightarrow{ID}})$: Parse C as (C_1, C_2, τ, σ), and $d_{\overrightarrow{ID}}$ as $(a_1, a_2, \cdots)$. First check if $\hat{e}(\tau, \prod_{j=1}^{k} F_{\vec{U}_j}(\mathsf{ID}_j) \cdot F_{\vec{V}}(w')) = \hat{e}(g, C_2 \cdot \sigma)$ where $w' = H(C_1, C_2, \tau, \overrightarrow{ID}, \mathsf{pk})$. Return $\perp$ if inequality holds or any parsing is not possible, otherwise pick $t \in_R \mathbb{Z}_p^*$ and return

$$D = (D_1, D_2, D_3) = (a_1 \cdot F_{\vec{V}}(w')^t, a_2, g^t).$$

$\mathsf{Dec}^U(C, \mathsf{sk}, D)$: Parse C as (C_1, C_2, τ, σ) and check if $\hat{e}(\tau, \prod_{j=1}^{k} F_{\vec{U}_j}(\mathsf{ID}_j) \cdot F_{\vec{V}}(w')) = \hat{e}(g, C_2 \cdot \sigma)$ where $w' = H(C_1, C_2, \tau, \overrightarrow{ID}, \mathsf{pk})$. If equality does not hold or parsing is not possible, return $\perp_C$. Next, parse D as

[4] One pairing computation can be saved by a technique in [21] (which is similar to the technique in [31]): pick $\xi \in_R \mathbb{Z}_p^*$ and compute $C_1 = m \cdot \hat{e}(Y, g_2 \cdot g^{\xi})^s / \hat{e}(X, g_1^{s\xi})$.

(D_1, D_2, D_3) and check if $\hat{e}(g, D_1) = \hat{e}(g_1, g_2)\hat{e}(D_2, \prod_{j=1}^{k} F_{\vec{U}_j}(\mathsf{ID}_j))\hat{e}(D_3, F_{\vec{V}}(w'))$[5]. If equality does not hold or parsing is not possible, return $\perp_D$. Otherwise, return

$$m \leftarrow C_1 \cdot \left(\frac{\hat{e}(C_2, D_2)\hat{e}(\sigma, D_3)}{\hat{e}(\tau, D_1)} \right)^{\mathsf{sk}}.$$

4.3 Analysis

Reminiscent to the HIBE scheme of Boneh, Boyen and Goh [7], the size of the ciphertext of our SMCLE scheme is independent of the hierarchy length. When the scheme is used as a TRE, the ciphertext size is not affected by the benefit brought by the hierarchy which minimizes the size of the trapdoors (see Section 5.5).

In the concrete SMCLE scheme of Chow, Boyd and González Nieto [18], partial decryption is done by using the pairing function $\hat{e}(\cdot, \cdot)$ to pair up part of the ciphertext and the ID-based private key. To make this partial decryption result verifiable requires random oracle for turning a generic interactive proof-of-knowledge (PoK) non-interactive. Our scheme employs a different technique such that the token generated by the partial decryption is publicly verifiable without interactive PoK.

Our scheme's security is asserted by Theorem 2 and 3. Refer to the single proof in Appendix A for details.

Theorem 2 *Our scheme is secure against Type-I attack (Definition 3) if h-wDHI problem is intractable.*

Theorem 3 *Our scheme is secure against Type-II attack (Definition 4) if 3-DDH problem is intractable.*

5 Applying General Certificateless Encryption to Timed-Release Encryption

Now we provide the formal evidence for our thesis – general certificateless encryption can be used as TRE.

5.1 Syntax of Timed-Release Encryption

For ease of discussion, we consider a definition supporting only a single-level of time-identifier as in [12]. It can be shown that our results hold for an h-level analog.

Definition 8. *A TRE scheme for time-identifiers of length n (where n is a polynomially-bounded function) is defined by the following sextuple of* PPT *algorithms:*

- Setup *(run by the server) is a probabilistic algorithm which takes a security parameter 1^λ, outputs a master secret key* Msk*, and the global parameters* Pub*. We assume that λ and $n = n(\lambda)$ are implicit in* Pub *and all other algorithms take* Pub *implicitly as an input.*
- Extract *(run by the server) is a possibly probabilistic algorithm which takes the master secret key* Msk *and a string $\mathsf{ID} \in \{0,1\}^n$, outputs a trapdoor key d_{ID} associated with the identity* ID*.*
- KGen *(run by a user) is a probabilistic algorithm which generates a public/private key pair $(\mathsf{pk}_u, \mathsf{sk}_u)$.*
- Enc *(run by a sender) is a probabilistic algorithm which takes a message m from some implicit message space, an identifier $\mathsf{ID} \in \{0,1\}^n$, and the receiver's public key pk_u as input, returns a ciphertext C.*
- Dec^S *(run by any one who holds the trapdoor, either a SEM or a receiver) is a possibly probabilistic algorithm which takes a ciphertext C and the trapdoor key d_{ID} as input, returns either a token D which can be seen as a partial decryption result of C, or an invalid flag $\perp$ (which is not in the message space).*
- Dec^U *(run by a receiver) is a possibly probabilistic algorithm which takes the ciphertext C, the receiver's secret key sk_u and a token D as input, returns either the plaintext, an invalid flag $\perp_D$ denoting D is an invalid token, or an invalid flag $\perp_C$ denoting the ciphertext is invalid.*

For correctness, we require that $\mathsf{Dec}^U(C, \mathsf{sk}, \mathsf{Dec}^S(C, \mathsf{Extract}(\mathsf{Msk}, \mathsf{ID}))) = m$ *for all* $\lambda \in \mathbb{N}$*, all* $(\mathsf{Pub}, \mathsf{Msk}) \xleftarrow{\$} \mathsf{Setup}(1^\lambda)$*, all* $(\mathsf{pk}, \mathsf{sk}) \xleftarrow{\$} \mathsf{KGen}$*, all message m, all identifier* ID *in* $\{0,1\}^n$ *and all* $C \xleftarrow{\$} \mathsf{Enc}(m, \mathsf{ID}, \mathsf{pk})$.

[5] The same trick for minimizing the number of pairing computations [31] involved in checking the ciphertext and the token can be incorporated to the final decryption step. The modified decryption algorithm only uses 4 pairing computations; however, it gives a random message (instead of an invalid flag $\perp$) for an invalid ciphertext.

5.2 Timed-Release Encryption from General Certificateless Encryption

Given a SMCLE scheme $\{\mathcal{SMC}.\mathsf{Setup}, \mathcal{SMC}.\mathsf{Extract}, \mathcal{SMC}.\mathsf{KGen}, \mathcal{SMC}.\mathsf{Enc}, \mathcal{SMC}.\mathsf{Dec}^S, \mathcal{SMC}.\mathsf{Dec}^U\}$, a TRE scheme $\{\mathcal{TRE}.\mathsf{Setup}, \mathcal{TRE}.\mathsf{Extract}, \mathcal{TRE}.\mathsf{KGen}, \mathcal{TRE}.\mathsf{Enc}, \mathcal{TRE}.\mathsf{Dec}^S, \mathcal{TRE}.\mathsf{Dec}^U\}$ can be built as below.

$\mathcal{TRE}.\mathsf{Setup}(1^\lambda, n)$: Given a security parameter λ and the length of the time-identifier n, execute $(\mathsf{Msk}, \mathsf{Pub}) \leftarrow \mathcal{SMC}.\mathsf{Setup}(1^\lambda, n)$, retain Msk as the master secret key and publish Pub as the global parameters.

$\mathcal{TRE}.\mathsf{Extract}(\mathsf{Msk}, \mathsf{ID})$: For a time-identifier $\mathsf{ID} \in \{0,1\}^n$, the time-server returns $d_{\mathsf{ID}} \leftarrow \mathcal{SMC}.\mathsf{Extract}(\mathsf{Msk}, \mathsf{ID})$.

$\mathcal{TRE}.\mathsf{KGen}()$: Return $(\mathsf{sk}, \mathsf{pk}) \leftarrow \mathcal{SMC}.\mathsf{KGen}()$ as the user's private/public key pair.

$\mathcal{TRE}.\mathsf{Enc}(m, \mathsf{ID}, \mathsf{pk})$: To encrypt $m \in \mathbb{G}_T$ for pk under the time $\mathsf{ID} \in \{0,1\}^n$, first perform any checking of pk that is required by the $\mathcal{SMC}$ scheme. If pk is a valid public key, return $\mathcal{SMC}.\mathsf{Enc}(m, \mathsf{ID}, \mathsf{pk})$.

$\mathcal{TRE}.\mathsf{Dec}^S(C, d_{\mathsf{ID}})$: To partially decrypt C by a time-dependent trapdoor d_{ID}, return $D \leftarrow \mathcal{SMC}.\mathsf{Dec}^S(C, d_{\mathsf{ID}})$.

$\mathcal{TRE}.\mathsf{Dec}^U(C, \mathsf{sk}, D)$: To decrypt C by the secret key sk and the token D, just return $\mathcal{SMC}.\mathsf{Dec}^U(C, \mathsf{sk}, D)$.

Theorem 4 *If $\mathcal{SMC}$ is an 1-level SMCLE scheme which is CCA-secure against Type-I adversary (Definition 3), $\mathcal{TRE}$ is CCA-secure against Type-I adversary (Definition 10 in Appendix B).*

Theorem 5 *If $\mathcal{SMC}$ is an 1-level SMCLE scheme which is CCA-secure against Type-II adversary (Definition 4), $\mathcal{TRE}$ is CCA-secure against Type-II adversary (Definition 11 in Appendix B).*

Proof. We prove the above theorems by contradiction. Suppose $\mathcal{A}$ is a PPT Type-X adversary such that $|\Pr[\mathbf{Exp}_{\mathcal{A}}^{\mathsf{CCA'-X}}(\lambda) = 1] - \frac{1}{2}| > \epsilon$, we construct an adversary $\mathcal{B}$ such that $|\Pr[\mathbf{Exp}_{\mathcal{A}}^{\mathsf{CCA-X}}(\lambda) = 1] - \frac{1}{2}| > \epsilon$ in the face of a SMCLE challenger $\mathcal{C}$ where the running times of $\mathcal{B}$ and $\mathcal{A}$ are equal.

Setup: When $\mathcal{C}$ gives $\mathcal{B}$ $(\mathsf{Pub}, \mathsf{Aux})$, $\mathcal{B}$ just forwards it to $\mathcal{A}$. The public key to be passed to $\mathcal{A}$ is either chosen from the a set of public key in Aux (in Type-II game), or chosen by $\mathcal{B}$ itself (in Type-I game).

First Phase of Queries: $\mathcal{B}$ forwards every request of $\mathcal{A}$ to the oracles of its own challenger $\mathcal{C}$. From the description of $\mathcal{TRE}$, we can see that every legitimate oracle query made by $\mathcal{A}$ can be answered faithfully.

Challenge: When $\mathcal{A}$ gives $\mathcal{B}$ $(m_0, m_1, \mathsf{pk}^*, \mathsf{ID}^*)$, $\mathcal{B}$ just forwards it to $\mathcal{C}$.

Second Phase of Queries: Again, $\mathcal{B}$ just forwards every request of $\mathcal{A}$ to the oracles of its own challenger $\mathcal{C}$. From the description of $\mathcal{TRE}$, it is easy to see that every oracle query which does not violate the restriction enforced by $\mathcal{A}$ also does not violate the restriction enforced by $\mathcal{C}$.

Output: Finally, $\mathcal{A}$ outputs a bit b, $\mathcal{B}$ forwards it to $\mathcal{C}$ as its own answer. The probability for $\mathcal{A}$ to win the TRE experiment simulated by $\mathcal{B}$ is equal to the probability for $\mathcal{B}$ to win the SMCLE game played against $\mathcal{C}$. It is easy to see that the running times of $\mathcal{A}$ and $\mathcal{B}$ are the same. □

Section 4 presented a CLE scheme in the standard model, the above theorems imply that our scheme can be instantiated as a TRE scheme without random oracle, which is the first one in the literature.

5.3 Certificateless Encryption from Timed-Release Encryption

One may expect that a general CLE can be constructed from any TRE. Nevertheless, note that the usage of time-identifier is only a specific instantiation of the timed-release idea. Other formulations of TRE which are different from Definition 8 exists and hence there will be syntactic differences. For example, there exists a TRE scheme [14] which time is denoted by the number of repeated computations of one-way hash function.

Note also that the notion of CLE supports an exponential number of arbitrary identifiers[6]. A CLE scheme cannot be realized by a TRE if the total number of time periods supported is too few.

[6] Even though the scheme may be insecure when more than a polynomial number of trapdoors are compromised by a single adversary.

While the syntax of general CLE and that of TRE are similar, there is an important difference in the definitions of security – the public keys in TRE are *certified* while there is no certification in CLE, which means it can be chosen adversarially. In typical TRE formulation [6, 13, 17, 22, 30], a single public key is *given* to the adversary as the target of attack. Target public key is also not adversarially chosen in cryptographic workflow scheme [1, 4]. However, we remark that the TRE formulation in [12] allows uncertified public keys.

5.4 Security-Mediator in Timed-Release Encryption

We introduce the concept of security-mediator in the TRE paradigm, which gives a new business model for the operation of the time-server. Traditional TRE only allows the time-server to release a system-wide time-dependent trapdoor. With the possibility of partial decryption, the time-server can charge for each decryption. The time-server can decrypt a ciphertext partially by the time-dependent trapdoor per request, while the partial decryption of one ciphertext would not help the decryption of any other ciphertext.

5.5 Time Hierarchy

Each identifier corresponds to a single time period, which means that the server has to publish t private keys on a bulletin board after t time-periods have passed. Given a hierarchical CLE, the amount data on the bulletin board can be reduced by using CHK forward secure encryption scheme [11] in reverse, as suggested in [7]. For a total of T time periods, the CHK framework is setup as a tree of depth $\lg T$. To encrypt a message for time $t < T$, the time identifier is the CHK identifier for time period $T - t$. Release of trapdoor is done in the same manner, the private key for the time period $T - t$ is released on the t^{th} time period. This single private key enables anyone to derive the private keys for CHK time periods $T - t, T - t + 1, \cdots, T$, which means the user can obtain the trapdoors for time in the range of $1, \cdots, t$. By using this trick, the server only needs to publish a single private key comprising $O(\lg^2 T)$ group elements at any time.

6 Conclusions

In the study of cryptography, we always seek for the strongest definition and try to achieve it. Previous models of certificateless encryption (CLE) were too restrictive. In particular, they cannot give the desired security properties when instantiated as timed-release encryption (TRE). Our generalized CLE model is sufficient to fulfill the requirements of TRE. All future CLE proposals in our general model automatically give secure TRE schemes. Our model is defined against full-identifier extraction, decryption under arbitrary public key, and partial decryption, which incorporates the strongest properties one may desire. Our concrete scheme yields the first strongly-secure (hierarchical) security-mediated CLE and the first TRE in the standard model.

A Formal Security Proof for Our Proposed Construction

We now define a series of games where each one is an interactive game between a simulator $\mathcal{S}$ and an adversary $\mathcal{A}$, which is either an insider attacker (Type-I adversary) or a curious server (Type-II adversary), depending on the allowed queries. The skeleton of the proof is based on the proof given in [21].

Game 1 (The Original Game). This game is the one played between a simulator $\mathcal{S}$ and an adversary $\mathcal{A}$ as specified in the experiment $\mathbf{Exp}^{\mathsf{CCA-X}}$. We use the following notation: For the queries, let $\mathcal{T} = \{\overrightarrow{ID}_1, \cdots, \overrightarrow{ID}_{q_E}\}$ denote the trapdoors extraction queries and $\mathcal{W} = \{w_1, \cdots, w_{q_D}\}$ be the set of strings involved in decryption queries where $w_j = H(C_1, C_2, \tau, \overrightarrow{ID}_j, \mathsf{pk}_j)$. For the challenges, let $\overrightarrow{ID}^*$ and pk^* denote the challenge identifier and the challenge public key respectively, and let $C^* = (C_1^*, C_2^*, \tau^*, \sigma^*)$ be the returned challenge ciphertext and let $w^* = H(C_1^*, C_2^*, \tau^*, \overrightarrow{ID}^*, \mathsf{pk}^*)$. The random bit ι is chosen by $\mathcal{S}$ in order to select which message is encrypted.

Game 2 (Change of Public Parameters). Let $Z_i = (g)^{\alpha^i}$, $1 \leq i \leq h+1$. This game is the same as Game 1 except that the generation of the parameters is changed. $\mathcal{S}$ picks $\alpha, \beta \in_R \mathbb{Z}_p$, and set $g_1 = Z_1$, $g_2 = Z_h \cdot g^\beta$.

If *mode* = II, $\mathcal{A}$ should obtain $\mathsf{Aux} = \mathsf{Msk}, \{\mathsf{pk}_1^*, \cdots \mathsf{pk}_{q_K}^*\}$ from $\mathcal{S}$. $\mathcal{S}$ computes $\mathsf{Msk} = \alpha^h + \beta$. For public keys, $\mathcal{S}$ randomly chooses θ_i from $\mathbb{Z}_p$, and computes $\mathsf{pk}_i^* = (X_i^*, Y_i^*) = (g^{\theta_i}, (g^\alpha)^{\theta_i}), \forall i \in \{1, \cdots, q_K\}$.

The simulator also changes the vectors as follows. Let ρ_u and ρ_v be integers such that $\rho_u(n+1) < p$ and $\rho_v(n+1) < p$. The exact choices of ρ_u and ρ_u will be determined later. The simulator randomly selects

- $\kappa_{u_1}, \cdots, \kappa_{u_n}, \kappa_v$ from $\{0, \cdots, \ell(n^{1/\ell} - 1)\}$,
- h many $(\ell+1)$-length vectors $\vec{x}_1, \cdots, \vec{x}_h$ from $\mathbb{Z}_{\rho_u}$, where each $\vec{x}_j = (x'_j, x_{j,1}, \cdots, x_{j,\ell})$.
- h many $(\ell+1)$-length vectors $\vec{y}_1, \cdots, \vec{y}_h$ from $\mathbb{Z}_p$, where each $\vec{y}_j = (y'_j, y_{j,1}, \cdots, y_{j,\ell})$.
- $(x'_v, x_{v,1}, \cdots, x_{v,n})$ from $\mathbb{Z}_{\rho_v}^{n+1}$
- $(y'_v, y_{v,1}, \cdots, y_{v,n})$ from $\mathbb{Z}_p^{n+1}$.

The hash keys for the identity-based key derivation, for $1 \leq j \leq h$, are set as:

$$u'_j = Z_{h-j+1}^{(p+\rho_u\kappa_j - x'_j)} \cdot g^{y'_j}, \quad u_{j,i} = Z_{h-j+1}^{-x'_{j,i}} \cdot g^{y_{j,i}} \text{ for } 1 \leq i \leq \ell.$$

The hash key for the ciphertext validity is set as (note that $g_2 = Z_h \cdot g^\beta$):

$$v' = g_2^{(p+\rho_v\kappa_v - x'_v)} \cdot g^{y'_v}, \qquad v_i = g_2^{-x_{v,i}} g^{y'_{v,i}} \text{ for } 1 \leq i \leq n.$$

Define the following functions

$$J_{u_1}(\mathsf{ID}_1) = p + \rho_u\kappa_1 - x'_1 - \sum_{i=1}^{\ell} x_{1,i}\mathsf{ID}_{1,i},\ K_{u_1}(\mathsf{ID}_1) = y'_1 + \textstyle\sum_{1=1}^{\ell} y_{1,i}\mathsf{ID}_{h,i},$$

$$\vdots \qquad\qquad \vdots$$

$$J_{u_h}(\mathsf{ID}_h) = p + \rho_u\kappa_h - x'_h - \sum_{i=1}^{\ell} x_{h,i}\mathsf{ID}_{h,i},\ K_{u_h}(\mathsf{ID}_h) = y'_h + \textstyle\sum_{1=1}^{\ell} y_{h,i}\mathsf{ID}_{h,i},$$

$$J_v(w) = p + \rho_v\kappa_v - x'_v - \sum_{i=1}^{\ell} x_{v,i}b_i, \qquad K_v(w) = y'_v + \textstyle\sum_{1=1}^{\ell} y_{v,i}b_i,$$

that take as input $\mathsf{ID}_j = (\mathsf{ID}_{j,1}, \cdots, \mathsf{ID}_{j,\ell})$ or $w = b_1 \cdots b_n$. The settings above give

$$F_{\overrightarrow{U}_j}(\mathsf{ID}_j) = u'_j \prod_{i=1}^{\ell} u_{j,i}^{\mathsf{ID}_{j,i}} = Z_{h-j+1}^{J_{u_j}(\mathsf{ID}_j)} \cdot g^{K_{u_j}(\mathsf{ID}_j)}, j \in \{1, \cdots, h\}$$

$$F_{\overrightarrow{V}}(w) = v' \prod_{j=1}^{n} {v_j}^{b_j} = g_2^{J_v(w)} \cdot g^{K_v(w)}$$

These changes do not change the distribution of the public parameters, so we have $\Pr[S_2] = \Pr[S_1]$.

Game 3 (Elimination of Hash Collisions). The simulator aborts and assumes $\mathcal{A}$ outputs a random bit in this game if $\mathcal{A}$ submits a decryption query $(C, \overrightarrow{ID}, \mathsf{pk} = (g^{\mathsf{sk}}, g_1^{\mathsf{sk}}))$ for a well-formed ciphertext $C = (C_1, C_2, \tau, \sigma)$ where $w = H(C_1, C_2, \tau, \overrightarrow{ID}, \mathsf{pk})$ is either equal to the same value as a previously submitted ciphertext or w^* of the challenge ciphertext.

For such a decryption query to be legal, we have $C \neq C^*$ or $(\overrightarrow{ID}, \mathsf{pk}) \neq (\overrightarrow{ID}^*, \mathsf{pk}^*)$. In either case, this implies a collision for H, which means we can construct an adversary $\mathcal{C}$ against the collision resistance of H such that $|\Pr[S_3] - \Pr[S_2]| \leq Adv_{\mathcal{C}}^{\mathrm{CR}}(k)$.

Game 4 (Preparation for the Simulation of the Challenge Ciphertext). Let $\overrightarrow{ID}^* = (\mathsf{ID}_1^*, \cdots, \mathsf{ID}_k^*)$ where $k \leq h$. This time $\mathcal{S}$ aborts if $J_{u_j}(\mathsf{ID}_j^*) \neq 0 \bmod p$ for any $j \in \{1, \cdots, k\}$ or $J_v(w^*) \neq 0 \bmod p$.

Since the values determining these functions are information theoretically hidden from $\mathcal{A}$, such ID^* and w^* can only be produced by chance. Therefore

$$\begin{aligned} & \Pr[J_v(w^*) = 0 \bmod p] \\ = & \Pr[J_v(w^*) = 0 \bmod p | J_v(w^*) = 0 \bmod \rho_v] \cdot \Pr[J_v(w^*) = 0 \bmod \rho_v] \\ = & \frac{1}{\rho_v(n+1)} \end{aligned}$$

Unless $\mathcal{S}$ aborts, Game 3 and Game 4 are identical and we have $|\Pr[S_4] - \Pr[S_3]| \leq \frac{1}{(\rho_u)^h \rho_v (\ell+1)^{h+1}}$ by a similar computation ($n \geq \ell$). The significance of this extra abort condition will be manifested in Game 8.

Game 5 (Artificial Abort for Consistent View of Adversary). Now $\mathcal{S}$ aborts if $J_{u_1}(\mathsf{ID}'_1) = \cdots = J_{u_k}(\mathsf{ID}'_k) = 0 \bmod \rho_u$ for some $\overrightarrow{ID}' = (\mathsf{ID}'_1, \cdots, \mathsf{ID}'_k) \in \mathcal{T}$ or $J_v(w') = 0 \bmod \rho_v$ for some $w' \in \mathcal{W}$.

Since $\mathcal{A}$'s power is dependent on the extraction and decryption queries, the above abort event is not independent of S_4, and we cannot relate the probability of S_4 and S_5 in a similar way as before.

This problem can be circumvented by the "re-normalization" technique due to Waters [42], such that "artificial aborts" are added to make sure that the probability of aborts is exactly equal to some negligible upper bound for the probability that E occurs for any set of oracle queries.

Conditioning on $\Pr[J_v(w^*) = 0 \bmod p]$ the theoretical lower bound of $\Pr[J_v(w^*) \neq 0 \bmod p]$ is $(1 - \frac{q_D}{\rho_v})$. Setting $\rho_v = 2q_D$ and will make it bounded by $1/2$. On the other hand, a lower bound on the probability for the first event is $\frac{1}{2(4\ell q_E 2^{n/\ell})^h}$ by setting $\rho_u = 4q_E$ [15].

We estimate the probability that $\mathcal{A}$'s oracle queries will cause $\mathcal{S}$ to abort by repeatedly sampling values determining $J_{u_1}(\cdot), \cdots, J_{u_h}(\cdot), J_v(\cdot)$. This would not involve re-running $\mathcal{A}$ as $\mathcal{A}$'s view (of the public parameters) remains unchanged by assuming y's are changing accordingly. Waters [42] has shown that a polynomial number of trials is sufficient to give an estimate of the abort probability η to within a negligible error term.

If $\mathcal{S}$ did not abort, we force an artificial abort with probability $(\eta - 1/(4(4\ell q_E 2^{n/\ell})^h))/\eta$, and $\mathcal{S}$ will abort with probability sufficiently close to $\frac{1}{4(4\ell q_E 2^{n/\ell})^h}$. Now we can say $\Pr[S_5] = \Pr[S_4]/4(4\ell q_E 2^{n/\ell})^h$. An exposition of Waters' technique can be found at [16].

Game 6 (Simulation of Extraction and Decryption). This game changes the simulation of all $\mathcal{A}$'s queries for trapdoor extractions, partial decryptions, and complete decryptions. We will have $\Pr[S_6] = \Pr[S_5]$.

Trapdoor extraction: For trapdoor key extraction query of $\overrightarrow{ID} = (\mathsf{ID}_1, \cdots, \mathsf{ID}_k)$ where $k \leq h$. Let $j' \in \{1, \cdots, k\}$ be a minimum one such that $J_{u_{j'}}(\mathsf{ID}_{j'}) \neq 0$. There exists such a j' or $\mathcal{S}$ has aborted in Game 5. $\mathcal{S}$ needs to return $d_{\overrightarrow{ID}} = (a_1, a_2, \vec{z}_{k+1}, \cdots, \vec{z}_h)$.

We first show how to compute $a_{1|j'}$, a "trapdoor for only $\mathsf{ID}_{j'}$" (without any appearance of any elements from other levels); then we will show how to compute a trapdoor $(a_1, a_2, \vec{z}_{k+1}, \cdots, \vec{z}_h)$ that matches the same implicit random factor used in $a_{1|j'}$. Recall that $F_{\vec{U}_{j'}}(\mathsf{ID}_{j'}) = Z_{h-j'+1}^{J_{u_{j'}}(\mathsf{ID}_{j'})} \cdot g^{K_{u_{j'}}(\mathsf{ID}_{j'})}$. $\mathcal{S}$ picks $r \in \mathbb{Z}_p^*$ and computes

$$a_{1|j'} = (Z_1^{\beta} \cdot Z_{j'}^{-\frac{K_{u_{j'}}(\mathsf{ID}_{j'})}{J_{u_{j'}}(\mathsf{ID}_{j'})}}) \cdot (Z_{h-j'+1}^{J_{u_{j'}}(\mathsf{ID}_{j'})} \cdot g^{K_{u_{j'}}(\mathsf{ID}_{j'})})^r$$

The second component of $a_{1|j'}$ is only for randomization. We will show the first component of $a_{1|j'}$ is in the form of $g_2^{\alpha}(F_{\vec{U}_{j'}}(\mathsf{ID}_{j'}))^{-\frac{\alpha^{j'}}{J_{u_{j'}}(\mathsf{ID}_{j'})}}$, which means $a_{1|j'}$ is in the form of $g_2^{\alpha}(F_{\vec{U}_{j'}}(\mathsf{ID}_{j'}))^{\tilde{r}}$ where $\tilde{r} = r - \frac{\alpha^{j'}}{J_{u_{j'}}(\mathsf{ID}_{j'})}$.

$$\begin{aligned}
& g_2^{\alpha}(F_{\vec{U}_{j'}}(\mathsf{ID}_{j'}))^{-\frac{\alpha^{j'}}{J_{u_{j'}}(\mathsf{ID}_{j'})}} \\
&= (Z_h \cdot g^{\beta})^{\alpha}(Z_{h-j'+1}^{J_{u_{j'}}(\mathsf{ID}_{j'})} \cdot g^{K_{u_{j'}}(\mathsf{ID}_{j'})})^{-\frac{\alpha^{j'}}{J_{u_{j'}}(\mathsf{ID}_{j'})}} \\
&= Z_{h+1} \cdot Z_1^{\beta} \cdot Z_{h+1}^{-\frac{J_{u_{j'}}(\mathsf{ID}_{j'})}{J_{u_{j'}}(\mathsf{ID}_{j'})}} \cdot Z_{j'}^{-\frac{K_{u_{j'}}(\mathsf{ID}_{j'})}{J_{u_{j'}}(\mathsf{ID}_{j'})}} \\
&= Z_1^{\beta} \cdot Z_{j'}^{-\frac{K_{u_{j'}}(\mathsf{ID}_{j'})}{J_{u_{j'}}(\mathsf{ID}_{j'})}}
\end{aligned}$$

To compute $a_1 = g_2^{\alpha} \cdot (\prod_{j=1}^{k} F_{\vec{U}_j}(\mathsf{ID}_j))^{\tilde{r}}$, $\mathcal{S}$ needs to compute $F_{\vec{U}_j}(\mathsf{ID}_j)^{\tilde{r}} = (Z_{h-j+1}^{J_{u_j}(\mathsf{ID}_j)})^{\tilde{r}} \cdot (g^{K_{u_j}(\mathsf{ID}_j)})^{\tilde{r}}$ for $j \neq j'$. We would like to compute it without knowing α and Z_{h+1}, but with the help of $(Z_1, \cdots, Z_h)$. Now the only difficulty comes from the fact that $\alpha^{j'}$ in $\tilde{r}$ is unknown. Note that the second term $(g^{K_{u_j}(\mathsf{ID}_j)})^{\alpha^{j'}}$ can be computed from $Z_{j'}$. We can see how the first term can be obtained by considering two different cases.

1. $j < j'$: $J_{u_j}(\mathsf{ID}_j) = 0$ by the choice of j'.
2. $j > j'$: $Z_{h-j+1}^{\alpha^{j'}} = Z_{h+1-(j-j')}$, note that $1 \leq j - j' \leq h - 1$.

By similar reasoning, since $k + 1 > j'$, it is easy to see that $\vec{z}_{k+1}, \cdots, \vec{z}_h$ can also be computed from $(Z_1, \cdots, Z_h)$. This completes the simulation of the trapdoor queries.

SEM partial decryption: $\mathcal{S}$ performs the usual validity checking to reject any invalid ciphertext C that is purported to be encrypted under $\overrightarrow{ID}$ and pk. For decrypting a valid ciphertext with hash w by the trapdoor of $\overrightarrow{ID}$, if $d_{\overrightarrow{ID}} = (a_1, a_2, \cdots)$ is computable by $\mathcal{S}$, it is easy to generate $(a_1 F_{\vec{V}}(w)^t, a_2, g^t)$ for a random $t \in \mathbb{Z}_p^*$.

$\mathcal{S}$ cannot generate the trapdoor for $d_{\overrightarrow{ID}}$ only if $J_{u_1}(\mathsf{ID}_1) = \cdots = J_{u_k}(\mathsf{ID}_k) = 0 \bmod \rho_u$. Note that $J_v(w) \neq 0 \bmod \rho_v$ or $\mathcal{S}$ has aborted in Game 5. Under this condition, $\mathcal{S}$ can generate the token similar to the generation of the trapdoor before. Recall that $F_{\vec{V}}(w) = (Z_h \cdot g^{\beta})^{J_v(w)} \cdot g^{K_v(w)}$, we have

$$\begin{aligned}
& g_2^{\alpha}(F_{\vec{V}}(w))^{-\frac{\alpha}{J_v(w)}} \\
&= (Z_h \cdot g^{\beta})^{\alpha}(Z_h^{J_v(w)} \cdot (g^{\beta})^{J_v(w)} \cdot g^{K_v(w)})^{-\frac{\alpha}{J_v(w)}} \\
&= Z_{h+1} \cdot Z_1^{\beta} \cdot Z_{h+1}^{-\frac{J_v(w)}{J_v(w)}} \cdot Z_1^{-\beta\frac{J_v(w)}{J_v(w)}} \cdot Z_1^{-\frac{K_v(w)}{J_v(w)}} \\
&= Z_1^{-\frac{K_v(w)}{J_v(w)}}
\end{aligned}$$

This means $Z_1^{-\frac{K_v(w)}{J_v(w)}}$ gives a token with the implicit random factor equals to $-\frac{\alpha}{J_v(w)}$. Randomization can be done easily by multiplying the above term by $(F_{\overrightarrow{V}}(w))^r$ where $r \in \mathbb{Z}_p^*$. Since $J_{u_1}(\mathsf{ID}_1) = \cdots = J_{u_k}(\mathsf{ID}_k) = 0 \bmod \rho_u$, all $\frac{\alpha}{J_v(w)}$ power terms appear in the construction of the token can be computed from Z_1.

User partial decryption: $\mathcal{A}$ queries $\mathcal{S}$'s oracle $\mathsf{DecO}^U(C, \mathsf{pk}, D)$. $\mathcal{S}$ performs the usual ciphertext validity checking to reject any invalid ciphertext C that is purported to be encrypted under $\overrightarrow{ID}$ and pk, and the token validity checking to reject any invalid token D that is purported to be a partial decryption of C. These validity checks prevent loss of information about the secret key sk. In particular, without the token checking, it is trivial for a Type-II adversary to derive the message in the challenge ciphertext by asking $\mathsf{DecO}^U(C^*, \mathsf{pk}^*, D')$ where D' is some invalid token derived from a valid one.

Suppose C is a valid ciphertext and D is valid for C and $\overrightarrow{ID}$, $\mathsf{DecO}^U(C, \mathsf{pk}, D)$ should give a correct decryption. For decrypting a valid ciphertext (C_1, C_2, τ, σ) with hash w, we have $\tau = g^s$ and $\sigma = F_{\overrightarrow{V}}(w)^s$ for some $s \in \mathbb{Z}_p^*$, i.e. $\sigma = g_2^{s \cdot J_v(w)} \cdot (g^s)^{K_v(w)}$. $\mathcal{S}$ can get g_2^s by $(\sigma/\tau^{K_v(w)})^{\frac{1}{J_v(w)}}$, $\hat{e}(Y, g_2)^s$ can thus be computed easily. Note that the secret key sk that matches pk is never explicitly used.

Complete decryption: After validity checking, $\mathcal{S}$ returns $m = C_1/\hat{e}(Y, (\sigma/\tau^{K_v(w)})^{\frac{1}{J_v(w)}})$ for valid ciphertext.

Game 7 (User Secret Key Extraction). If *mode* = II, $\mathcal{A}$ may issue UskO query on some public key $\mathsf{pk}_u \in \{\mathsf{pk}_1^*, \cdots \mathsf{pk}_{q_K}^*\}$. $\mathcal{S}$ picks a random integer q' from $\{1, \cdots, q_K\}$. If $\mathcal{A}$ issues the query $\mathsf{UskO}(\mathsf{pk}_{q'}^*)$, $\mathcal{S}$ aborts; returns θ_i for $i \neq q'$. This gives $\Pr[S_7] = \Pr[S_6]$ for *mode* = I and $\Pr[S_7] = \Pr[S_6]/q_K$ for *mode* = II.

Game 8 (Simulation of the Ciphertext / Embedding of the Problem Instance). Depending on whether the adversary is an insider or the server, we have different modes of simulations. Now $\mathcal{S}$ introduces a variable $\gamma \in_R \mathbb{Z}_p^*$ and sets $\tau^* = g^\gamma$.

If *mode* = I, g_1 is set to $Z_1 = g^\alpha$. $\mathcal{A}$ chooses an identifier $\overrightarrow{ID}^* = (\mathsf{ID}_1^*, \cdots, \mathsf{ID}_k^*)$, a public key $\mathsf{pk}^* = (X^*, Y^*)$ to be challenged with. $\mathcal{S}$ proceeds if $\hat{e}(Y^*, g) = \hat{e}(X^*, g_1)$. Let $T = (g^{\alpha^{h+1}})^\gamma$, $\mathcal{S}$ computes C_1^* by

$$\begin{aligned}
& m_\iota \cdot \hat{e}(X^*, T) \cdot (Y^*, g^\gamma)^\beta \\
= & m_\iota \cdot \hat{e}(X^*, (g^{\alpha^{h+1}})^\gamma) \cdot (Y^*, g^\gamma)^\beta \\
= & m_\iota \cdot \hat{e}(Y^*, g^{\alpha^h})^\gamma \cdot (Y^*, g^\beta)^\gamma \\
= & m_\iota \cdot \hat{e}(Y^*, Z_h \cdot g^\beta)^\gamma \\
= & m_\iota \cdot \hat{e}(Y^*, g_2)^\gamma
\end{aligned}$$

Note that it is the first time in the simulation that β is used directly (i.e. not in the form of g^β) except the computation of Msk, which is fine since $\mathcal{S}$ does not need to compute it explicitly for a Type-I adversary.

If *mode* = II, $\mathcal{S}$ introduces a variable $\delta \in_R \mathbb{Z}_p^*$, and compute $(X_{q'}^*, Y_{q'}^*)$ by $((g^\delta)^{\theta_{q'}}, (g^\delta)^{\theta_{q'}\alpha})$ instead. Under the artificial abort condition in Game 7, $\mathcal{S}$ has guessed the public key $\mathcal{A}$ wants to attack correctly. Let $T = g^{\beta\gamma\delta}$, $\mathcal{S}$ computes C_1^* by

$$\begin{aligned}
& m_\iota \cdot (\hat{e}(g^\delta, g^\gamma)^{\alpha^{h+1}} \cdot \hat{e}(g^\alpha, T))^{\theta_i} \\
= & m_\iota \cdot (\hat{e}(g^\delta, g^{\alpha^{h+1}})^\gamma \cdot \hat{e}(g^\alpha, g^{\beta\gamma\delta}))^{\theta_i} \\
= & m_\iota \cdot \hat{e}(g^{\delta\theta_i\alpha}, g^{\alpha^h})^\gamma \cdot \hat{e}(g^{\delta\theta_i\alpha}, g^\beta)^\gamma \\
= & m_\iota \cdot \hat{e}(Y^*, Z_h \cdot g^\beta)^\gamma \\
= & m_\iota \cdot \hat{e}(Y^*, g_2)^\gamma
\end{aligned}$$

Note that it is the first time in the simulation that α is used directly (i.e. not in the form of $g^\alpha, \cdots, g^{\alpha^h}$).

In both modes, $\mathcal{S}$ sets $C_2^* = \prod_{j=1}^k (g^\gamma)^{K_{u_j}(\mathsf{ID}_j^*)}$, $\sigma^* = (g^\gamma)^{K_v(w^*)}$ where $w^* = H(C_1^*, C_2^*, \tau^*, \overrightarrow{ID}^*, \mathsf{pk}^*)$ for the rest of the challenge, which is a perfect simulation if $\mathcal{S}$ did not abort in Game 4. We have $\Pr[S_8] = \Pr[S_7]$.

Game 9 (The Indistinguishability Cards). If $mode = \mathrm{I}$, $\mathcal{S}$ forgets (α, γ). If $mode = \mathrm{II}$, $\mathcal{S}$ forgets (β, γ, δ). Note that $\mathcal{S}$ can simulate the game in both modes as long as $(g^{\alpha}, \cdots, g^{\alpha^h}, g^{\gamma})$ are known for $mode = \mathrm{I}$ or $(g^{\beta}, g^{\gamma}, g^{\delta})$ are known for $mode = \mathrm{II}$, except computing the term T. Now $\mathcal{S}$ just picks a $T \in_R \mathbb{G}$. The transition from Game 8 to Game 9 is based on the intractability of either h-wDHI or 3-DDH. Both games are equal unless there exists a PPT algorithm $\mathcal{D}$ that distinguishes T from random. Therefore, we have $|\Pr[S_9] - \Pr[S_8]| \leq Adv^{\mathrm{X}}_{\mathcal{D}}(k)$ where X is either h-wDHI or 3-DDH. Finally, C_1^* perfectly hides m_ι from $\mathcal{A}$, we have $\Pr[S_9] = 1/2$.

B Security Models of Timed-Release Encryption

We following the typical TRE formulation [6, 13, 17, 22, 30] such that public key is certified and the typical TRE security model [13, 17, 22, 30] such that only a single public key is considered. However, we extend the existing notion such that partial decryption by a security-mediator is supported.

We consider the two kinds of adversaries. A Type-I adversary models any coalition of rogue users, and who aims to break the confidentiality of another user's ciphertext. A Type-II adversary that models a curious time server, who aims to break the confidentiality of a user's ciphertext. Security against these adversaries are modeled by the experiment below for $\mathsf{X} \in \{\mathrm{I}, \mathrm{II}\}$, denoting whether an PPT adversary $\mathcal{A} = (\mathcal{A}_{\mathsf{find}}, \mathcal{A}_{\mathsf{guess}})$ is of Type-I or Type-II. The allowed oracle queries $\mathcal{O}$ and the auxiliary information Aux depends on X.

Definition 9. Experiment $\mathbf{Exp}^{\mathsf{CCA}'-\mathsf{X}}_{\mathcal{A}}(\lambda)$

$(\mathsf{Pub}, \mathsf{Msk}) \xleftarrow{\$} \mathsf{Setup}(1^\lambda)$
$(\mathsf{pk}^*, \mathsf{sk}^*) \xleftarrow{\$} \mathsf{KGen}$
$(m_0, m_1, \mathsf{ID}^*, \mathsf{state}) \xleftarrow{\$} \mathcal{A}^{\mathcal{O}}_{\mathsf{find}}(\mathsf{Pub}, \mathsf{Aux}, \mathsf{pk}^*)$
$b \xleftarrow{\$} \{0,1\}$, $C^* \xleftarrow{\$} \mathsf{Enc}(m_b, \mathsf{ID}^*, \mathsf{pk}^*)$
$b' \xleftarrow{\$} \mathcal{A}^{\mathcal{O}}_{\mathsf{guess}}(C^*, \mathsf{state})$
If $(|m_0| \neq |m_1|) \vee (b \neq b')$ *then return 0 else return 1*

where $\mathcal{O}$ *refers to a set of four oracles* $\mathsf{Extract}(\cdot), \mathsf{Dec}^S(\cdot,\cdot), \mathsf{Dec}^U(\cdot,\cdot,\cdot), \mathsf{Dec}(\cdot,\cdot,\cdot)$ *defined as below.*

1. *An* Extract *oracle that takes an identifier* $\mathsf{ID} \in \{0,1\}^n$ *as input and returns its trapdoor* d_{ID}.
2. *A* Dec^S *oracle that takes a ciphertext* C *and an identifier* ID*, and outputs* $\mathsf{Dec}^S(C, d_{\mathsf{ID}})$*. Note that* C *may or may not be encrypted under* ID.
3. *A* Dec^U *oracle that takes a ciphertext* C*, a public key* pk *and a token* D*, and outputs* $\mathsf{Dec}^U(C, \mathsf{sk}, D)$ *where* sk *is the secret key that matches* pk.
4. *A* Dec *oracle that takes a ciphertext* C*, an identifier* ID*, and a public key* pk*, and outputs* $\mathsf{Dec}^U(C, \mathsf{sk}, D)$ *where* sk *is the secret key that matches* pk *and* $D = \mathsf{Dec}^S(C, d_{\mathsf{ID}})$*. Note that* C *may or may not be encrypted under* ID *and* pk.

Definition 10. *A timed-release encryption scheme is* (t, q_E, q_D, ϵ) *CCA-secure against a Type-I adversary if* $|\Pr[\mathbf{Exp}^{\mathsf{CCA}'-\mathsf{I}}_{\mathcal{A}}(\lambda) = 1] - \frac{1}{2}| \leq \epsilon$ *for all* t*-time adversary* $\mathcal{A}$ *making at most* q_E *extraction queries and* q_D *decryption queries (of any type), subjects to the following constraints:*

1. $\mathsf{Aux} = (\mathsf{sk}^*)$*, i.e. the user secret key is given to the adversary.*
2. *No* $\mathsf{Extract}(\mathsf{ID}^*)$ *query throughout the game.*
3. *No* $\mathsf{Dec}^S(C^*, \mathsf{ID}^*)$ *query throughout the game.*
4. *No* $\mathsf{Dec}(C^*, \mathsf{ID}^*, \mathsf{pk}^*)$ *query throughout the game.*

Definition 11. *A timed-release encryption scheme is* (t, q_D, ϵ) *CCA-secure against a Type-II adversary if* $|\Pr[\mathbf{Exp}^{\mathsf{CCA}'-\mathsf{II}}_{\mathcal{A}}(\lambda) = 1] - \frac{1}{2}| \leq \epsilon$ *for all* t*-time adversary* $\mathcal{A}$ *making at most* q_D *decryption queries (of any type), subjects to the following conditions:*

1. $\mathsf{Aux} = (\mathsf{Msk})$*, i.e. the master secret key is given to the adversary.*
2. *No* $\mathsf{Dec}^U(C^*, \mathsf{pk}^*, D)$ *query throughout the game, where* D *is obtained from* $\mathsf{Dec}^S(C^*, \mathsf{ID}^*)$.
3. *No* $\mathsf{Dec}(C^*, \mathsf{ID}^*, \mathsf{pk}^*)$ *query throughout the game.*
