

Aggregating CL-Signatures Revisited: Extended Functionality and Better Efficiency

Moti Yung[‡]

Abstract

Aggregate signature is public-key signature that allows anyone to aggregate different signatures generated by different signers on different messages into a short (called aggregate) signature. The notion has many applications where compressing the signature space is important: in infrastructure: secure routing protocols, in security: compressed certificate chain signature, in signing incrementally changed data: such as software module authentications, and in transaction systems: like in secure high-scale repositories and logs, typical in financial transactions. In spite of its importance, the state of the art of the primitive is such that it has not been easy to devise a suitable aggregate signature scheme that satisfies the conditions of real applications, with reasonable parameters: short public key size, short aggregate signatures size, and efficient aggregate signing/verification.

In this paper, we propose two aggregate signature schemes based on the Camenisch-Lysyanskaya (CL) signature scheme whose security is reduced to that of CL-signature (i.e., secure under the LRSW assumption) which substantially improve efficiency conditions for real applications. The first scheme is an “efficient sequential aggregate signature” scheme with the shortest size public key, to date, and very efficient aggregate verification requiring only a constant number of pairing operations and l number of exponentiations (l being the number of signers). The second scheme is an “efficient synchronized aggregate signature” scheme with a very short public key size, and with the shortest (to date) size of aggregate signatures among synchronized aggregate signature schemes. Signing and aggregate verification are very efficient: they take constant number of pairing operations and l number of exponentiations, as well. The security of the schemes is proved by reducing from the CL-signature in the standard (first scheme) and random oracle (second scheme) models.

Furthermore, our schemes are compatible: a signer of our aggregate signature schemes can dynamically use two modes of aggregation “sequential” and “synchronized,” employing the same private/public key. This multi-modal scheme allows for application flexibility depending on real world scenario: For example, it can be used sequentially to sign incrementally generated legal documents, and synchronously to aggregate the end-of-day logs of all branches of an institute into a single location with a single aggregate signature.

Keywords: Public-key signature, Aggregate information applications, Aggregate signature, CL signature, Bilinear pairing.

1 Introduction

Public-key signature (PKS) is a central cryptographic primitive with numerous applications. However, constructing a PKS scheme that is efficient, secure, and flexible enough for a range of possible appli-

cations is not easy. Among such schemes, CL signature, proposed by Camenisch and Lysyanskaya [16], is one of the pairing-based signature schemes [13, 11, 16, 28] that satisfies these conditions. It was widely used as a basic component in various cryptosystems such as anonymous credential systems, group signature, RFID encryption, batch verification signature, ring signature [16, 3, 2, 15, 7], as well as in aggregate signature [26].

Public-key aggregate signature (PKAS), introduced by Boneh, Gentry, Lynn, and Shacham, is a special type of PKS that enables anyone to aggregate different signatures generated by different signers on different messages into a short aggregate signature [12]. Boneh et al. proposed the first full aggregate signature scheme in bilinear groups and proved its security under the CDH assumption in the random oracle model. After the introduction of aggregate signatures, various types of aggregate signatures such as sequential aggregate signatures and synchronized aggregate signatures were proposed [23, 19, 22, 5, 8, 25, 9, 1, 14, 18, 20, 21]. PKAS has numerous applications. In network and infrastructure: secure routing protocols, public-key infrastructure systems (signing certificate chains), sensor network systems, proxy signatures, as well as in applications: dynamically changing document composition (in particular, secure updating of software modules), secure transaction signing, secure work flow, and secure logs and repositories [12, 9, 1, 10]. In all these applications, compressing the space consumed by signatures is the major advantage. Note that in the area of financial transactions, in particular, logs and repositories are very large due to regulatory requirements to hold records for long time periods. The effect of compressing signatures by aggregation increases with the number of data items; thus it is quite plausible that the financial sector may find variations of aggregate signature most useful.

Though PKAS can reduce the size of signers' signatures by using the aggregation technique, it cannot reduce the size of signers' public keys since the public keys are not aggregated. Thus, the total information the verifier needs to access is still proportional to the number of signers in the aggregate signature, since the verifier should retrieve all public keys of signers from a certificate storage. Therefore, it is very important to reduce the size of public keys. Note that an ideal solution for this problem is to use identity-based aggregate signature (IBAS) that represents the public key of a signer as an identity string. However, IBAS requires a trust structure different from public key infrastructure, namely, the existence of an additional trusted authority, (the current IBAS schemes are in [19, 9, 20] and are all secure in the random oracle model.) To construct a PKAS scheme with short public keys, Schröder proposed a sequential aggregate signature scheme with short public keys based on the CL signature scheme [26]. In the scheme of Schröder, the public key consists of two group elements and the aggregate signature consists of four group elements, but the aggregate verification algorithm requires l pairing operations and l exponentiations where l is the number of signers in the aggregate signature. Therefore, this work, while nicely pointing at the CL signature as a source of efficiency for the context of aggregate signatures, still leaves out desired properties to build upon while exploiting the flexibility of the CL-signature: can we make the public key shorter? can we require substantially less work in verification? and, can we build other modes of aggregate signatures? While asking such questions, we revisit the subject of aggregate signature based on CL-signatures.

1.1 Our Contributions

In this paper, we indeed solve the problem of constructing a PKAS scheme that has short public keys, short aggregate signatures, and an efficient aggregate verification algorithm. We first propose an efficient sequential aggregate signature scheme based on the CL signature scheme and prove its security based on that of CL signature (i.e., the LRSW assumption) in the standard model. A sequential aggregate sig-

nature assumes that the aggregation mode is done in linear order: signed message after signed message. In this scheme, the public key consists of just one group element and the aggregate signature consists of just three group element. The size of the public key is the shortest among all sequential aggregate schemes to date (except IBAS schemes). The aggregate verification algorithm of our scheme is quite efficient since it just requires five pairing operations and l exponentiations (or multi-exponentiations). Therefore our scheme simultaneously satisfies the conditions of short public keys, short aggregate signatures, and efficient aggregate verification.

Next, we propose an efficient synchronized aggregate signature scheme based on the CL signature scheme and prove its security based on the CL-signature security in the random oracle model (the random oracle can be removed if the number of messages is restricted to be polynomial). Synchronized aggregate signature is a mode where the signers of messages to be aggregated are synchronized, but aggregation can take any order. In this scheme, the public key consists of just one group element and the aggregate signature consists of one group element and one integer. The size of the aggregate signature is the shortest among all synchronized aggregate signature schemes to date. The aggregate verification algorithm of this scheme is also quite efficient since it just requires three pairing operations and l exponentiations (or multi-exponentiations).

Additionally, our two aggregate signature schemes can be combined to give a new notion of *aggregate “multi-modal” signature scheme*: A scheme which supports, both, sequential aggregation or synchronized aggregation, since the public key and the private key of two schemes are the same. This property can increase the utility and flexibility of the suggested scheme(s).

Technically speaking, in order to construct our schemes from the CL signature scheme, we employ two techniques: the first one is an adaptation of the “randomness re-use” technique of Lu et al. [22], and the second one is a newly devised “public key sharing” technique. Our “public key sharing” technique distributes the element Y of the public key among all signers by placing the public key element Y of the CL signature into the public parameters. In this case, the private key and the public key of a signer are x and $X = g^x$ instead of x, y and $X = g^x, Y = g^y$ respectively. The signer can then generate the original CL signature as $\sigma = (A = g^r, B = Y^r, C = A^x B^{xM})$. Furthermore, the signer can also generate a sequential aggregate signature as $\sigma_\Sigma = (A = g^r, B = Y^r, C = A^{\sum x_i} B^{\sum x_i M_i})$ since he only needs to aggregate the elements related to the public keys $\{X_i\}$ by using the “randomness re-use” technique. To construct a synchronized aggregate signature scheme from the sequential aggregate signature scheme, we force all signers to use the same elements A and B by using the synchronized time period information. That is, a signer first sets $A = H(0||w)$ and $B = H(1||w)$ where H is a hash function and w is a time period, and he generates a synchronized aggregate signature as $\sigma_\Sigma = (C = A^{\sum x_i} B^{\sum x_i M_i}, w)$.

1.2 Related Works

Given the importance of aggregation to saving signature space, much work has been invested in the various notions allowing aggregation.

Full Aggregation. The notion of public-key aggregate signature (PKAS) was introduced by Boneh, Gentry, Lynn, and Shacham [12]. They proposed the first PKAS scheme in bilinear groups that supports full aggregation such that anyone can freely aggregate different signatures signed by different signers on different messages into a short aggregate signature [12]. The PKAS scheme of Boneh et al. requires l number of pairing operations in the aggregate verification algorithm where l is the number of signers in the aggregate signature. Bellare et al. modified the PKAS scheme of Boneh et al. to remove the restriction such that the message should be different by hashing a message with the public key of a

signer [5].

Sequential Aggregation. The concept of sequential aggregate signature was introduced by Lysyanskaya, Micali, Reyzin, and Shacham [23]. In sequential aggregate signature, a signer can generate an aggregate signature by adding his signature to the previous aggregate signature that was received from a previous signer. Lysyanskaya et al. proposed a sequential PKAS scheme using certified trapdoor permutations, and they proved its security in random oracle models [23]. Neven proposed a sequential PKAS scheme that reduces not only the size of signatures but also the size of total information that is transmitted [25]. Boldyreva et al. proposed an identity-based sequential aggregate signature (IBSAS) scheme (in the trust model of identity-based schemes with a trusted private keys authority), in bilinear groups and proved its security under an interactive assumption in the random oracle model [9]. Recently, Gerbush et al. showed that a modified IBSAS scheme of Boldyreva et al. in composite order bilinear groups can be proven under static assumptions in the random oracle model [20].

The first sequential PKAS scheme without random oracles was proposed by Lu et al. [22]. They constructed a sequential PKAS scheme based on the PKS scheme of Waters and proved its security under the CDH assumption without random oracles. However, this sequential PKAS scheme has a disadvantage such that the size of public keys is very long. To reduce the size of public keys in PKAS schemes, Schröder proposed the CL signature based scheme discussed above [26]. Recently, Lee et al. proposed efficient sequential PKAS scheme with short public keys and proved its security under static assumptions without random oracles [21].

In sequential PKAS schemes, a signer generally should verify the validity of the previous aggregate signature (the aggregate-so-far) handed to him from a previous signer before he adds his signature into the aggregate signature. To verify the previous aggregate signature, the signer should retrieve all public keys of previous signers and should run the aggregate verification algorithm. Thus verifying the previous aggregate signature is the most expensive operation in the aggregate signing algorithm. To solve this problem, sequential PKAS schemes that do not require to verify the previous aggregate signature were proposed [14, 18].

Synchronized Aggregation. The concept of synchronized aggregate signature was introduced by Gentry and Ramzan [19]. In synchronized aggregate signature, all signers have synchronized time information and individual signatures generated by different signers within the same time period can be aggregated into a short aggregate signature. They proposed an identity-based synchronized aggregate signature scheme in bilinear groups and proved its security under the CDH assumption in the random oracle model [19]. Ahn et al. proposed an efficient synchronized PKAS scheme based on the PKS scheme of Hohenberger and Waters and proved its security under the CDH assumption without random oracles [1].

Interactive Aggregation. Interactive aggregate signature is aggregate signature such that a signer generates an aggregate signature after having interactive communications with other signers through a broadcast channel. Bellare and Neven proposed an identity-based multi-signature scheme under the RSA assumption in the random oracle model [6], and Bagherzandi and Jareki proposed an identity-based aggregate signature scheme and proved its security under the RSA assumption in the random oracle model [4]. However, the interactive communications between signers are expensive (signing becomes a protocol among parties), and the heavy message transmission between signers may eliminate some of the advantage of signature aggregation.

2 Preliminaries

In this section, we first define the public key signature and its security model. Next, we define bilinear groups, and introduce the LRSW assumption which is associated with the security of the CL signature scheme, which is, then, presented as well.

2.1 Public Key Signature

A public key signature (PKS) scheme consists of three PPT algorithms **KeyGen**, **Sign**, and **Verify**, which are defined as follows: The key generation algorithm **KeyGen**(1^λ) takes as input a security parameter 1^λ , and outputs a public key PK and a private key SK . The signing algorithm **Sign**(M, SK) takes as input a message M and a private key SK , and outputs a signature σ . The verification algorithm **Verify**(σ, M, PK) takes as input a signature σ , a message M , and a public key PK , and outputs either 1 or 0 depending on the validity of the signature.

The correctness requirement is that for any (PK, SK) output by **KeyGen** and any $M \in \mathcal{M}$, we have that **Verify**(**Sign**(M, SK), M, PK) = 1. We can relax this notion to require that the verification is correct with overwhelming probability over all the randomness of the experiment.

The security notion of existential unforgeability under a chosen message attack is defined in terms of the following experiment between a challenger \mathcal{C} and a PPT adversary \mathcal{A} : \mathcal{C} first generates a key pair (PK, SK) by running **KeyGen**, and gives PK to \mathcal{A} . Then \mathcal{A} , adaptively and polynomially many times, requests a signature query on a message M under the challenge public key PK , and receives a signature σ . Finally, \mathcal{A} outputs a forged signature σ^* on a message M^* . \mathcal{C} then outputs 1 if the forged signature satisfies the following two conditions, or outputs 0 otherwise: 1) **Verify**(σ^*, M^*, PK) = 1 and 2) M^* was not queried by \mathcal{A} to the signing oracle. The advantage of \mathcal{A} is defined as $\text{Adv}_{\mathcal{A}}^{\text{PKS}} = \Pr[\mathcal{C} = 1]$ where the probability is taken over all the randomness of the experiment. A PKS scheme is existentially unforgeable under a chosen message attack if all PPT adversaries have at most a negligible advantage in the above experiment (for large enough security parameter).

2.2 Bilinear Groups

Let \mathbb{G} and \mathbb{G}_T be multiplicative cyclic groups of prime order p . Let g be a generator of \mathbb{G} . The bilinear map $e : \mathbb{G} \times \mathbb{G} \rightarrow \mathbb{G}_T$ has the following properties:

1. Bilinearity: $\forall u, v \in \mathbb{G}$ and $\forall a, b \in \mathbb{Z}_p$, $e(u^a, v^b) = e(u, v)^{ab}$.
2. Non-degeneracy: $\exists g$ such that $e(g, g)$ has order p , that is, $e(g, g)$ is a generator of \mathbb{G}_T .

We say that \mathbb{G}, \mathbb{G}_T are bilinear groups if the group operations in \mathbb{G} and \mathbb{G}_T as well as the bilinear map e are all efficiently computable.

2.3 Complexity Assumption

The security of our aggregate signature schemes is based on the following LRSW assumption. The LRSW assumption was introduced by Lysyanskaya, et al. [24] and it is secure under the generic group model defined by Shoup [27] (and adapted to bilinear groups in [16]).

Assumption 2.1 (LRSW). *Let \mathcal{G} be an algorithm that on input the security parameter 1^λ , outputs the parameters for a bilinear group as $(p, \mathbb{G}, \mathbb{G}_T, e, g)$. Let $X, Y \in \mathbb{G}$ such that $X = g^x, Y = g^y$ for some*

$x, y \in \mathbb{Z}_p$. Let $O_{X,Y}(\cdot)$ be an oracle that on input a value $M \in \mathbb{Z}_p$ outputs a triple (a, a^y, a^{x+My}) for a randomly chosen $a \in \mathbb{G}$. Then for all probabilistic polynomial time adversaries \mathcal{A} ,

$$\begin{aligned} & \Pr[(p, \mathbb{G}, \mathbb{G}_T, e, g) \leftarrow \mathcal{G}(1^\lambda), x \leftarrow \mathbb{Z}_p, y \leftarrow \mathbb{Z}_p, X = g^x, Y = g^y, \\ & (M, a, b, c) \leftarrow \mathcal{A}^{O_{X,Y}(\cdot)}(p, \mathbb{G}, \mathbb{G}_T, e, g, X, Y) : \\ & M \notin Q \wedge M \in \mathbb{Z}_p^* \wedge a \in \mathbb{G} \wedge b = a^y \wedge c = a^{x+My}] < 1/\text{poly}(\lambda) \end{aligned}$$

where Q is the set of queries that \mathcal{A} made to $O_{X,Y}(\cdot)$.

2.4 The CL Signature Scheme

The CL signature scheme is a public-key signature scheme that was proposed by Camenisch and Lysyanskaya and the security was proven under the LRSW assumption without random oracles [16]. Although the security of the CL signature scheme is based on this interactive assumption, it is flexible and widely used for the constructions of various cryptosystems such as anonymous credentials, group signatures, ring signatures, batch verification, and aggregate signatures [24, 16, 7, 15, 26] (this is so, perhaps due to its relatively elegant and simple algebraic structure).

PKS.KeyGen(1^λ): The key generation algorithm first generates the bilinear groups \mathbb{G}, \mathbb{G}_T of prime order p of bit size $\Theta(\lambda)$. Let g be the generator of \mathbb{G} . It selects two random exponents $x, y \in \mathbb{Z}_p$ and sets $X = g^x, Y = g^y$. It outputs a private key as $SK = (x, y)$ and a public key as $PK = (p, \mathbb{G}, \mathbb{G}_T, e, g, X, Y)$.

PKS.Sign(M, SK): The signing algorithm takes as input a message $M \in \mathbb{Z}_p^*$ and a private key $SK = (x, y)$. It selects a random element $A \in \mathbb{G}$ and computes $B = A^y, C = A^x B^{xM}$. It outputs a signature as $\sigma = (A, B, C)$.

PKS.Verify(σ, M, PK): The verification algorithm takes as input a signature $\sigma = (A, B, C)$ on a message $M \in \mathbb{Z}_p^*$ under a public key $PK = (p, \mathbb{G}, \mathbb{G}_T, e, g, X, Y)$. It verifies that $e(A, Y) \stackrel{?}{=} e(B, g)$ and $e(C, g) \stackrel{?}{=} e(A, X) \cdot e(B, X)^M$. If these equations hold, then it outputs 1. Otherwise, it outputs 0.

Theorem 2.2 ([16]). *The CL signature scheme is existentially unforgeable under a chosen message attack if the LRSW assumption holds.*

3 Sequential Aggregate Signature

In this section, we first define the sequential aggregate signature and its security model. After that, we propose an efficient sequential aggregate signature scheme based on the CL signature scheme, and prove its security under the LRSW assumption.

3.1 Definitions

Sequential aggregate signature (SeqAS) is a special type of public-key aggregate signature (PKAS) that allows each signer to sequentially add his signature on a different message to the aggregate signature [23]. That is, a signer with an index i receives an aggregate signature σ_Σ^i from the signer of an index $i-1$, and he generates a new aggregate signature σ_Σ by aggregating his signature on a message M to

the received aggregate signature. The resulting aggregate signature has the same size of the previous aggregate signature.

Formally, a SeqAS scheme consists of four PPT algorithms **Setup**, **KeyGen**, **AggSign**, and **AggVerify**, which are defined as follows:

- **Setup**(1^λ). The setup algorithm takes as input a security parameter 1^λ and outputs public parameters PP .
- **KeyGen**(PP). The key generation algorithm takes as input the public parameters PP , and outputs a public key PK and a private key SK .
- **AggSign**($\sigma'_\Sigma, \mathbf{M}, \mathbf{PK}, M, SK, PP$). The aggregate signing algorithm takes as input an aggregate-so-far σ'_Σ on messages $\mathbf{M} = (M_1, \dots, M_k)$ under public keys $\mathbf{PK} = (PK_1, \dots, PK_k)$, a message M , and a private key SK with PP , and outputs a new aggregate signature σ_Σ .
- **AggVerify**($\sigma_\Sigma, \mathbf{M}, \mathbf{PK}, PP$). The aggregate verification algorithm takes as input an aggregate signature σ_Σ on messages $\mathbf{M} = (M_1, \dots, M_l)$ under public keys $\mathbf{PK} = (PK_1, \dots, PK_l)$ and the public parameters PP , and outputs either 1 or 0 depending on the validity of the aggregate signature.

The correctness requirement is that for each PP output by **Setup**, for all (PK, SK) output by **KeyGen**, any M , we have that $\mathbf{AggVerify}(\mathbf{AggSign}(\sigma'_\Sigma, \mathbf{M}', \mathbf{PK}', M, SK, PK, PP), \mathbf{M}' || M, \mathbf{PK}' || PK, PP) = 1$ where σ'_Σ is a valid aggregate-so-far signature on messages \mathbf{M}' under public keys \mathbf{PK}' .

The security model of SeqAS was introduced by Lysyanskaya et al. [23]. In this paper, we follow the security model that was proposed by Lu et al. [22]. The security model of Lu et al. is a more restricted model that requires the adversary to correctly generate other signers' public keys and private keys except the challenge signer's key. To ensure the correct generation of public keys and private keys, the adversary should submit the corresponding private keys of the public keys to the challenger before using the public keys. A realistic solution of this is for the signer to prove that he knows the corresponding private key of the public key by using zero-knowledge proofs when he requests the certification of his public key.

In the security model of SeqAS, the public parameters and the challenge public key PK^* are given to the adversary. The adversary can request the certification of a public key through a certification query by providing a public key and a private key. It also can request a sequential aggregate signature on a message under the challenge public key by providing an aggregate-so-far that was generated from the certified public keys. Finally, it outputs a forged aggregate signature σ_Σ^* . The adversary breaks the SeqAS scheme if the forged sequential aggregate signature is valid and non-trivial.

Formally, the security notion of existential unforgeability under a chosen message attack is defined in terms of the following experiment between a challenger \mathcal{C} and a PPT adversary \mathcal{A} :

Setup: \mathcal{C} first initializes a key-pair list $KeyList$ as empty. Next, it runs **Setup** to obtain public parameters PP and **KeyGen** to obtain a key pair (PK, SK) , and gives PK to \mathcal{A} .

Certification Query: \mathcal{A} adaptively requests the certification of a public key by providing a key pair (PK, SK) . Then \mathcal{C} adds the key pair (PK, SK) to $KeyList$ if the key pair is a valid one.

Signature Query: \mathcal{A} adaptively requests a sequential aggregate signature (by providing an aggregate-so-far σ'_Σ on messages \mathbf{M}' under public keys \mathbf{PK}'), on a message M to sign under the challenge public key PK , and receives a sequential aggregate signature σ_Σ .

Output: Finally (after a sequence of the above queries), \mathcal{A} outputs a forged sequential aggregate signature σ_{Σ}^* on messages \mathbf{M}^* under public keys \mathbf{PK}^* . \mathcal{C} outputs 1 if the forged signature satisfies the following three conditions, or outputs 0 otherwise: 1) $\text{AggVerify}(\sigma_{\Sigma}^*, \mathbf{M}^*, \mathbf{PK}^*, PP) = 1$, 2) The challenge public key PK must exist in \mathbf{PK}^* and each public key in \mathbf{PK}^* except the challenge public key must be in $KeyList$, and 3) The corresponding message M in \mathbf{M}^* of the challenge public key PK must not have been queried by \mathcal{A} to the sequential aggregate signing oracle.

The advantage of \mathcal{A} is defined as $\text{Adv}_{\mathcal{A}}^{\text{SeqAS}} = \Pr[C = 1]$ where the probability is taken over all the randomness of the experiment. A SeqAS scheme is existentially unforgeable under a chosen message attack if all PPT adversaries have at most a negligible advantage (for large enough security parameter) in the above experiment.

3.2 Construction

We first describe the design idea of our SeqAS scheme. To construct a SeqAS scheme, we use the “public key sharing” technique such that the element Y in the public key of the original CL signature scheme can be shared with all signers. The modified CL signature scheme that shares the element Y of the public key is described as follows: The setup algorithm publishes the public parameters that contain the description of bilinear groups and an element Y . Each signer generates a private key $x \in \mathbb{Z}_p$ and a public key $X = g^x$. A signer who has the private key x of the public key X can generate an original CL signature $\sigma = (A, B, C)$ on a message M just using the private key x and a random r as $A = g^r$, $B = Y^r$, and $C = A^x B^{xM}$ since the element Y is given in the public parameters. This modified CL signature scheme is still secure under the LRSW assumption.

We construct a SeqAS scheme based on the modified CL signature scheme that supports “public key sharing” by using the “randomness re-use” technique of Lu et al. [22]. It is easy to sequentially aggregate signatures if the element Y is shared with all signers since we only need to consider the aggregation of the $\{X_i\}$ values of signers instead of the $\{X_i, Y_i\}$ values of signers. For instance, the first signer who has a private key x_1 generates a signature $\sigma_1 = (A_1, B_1, C_1)$ on a message M_1 as $A_1 = g^{r_1}$, $B_1 = Y^{r_1}$, and $C_1 = (g^{r_1})^{x_1} (Y^{r_1})^{x_1 M_1}$. The second signer with a private key x_2 generates a sequential aggregate signature $\sigma_2 = (A_2, B_2, C_2)$ on a message M_2 as $A_2 = A_1$, $B_2 = B_1$, and $C_2 = C_1 (A_1)^{x_2} (B_1)^{x_2 M_2}$ by using the “randomness re-use” technique. Therefore a sequential aggregate signature of signers is formed as $\sigma_{\Sigma} = (A = g^r, B = Y^r, C = A^{\sum x_i} B^{\sum x_i M_i})$. Additionally, each signer should re-randomize the aggregate signature to prevent a simple attack.

Our SeqAS scheme is described as follows:

SeqAS.Setup(1^λ): The setup algorithm first generates the bilinear groups \mathbb{G}, \mathbb{G}_T of prime order p of bit size $\Theta(\lambda)$. Let g be the generator of \mathbb{G} . It chooses a random element $Y \in \mathbb{G}$ and outputs public parameters as $PP = (p, \mathbb{G}, \mathbb{G}_T, e, g, Y)$.

SeqAS.KeyGen(PP): The key generation algorithm takes as input the public parameters PP . It selects a random exponent $x \in \mathbb{Z}_p$ and sets $X = g^x$. Then it outputs a private key as $SK = x$ and a public key as $PK = X$.

SeqAS.AggSign($\sigma_{\Sigma}^l, \mathbf{M}^l, \mathbf{PK}^l, M, SK, PP$): The aggregate signing algorithm takes as input an aggregate-so-far $\sigma_{\Sigma}^l = (A^l, B^l, C^l)$ on messages $\mathbf{M}^l = (M_1, \dots, M_k)$ under public keys $\mathbf{PK}^l = (PK_1, \dots, PK_k)$ where $PK_i = X_i$, a message $M \in \mathbb{Z}_p^*$, and a private key $SK = x$ with PP . It first checks the validity of σ_{Σ}^l by calling $\text{AggVerify}(\sigma_{\Sigma}^l, \mathbf{M}^l, \mathbf{PK}^l, PP)$. If σ_{Σ}^l is not valid, then it halts. It checks that the

public key PK of SK does not already exist in \mathbf{PK}' . If the public key already exists, then it halts. Note that if $k = 0$, then $\sigma_\Sigma' = (1, Y, 1)$. It selects a random exponent $r \in \mathbb{Z}_p$ and computes

$$A = (A')^r, B = (B')^r, C = (C' \cdot (A')^x \cdot (B')^{xM})^r.$$

It outputs an aggregate signature as $\sigma_\Sigma = (A, B, C)$.

SeqAS.AggVerify($\sigma_\Sigma, \mathbf{M}, \mathbf{PK}, PP$): The aggregate verification algorithm takes as input an aggregate signature $\sigma_\Sigma = (A, B, C)$ on messages $\mathbf{M} = (M_1, \dots, M_l)$ under public keys $\mathbf{PK} = (PK_1, \dots, PK_l)$ where $PK_i = X_i$. It first checks that any M_i is in \mathbb{Z}_p^* , any public key does not appear twice in \mathbf{PK} , and any public key in \mathbf{PK} has been certified. If these checks fail, then it outputs 0. If $l = 0$, then it outputs 1 if $\sigma_\Sigma = (1, Y, 1)$, 0 otherwise. Next, it verifies that

$$e(A, Y) \stackrel{?}{=} e(B, g) \quad \text{and} \quad e(C, g) \stackrel{?}{=} e\left(A, \prod_{i=1}^l X_i\right) \cdot e\left(B, \prod_{i=1}^l X_i^{M_i}\right).$$

If these equations hold, then it outputs 1. Otherwise, it outputs 0.

A sequential aggregate signature $\sigma_\Sigma = (A, B, C)$ on messages $\mathbf{M} = (M_1, \dots, M_l)$ under public keys $\mathbf{PK} = (PK_1, \dots, PK_l)$ has the following form

$$A = g^r, B = Y^r, C = (g^r)^{\sum_{i=1}^l x_i} (Y^r)^{\sum_{i=1}^l x_i M_i}$$

where $PK_i = X_i = g^{x_i}$.

3.3 Security Analysis

We prove the security of our SeqAS scheme based on the security of the CL signature scheme in the standard model. Therefore, our SeqAS scheme is existentially unforgeable under a chosen message attack under the LRSW assumption since the security of the CL signature scheme is proven under the LRSW assumption.

Theorem 3.1. *The above SeqAS scheme is existentially unforgeable under a chosen message attack if the CL signature scheme is existentially unforgeable under a chosen message attack. That is, for any PPT adversary \mathcal{A} for the above SeqAS scheme, there exists a PPT algorithm \mathcal{B} for the CL signature scheme such that $\text{Adv}_{\mathcal{A}}^{\text{SeqAS}}(\lambda) \leq \text{Adv}_{\mathcal{B}}^{\text{CL}}(\lambda)$.*

Proof. The main idea of the security proof is that the aggregated signature of our SeqAS scheme is independent of the order of aggregation, and the simulator of the SeqAS scheme possesses the private keys of all signers except the private key of the challenge public key. That is, if the adversary requests a sequential aggregate signature, then the simulator first obtains a CL signature from the target scheme's signing oracle and runs the aggregate signing algorithm to generate a sequential aggregate signature. If the adversary finally outputs a forged sequential aggregate signature that is non-trivial, then the simulator extracts the CL signature of the challenge public key from the forged aggregate signature by using the private keys of other signers.

Suppose there exists an adversary \mathcal{A} that forges the above SeqAS scheme with a non-negligible advantage ε . A simulator \mathcal{B} that forges the CL signature scheme is first given: a challenge public key $PK_{CL} = (p, \mathbb{G}, \mathbb{G}_T, e, g, X, Y)$. Then \mathcal{B} that interacts with \mathcal{A} is described as follows:

Setup: \mathcal{B} first constructs $PP = (p, \mathbb{G}, \mathbb{G}_T, e, g, Y)$ and $PK^* = X$ from PK_{CL} . Next, it initializes a key-pair list $KeyList$ as an empty one and gives PP and PK^* to \mathcal{A} .

Certification Query: \mathcal{A} adaptively requests the certification of a public key by providing a public key $PK_i = X_i$ and its private key $SK_i = x_i$. \mathcal{B} checks the private key and adds the key pair (PK_i, SK_i) to $KeyList$.

Signature Query: \mathcal{A} adaptively requests a sequential aggregate signature query by providing an aggregate-so-far σ'_Σ on messages $\mathbf{M}' = (M_1, \dots, M_k)$ under public keys $\mathbf{PK}' = (PK_1, \dots, PK_k)$, and a message M to sign under the challenge private key of PK^* . \mathcal{B} proceeds the aggregate signature query as follows:

1. It first checks that the signature σ'_Σ is valid by calling **SeqAS.AggVerify** and that each public key in \mathbf{PK}' exits in $KeyList$.
2. It queries its signing oracle that simulates **PKS.Sign** on the message M for the challenge public key PK^* and obtains a signature σ .
3. For each $1 \leq i \leq k$, it constructs an aggregate signature on message M_i using **SeqAS.AggSign** since it knows the private key that corresponds to PK_i . The resulting signature is an aggregate signature for messages $\mathbf{M}' || M$ under public keys $\mathbf{PK}' || PK^*$ since this scheme does not check the order of aggregation. It gives the result signature σ_Σ to \mathcal{A} .

Output: \mathcal{A} outputs a forged aggregate signature $\sigma_\Sigma^* = (A^*, B^*, C^*)$ on messages $\mathbf{M}^* = (M_1, \dots, M_l)$ under public keys $\mathbf{PK}^* = (PK_1, \dots, PK_l)$ for some l . Without loss of generality, we assume that $PK_1 = PK^*$. \mathcal{B} proceeds as follows:

1. \mathcal{B} first checks the validity of σ_Σ^* by calling **SeqAS.AggVerify**. Additionally, the forged signature should not be trivial: the challenge public key PK^* must be in \mathbf{PK}^* , and the message M_1 must not be queried by \mathcal{A} to the signature query oracle.
2. For each $2 \leq i \leq l$, it parses $PK_i = X_i$ from \mathbf{PK}^* , and it retrieves the private key $SK_i = x_i$ of PK_i from $KeyList$. It then computes

$$A = A^*, \quad B = B^*, \quad C = C^* \cdot \left((A^*)^{\sum_{i=2}^l x_i} (B^*)^{\sum_{i=2}^l x_i M_i} \right)^{-1}.$$

3. It outputs $\sigma^* = (A, B, C)$ on a message $M^* = M_1$ as a non-trivial forgery of the CL signature scheme since it did not make a signing query on M_1 .

To finish the proof, we first show that the distribution of the simulation is correct. It is obvious that the public parameters and the public key are correctly distributed. The distribution of the sequential aggregate signatures is correct since this scheme does not check the order of aggregation. Finally, we can show that the resulting signature $\sigma^* = (A, B, C)$ of the simulator is a valid signature for the CL signature scheme on the message M_1 under the public key PK^* since it satisfies the following equation:

$$\begin{aligned} e(C, g) &= e\left(C^* \cdot \left((A^*)^{\sum_{i=2}^l x_i} (B^*)^{\sum_{i=2}^l x_i M_i} \right)^{-1}, g\right) \\ &= e\left((A^*)^{\sum_{i=1}^l x_i} (B^*)^{\sum_{i=1}^l x_i M_i} \cdot (A^*)^{-\sum_{i=2}^l x_i} (B^*)^{-\sum_{i=2}^l x_i M_i}, g\right) \\ &= e\left((A^*)^{x_1} (B^*)^{x_1 M_1}, g\right) = e(A^*, g^{x_1}) \cdot e(B^*, g^{x_1 M_1}) \\ &= e(A, X) \cdot e(B, X^{M^*}). \end{aligned}$$

This completes our proof. □

3.4 Discussions

Efficiency. The public key of our SeqAS scheme consists of just one group element and the aggregate signature consists of three group elements, since the public key element Y of the CL signature scheme is moved to the public parameters of our scheme. The aggregate signing algorithm requires one aggregate verification and five exponentiations, and the aggregate verification algorithm requires five pairing operations and l exponentiations where l is the number of signers in the aggregate signature. In the SeqAS scheme of Schröder [26], the public key consists of two group elements, the aggregate signature consists of four group elements, and the aggregate verification algorithm requires l pairing operations and l exponentiations. Therefore, our SeqAS scheme is more efficient than the SeqAS scheme of Schröder.

Asymmetric Bilinear Groups. We can use asymmetric bilinear groups instead of symmetric bilinear groups to reduce the size of aggregate signatures. Let $\mathbb{G}, \hat{\mathbb{G}}, \mathbb{G}_T$ be the cyclic groups of prime order p . We say that $\mathbb{G}, \hat{\mathbb{G}}, \mathbb{G}_T$ are asymmetric bilinear groups if there exists the bilinear map $e : \mathbb{G} \times \hat{\mathbb{G}} \rightarrow \mathbb{G}_T$ that has bilinearity and non-degeneracy properties. The SeqAS scheme in asymmetric bilinear groups is described as follows: the public parameters is $PP = (p, \mathbb{G}, \hat{\mathbb{G}}, \mathbb{G}_T, e, g, \hat{g}, Y, \hat{Y})$, the private key and the public key are $SK = x$ and $PK = \hat{X} \in \hat{\mathbb{G}}$ respectively, and the aggregate signature is $\sigma_\Sigma = (A = g^r, B = Y^r, C = A^{\sum x_i} B^{\sum x_i M_i}) \in \mathbb{G}^3$. For instance, if we instantiate the asymmetric bilinear groups using the 175-bit MNT curve with embedding degree 6 to guarantee 80-bit security level, the size of public key is 525 bit and the size of aggregate signature is 525 bit. In the 175-bit MNT curve, the SeqAS scheme of Lu et al. [22] has 113 kilo-bits size of the public key and 350 bit size of the aggregate signature, and the SeqAS scheme of Schröder [26] has 1050 bit size of the public key and 700 bit size of the aggregate signature.

Public-Key Signature. We can easily derive a new PKS scheme from our SeqAS scheme. Compared to the CL signature scheme, the new PKS scheme has an advantage such that the public key just consists of one group element X instead of two group elements X, Y since the element Y is moved to the public parameters. A signer who has a private key x can generate a signature $\sigma = (A, B, C)$ as $A = g^r, B = Y^r$, and $C = A^x B^{xM}$. A verifier can verify the signature by checking that $e(A, Y) = e(B, g)$ and $e(C, g) = e(A, X) \cdot e(B, X^M)$. This new PKS scheme is also secure under the LRSW assumption.

4 Synchronized Aggregate Signature

In this section, we first define the synchronized aggregate signature and its security model. Next, we propose an efficient synchronized aggregate signature scheme based on the CL signature scheme, and prove its security in the random oracle model under the LRSW assumption.

4.1 Definitions

Synchronized aggregate signature (SyncAS) is a special type of public-key aggregate signature (PKAS) that allows anyone to aggregate signer's signatures on different messages with a same time period into a short aggregate signature if all signers have the synchronized time period information like a clock [19, 1]. In SyncAS scheme, each signer has a synchronized time period or has an access to public time information. Each signer can generate an individual signature on a message M and a time period w . Note that the signer can generate just one signature per one time period. After that, anyone can aggregate individual signatures of other signers into a short aggregate signature σ_Σ if the individual

signatures are generated on the same time period w . The resulting aggregate signature has the same size of the individual signature.

Formally, a SyncAS scheme consists of six PPT algorithms **Setup**, **KeyGen**, **Sign**, **Verify**, **Aggregate**, and **AggVerify**, which are defined as follows:

- **Setup**(1^λ). The setup algorithm takes as input a security parameter 1^λ and outputs public parameters PP .
- **KeyGen**(PP). The key generation algorithm takes as input the public parameters PP , and outputs a public key PK and a private key SK .
- **Sign**(M, w, SK, PP). The signing algorithm takes as input a message M , a time period w , and a private key SK with PP , and outputs an individual signature σ .
- **Verify**(σ, M, PK, PP). The verification algorithm takes as input a signature σ on a message M under a public key PK , and outputs either 1 or 0 depending on the validity of the signature.
- **Aggregate**($\mathbf{S}, \mathbf{M}, \mathbf{PK}$). The aggregation algorithm takes as input individual signatures $\mathbf{S} = (\sigma_1, \dots, \sigma_l)$ on messages $\mathbf{M} = (M_1, \dots, M_l)$ under public keys $\mathbf{PK} = (PK_1, \dots, PK_l)$, and outputs an aggregate signature σ_Σ .
- **AggVerify**($\sigma_\Sigma, \mathbf{M}, \mathbf{PK}, PP$). The aggregate verification algorithm takes as input an aggregate signature σ_Σ on messages $\mathbf{M} = (M_1, \dots, M_l)$ under public keys $\mathbf{PK} = (PK_1, \dots, PK_l)$, and outputs either 1 or 0 depending on the validity of the aggregate signature.

The correctness requirement is that for each PP output by **Setup**, for all (PK, SK) output by **KeyGen**, any M , we have that $\mathbf{AggVerify}(\mathbf{Aggregate}(\mathbf{S}, \mathbf{M}, \mathbf{PK}), \mathbf{M}, \mathbf{PK}, PP) = 1$ where \mathbf{S} is individual signatures on messages \mathbf{M} under public keys \mathbf{PK} .

The security model of SyncAS was introduced by Gentry and Ramzan [19]. In this paper, we follow the security model that was proposed by Ahn et al. [1]. The security model of Ahn et al. is a more restricted model that requires the adversary to correctly generate other signers' public keys and private keys except the challenge signer's key. To ensure the correct generation of public keys and private keys, the adversary should submit the private key of the public key, or he should prove that he knows the corresponding private key by using zero-knowledge proofs.

In the security model of SyncAS, the public parameters and the challenge public key PK^* are given to the adversary at first. The adversary can request the certification of a public key through a certification query by providing the public key and the corresponding private key. It also can request a signature on a message M and a time period w that was not used before under the challenge public key. Finally, it outputs a forged synchronized aggregate signature σ_Σ^* . The adversary breaks the SyncAS scheme if the forged synchronized aggregate signature of the adversary is valid and non-trivial.

Formally, the security notion of existential unforgeability under a chosen message attack is defined in terms of the following experiment between a challenger \mathcal{C} and a PPT adversary \mathcal{A} :

Setup: \mathcal{C} first initializes a key-pair list $KeyList$ as empty. Next, it runs **Setup** to obtain public parameters PP and **KeyGen** to obtain a key pair (PK, SK) , and gives PK to \mathcal{A} .

Certification Query: \mathcal{A} adaptively requests the certification of a public key by providing a key pair (PK, SK) . Then \mathcal{C} adds the key pair (PK, SK) to $KeyList$ if the key pair is a valid one.

Hash Query: \mathcal{A} adaptively requests a hash on a string for various hash functions, and receives a hash value.

Signature Query: \mathcal{A} adaptively requests a signature on a message M and a time period w that was not used before to sign under the challenge public key PK , and receives an individual signature σ .

Output: Finally (after a sequence of the above queries), \mathcal{A} outputs a forged synchronized aggregate signature σ_{Σ}^* on messages \mathbf{M}^* under public keys \mathbf{PK}^* . \mathcal{C} outputs 1 if the forged signature satisfies the following three conditions, or outputs 0 otherwise: 1) $\text{AggVerify}(\sigma_{\Sigma}^*, \mathbf{M}^*, \mathbf{PK}^*, PP) = 1$, 2) The challenge public key PK must exist in \mathbf{PK}^* and each public key in \mathbf{PK}^* except the challenge public key must be in $KeyList$, and 3) The corresponding message M in \mathbf{M}^* of the challenge public key PK must not have been queried by \mathcal{A} to the signing oracle.

The advantage of \mathcal{A} is defined as $\text{Adv}_{\mathcal{A}}^{\text{SyncAS}} = \Pr[\mathcal{C} = 1]$ where the probability is taken over all the randomness of the experiment. A SyncAS scheme is existentially unforgeable under a chosen message attack if all PPT adversaries have at most a negligible advantage (for large enough security parameter) in the above experiment.

4.2 Construction

We first describe the design idea of our SyncAS scheme. In the previous section, we proposed a modified CL signature scheme that shares the element Y in the public parameters. The signature of this modified CL signature scheme is formed as $\sigma = (A = g^r, B = Y^r, C = A^x B^{xM})$. If we can force signers to use the same $A = g^r$ and $B = Y^r$ in signatures, then we easily obtain an aggregate signature as $\sigma_{\Sigma} = (A = g^r, B = Y^r, C = A^{\sum x_i} B^{\sum x_i M_i})$ by just multiplying individual signatures of signers. In synchronized aggregate signatures, it is possible to force signers to use the same A and B since all signers have the same time period w . Therefore, each signer first sets $A = H(0||w)$ and $B = H(1||w)$ using the hash function H and the time period w , and then he generates an individual signature $\sigma = (C = A^x B^{xM}, w)$. We need to hash a message for the proof of security.

Let \mathcal{W} be a set of positive integers such as $\{0, 1\}^{32}$. Our SyncAS scheme is described as follows:

SyncAS.Setup(1^λ): The setup algorithm first generates the bilinear groups \mathbb{G}, \mathbb{G}_T of prime order p of bit size $\Theta(\lambda)$. Let g be the generator of \mathbb{G} . It chooses two hash functions $H_1 : \{0, 1\} \times \mathcal{W} \rightarrow \mathbb{G}$ and $H_2 : \{0, 1\}^* \times \mathcal{W} \rightarrow \mathbb{Z}_p^*$. It outputs public parameters as $PP = (p, \mathbb{G}, \mathbb{G}_T, e, g, H_1, H_2)$.

SyncAS.KeyGen(PP): The key generation algorithm takes as input the public parameters PP . It selects a random exponent $x \in \mathbb{Z}_p$ and sets $X = g^x$. Then it outputs a private key as $SK = x$ and a public key as $PK = X$.

SyncAS.Sign(M, w, SK, PP): The signing algorithm takes as input a message $M \in \{0, 1\}^*$, a time period $w \in \mathcal{W}$, and a private key $SK = x$ with PP . It first sets $A = H_1(0||w), B = H_1(1||w), h = H_2(M||w)$ and computes $C = A^x B^{xh}$. It outputs a signature as $\sigma = (C, w)$.

SyncAS.Verify(σ, M, PK, PP): The verification algorithm takes as input a signature $\sigma = (C, w)$ on a message M under a public key $PK = X$. It first checks that the public key has been certified. If these checks fail, then it outputs 0. Next, it sets $A = H_1(0||w), B = H_1(1||w), h = H_2(M||w)$ and verifies that $e(C, g) \stackrel{?}{=} e(AB^h, X)$. If this equation holds, then it outputs 1. Otherwise, it outputs 0.

SyncAS.Aggregate($\mathbf{S}, \mathbf{M}, \mathbf{PK}, PP$): The aggregation algorithm takes as input signatures $\mathbf{S} = (\sigma_1, \dots, \sigma_l)$ on messages $\mathbf{M} = (M_1, \dots, M_l)$ under public keys $\mathbf{PK} = (PK_1, \dots, PK_l)$ where $\sigma_i = (C'_i, w'_i)$ and $PK_i = X_i$. It first checks that that w'_1 is equal to w'_i for $i = 2$ to l . If it fails, it halts. Next, it sets $w = w'_1$ and computes $C = \prod_{i=1}^l C'_i$. It outputs an aggregate signature as $\sigma_\Sigma = (C, w)$.

SyncAS.AggVerify($\sigma_\Sigma, \mathbf{M}, \mathbf{PK}, PP$): The aggregate verification algorithm takes as input an aggregate signature $\sigma_\Sigma = (C, w)$ on messages $\mathbf{M} = (M_1, \dots, M_l)$ under public keys $\mathbf{PK} = (PK_1, \dots, PK_l)$ where $PK_i = X_i$. It first checks that any public key does not appear twice in \mathbf{PK} and that any public key in \mathbf{PK} has been certified. If these checks fail, then it outputs 0. Next, it sets $A = H_1(0||w), B = H_1(1||w), h_i = H_2(M_i||w)$ for all $1 \leq i \leq l$ and verifies that

$$e(C, g) \stackrel{?}{=} e\left(A, \prod_{i=1}^l X_i\right) \cdot e\left(B, \prod_{i=1}^l X_i^{h_i}\right).$$

If this equation holds, then it outputs 1. Otherwise, it outputs 0.

A synchronized aggregate signature $\sigma_\Sigma = (C, w)$ on messages $\mathbf{M} = (M_1, \dots, M_l)$ under public keys $\mathbf{PK} = (PK_1, \dots, PK_l)$ has the following form

$$C = H_1(0||w)^{\sum_{i=1}^l x_i} H_1(1||w)^{\sum_{i=1}^l x_i H_2(M_i||w)}$$

where $PK_i = X_i = g^{x_i}$.

4.3 Security Analysis

We prove the security of our SyncAS scheme based on the security of the CL signature scheme in the random oracle model. Therefore, our SyncAS scheme is existentially unforgeable under a chosen message attack under the LRSW assumption since the CL signature is proven under the LRSW assumption.

Theorem 4.1. *The above SyncAS scheme is existentially unforgeable under a chosen message attack if the CL signature scheme is existentially unforgeable under a chosen message attack. That is, for any PPT adversary \mathcal{A} for the above SyncAS scheme, there exists a PPT algorithm \mathcal{B} for the CL signature scheme such that $\text{Adv}_{\mathcal{A}}^{\text{SyncAS}}(\lambda) \leq q_{H_1} q_{H_2} \cdot \text{Adv}_{\mathcal{B}}^{\text{CL}}(\lambda)$ where q_{H_1} and q_{H_2} are the maximum number of hash queries.*

Proof. The main idea of the security proof is that the random oracle model supports the programmability of hash functions, the adversary can request just one signature per one time period in this security model, and the simulator possesses the private keys of all signers except the private key of the challenge public key. In the proof, the simulator first guesses the time period w' of the forged synchronized aggregate signature and selects a random query index k of the hash function H_2 . After that, if the adversary requests a signature on a message M and a time period w such that $w \neq w'$, then he can easily generate the signature by using the programmability of the random oracle model. If the adversary requests a signature for the time period $w = w'$, then he can generate the signature if the query index i is equal to the index k . Otherwise, the simulator should abort the simulation. Finally, if the adversary outputs a forged synchronized aggregate signature that is non-trivial on the time period w' , then the simulator extracts the CL signature of the challenge public key from the forged aggregate signature by using the private keys of other signers.

Suppose there exists an adversary \mathcal{A} that forges the above SyncAS scheme with a non-negligible advantage ε . A simulator \mathcal{B} that forges the CL signature scheme is first given: a challenge public key $PK_{CL} = (p, \mathbb{G}, \mathbb{G}_T, e, g, X, Y)$. Then \mathcal{B} that interacts with \mathcal{A} is described as follows:

Setup: \mathcal{B} first constructs $PP = (p, \mathbb{G}, \mathbb{G}_T, e, g, H_1, H_2)$ and $PK^* = X$ from PK_{CL} . It chooses a random value $h' \in \mathbb{Z}_p^*$ and queries its signing oracle **PKS.Sign** to obtain $\sigma' = (A', B', C')$. Let q_{H_1} and q_{H_2} be the maximum number of H_1 and H_2 hash queries respectively. It chooses a random index k such that $1 \leq k \leq q_{H_2}$ and guesses a random time period $w' \in \mathcal{W}$ of the forged signature. Next, it initializes a key-pair list *KeyList*, hash lists *H₁-List*, *H₂-List* as an empty one and gives PP and PK^* to \mathcal{A} .

Certification Query: \mathcal{A} adaptively requests the certification of a public key by providing a public key $PK_i = X_i$ and its private key $SK_i = x_i$. \mathcal{B} checks the private key and adds the key-pair (PK_i, SK_i) to *KeyList*.

Hash Query: \mathcal{A} adaptively requests a hash value for H_1 and H_2 respectively. If this is a H_1 hash query on a bit b and a time period w_i , then \mathcal{B} treats the query as follows:

- If $b = 0$ and $w_i \neq w'$, then it selects a random exponent $r_i \in \mathbb{Z}_p$ and sets $H_1(0||w_i) = g^{r_i}$.
- If $b = 0$ and $w_i = w'$, then it sets $H_1(0||w_i) = A'$.
- If $b = 1$ and $w_i \neq w'$, then it selects a random exponent $s_i \in \mathbb{Z}_p$ and sets $H_1(1||w_i) = g^{s_i}$.
- If $b = 1$ and $w_i = w'$, then it sets $H_1(1||w_i) = B'$.

If this is a H_2 hash query on a message M_i and a time period w_j , then \mathcal{B} treats the query as follows:

- If $i \neq k$ or $w_j \neq w'$, then it selects a random value $h_{i,j} \in \mathbb{Z}_p$ and sets $H_2(M_i||w_j) = h_{i,j}$.
- If $i = k$ and $w_j = w'$, then it sets $H_2(M_i||w_j) = h'$.

Note that the simulator keeps the tuple $(b_i, w_i, r_i, H_1(b_i||w_i))$ in *H₁-List* and the tuple $(M_i, w_j, h_{i,j})$ in *H₂-List*.

Signature Query: \mathcal{A} adaptively requests a signature by providing a message M_i and a time period w_j to sign under the challenge private key of PK^* . \mathcal{B} proceeds the signature query as follows:

- If $w_i \neq w'$, then it responses $\sigma_{i,j} = (X^{r_i} X^{s_i h_{i,j}}, w_j)$ where r_i, s_i , and $h_{i,j}$ are retrieved from the *H₁-List* and *H₂-List*.
- If $w_i = w'$ and $i = k$, then it responses $\sigma_{i,j} = (C', w_j)$.
- If $w_i = w'$ and $i \neq k$, it aborts the simulation.

Output: \mathcal{A} outputs a forged aggregate signature $\sigma_\Sigma^* = (C^*, w^*)$ on messages $\mathbf{M}^* = (M_1, \dots, M_l)$ under public keys $\mathbf{PK}^* = (PK_1, \dots, PK_l)$ for some l . Without loss of generality, we assume that $PK_1 = PK^*$. \mathcal{B} proceeds as follows:

1. It checks the validity of σ_Σ^* by calling **SyncAS.AggVerify**. Additionally, the forged signature should not be trivial: the challenge public key PK^* must be in \mathbf{PK}^* , and the message M_1 must not be queried by \mathcal{A} to the signature query oracle.
2. If $w^* \neq w'$, then it aborts the simulation since it fails to guess the forged time period.

3. For each $2 \leq i \leq l$, it retrieves the private key $SK_i = x_i$ of PK_i from $KeyList$ and sets $h_{i,*} = H_2(M_i || w^*)$. Next, it computes

$$A = A^*, B = B^*, C = C^* \cdot \left((A^*)^{\sum_{i=2}^l x_i} (B^*)^{\sum_{i=2}^l x_i h_{i,*}} \right)^{-1}.$$

4. If $H_2(M_1 || w^*) = h'$, then it also aborts the simulation.
5. It outputs $\sigma^* = (A, B, C)$ on a message $h_{1,*}$ as a non-trivial forgery of the CL signature scheme since $h_{1,*} \neq h'$ where $h_{1,*} = H_2(M_1 || w^*)$.

To finish the proof, we first show that the distribution of the simulation is correct. It is obvious that the public parameters and the public key are correctly distributed. The distribution of the signatures is also correct. Next, we show that the resulting signature $\sigma^* = (A, B, C)$ of the simulator is a valid signature for the CL signature scheme on the message $h_{1,*} \neq h'$ under the public key PK^* since it satisfies the following equation:

$$\begin{aligned} e(C, g) &= e\left(C^* \cdot \left((A^*)^{\sum_{i=2}^l x_i} (B^*)^{\sum_{i=2}^l x_i H_2(M_i || w^*)} \right)^{-1}, g\right) \\ &= e\left((A^*)^{\sum_{i=1}^l x_i} (B^*)^{\sum_{i=1}^l x_i h_{i,*}} \cdot (A^*)^{-\sum_{i=2}^l x_i} (B^*)^{-\sum_{i=2}^l x_i h_{i,*}}, g\right) \\ &= e\left((A^*)^{x_1} (B^*)^{x_1 h_{1,*}}, g\right) = e(A^*, g^{x_1}) \cdot e(B^*, g^{x_1 h_{1,*}}) \\ &= e(A', X) \cdot e(B', X^{h_{1,*}}). \end{aligned}$$

We now analyze the success probability of the simulator \mathcal{B} . At first, \mathcal{B} succeeds the simulation if he does not abort in the simulation of signature queries and he correctly guesses the time period w^* such that $w^* = w'$ in the forged aggregate signature from the adversary \mathcal{A} . \mathcal{B} aborts the simulation of signature queries if the time period w' is given from \mathcal{A} and he incorrectly guessed the index k since he cannot generate a signature. Thus \mathcal{B} succeeds the simulation of signature queries at least $1/q_{H_2}$ probability since the outputs of H_2 are independently random. Next, \mathcal{B} can correctly guess the time period w^* of the forged aggregate signature with at least $1/q_{H_1}$ probability since he randomly chooses a random w' . Note that the probability $H_2(M_2 || w^*) = h'$ is negligible. Therefore, the success probability of \mathcal{B} is at least $1/q_{H_1} q_{H_2} \cdot Adv_{\mathcal{A}}^{SyncAS}$ where $Adv_{\mathcal{A}}^{SyncAS}$ is the success probability of \mathcal{A} . This completes our proof. \square

4.4 Discussions

Efficiency. The public key of our SyncAS scheme consists of just one group element since our SyncAS scheme is derived from the SeqAS scheme of the previous section, and the synchronized aggregate signature consists of one group element and one integer since anyone can compute A, B using the hash functions. The signing algorithm requires two group hash operations and two exponentiations, and the aggregate verification algorithm requires two group hash operations, three pairing operations, and l exponentiations where l is the number of signers in the aggregate signature. Our SyncAS scheme provides the shortest aggregate signature size compared to the previous SyncAS schemes [19, 1] since the aggregate signature of previous SyncAS schemes consists of two group elements and one integer. Additionally the signing and verification algorithms of our scheme are efficient compared to the previous SyncAS schemes.

Asymmetric Bilinear Groups. To reduce the size of aggregate signatures, we can use asymmetric bilinear groups instead of symmetric bilinear groups. The SyncAS scheme in asymmetric bilinear

groups is described as follows: the public parameters is $PP = (p, \mathbb{G}, \hat{\mathbb{G}}, \mathbb{G}_T, e, g, \hat{g}, H_1, H_2)$, the private key and the public key are $SK = x$ and $PK = \hat{X}$ respectively, the individual signature is $\sigma = (C = H_1(0||w)^x H_1(1||w)^{xH_2(M||w)}, w)$, and the aggregate signature is $\sigma_\Sigma = (C = H_1(0||w)^{\sum x_i} H_1(1||w)^{\sum x_i H_2(M_i||w_i)}, w)$. For instance, if we instantiate the asymmetric bilinear groups using the 175-bit MNT curve with embedding degree 6 to guarantee 80-bit security level, the size of aggregate signature is 207 bit since the size of a time period can be 32 bit.

Combined (Multi-Modal) Aggregate Signature. We can construct a combined aggregate signature scheme that supports sequential aggregation and synchronized aggregation at the same time by combining our SeqAS scheme and our SyncAS scheme since the private key and the public key of our two schemes are the same. In the combined aggregate signature scheme, the public parameters is $PP = (p, \mathbb{G}, \mathbb{G}_T, e, g, Y, H_1, H_2)$, the private key and the public key are $SK = x$ and $PK = X$ respectively. A signer with a private key can generate a sequential aggregate signature or a synchronized aggregate signature. The security model of the combined aggregate signatures can be defined by combining the security models of SeqAS schemes and SyncAS schemes. In this security model, the adversary is given sequential aggregate signatures and synchronized aggregate signatures, and it finally outputs a forged (sequential or synchronized) aggregate signature. The security proof of the combined aggregate signature scheme easily follows from the security proof of SeqAS schemes and the security proof of SyncAS schemes since the simulator’s simulations of SeqAS signatures and SyncAS signatures can be done without interference.

Public-Key Signature. We can also derive another PKS scheme from our SyncAS scheme. The derived PKS scheme has a restriction such that a signer should use a random value w that was not used before. This derived PKS scheme is the same as the CL* signature scheme that was proposed by Camenisch et al. [15]. The CL* signature scheme supports batch verification that enables a verifier to quickly check the validity of many signatures on different messages and different signers. Compared to the CL signature scheme, the signature of the CL* signature scheme consists of one group element and one integer instead of three group elements, and the signature verification algorithm of the CL* signature scheme just requires two pairing operations instead of five pairing operations.

Removing Random Oracles. If the number of messages is restricted to be polynomial, then Camenisch et al. showed that random oracles can be removed in the CL* signature scheme by using the universal one-way hash function of Canetti et al. [17, 15]. We also can use the universal one-way hash function in our SyncAS scheme if the number of messages is restricted to be polynomial. However, the SeqAS scheme using the universal one-way hash function of Canetti et al. is inefficient since it requires large number of exponentiations.

5 Conclusion

In this paper we concentrated on the notion of aggregate signatures which applications are in reducing space of signatures for large repositories (such as in the legal, financial, and infrastructure areas). We proposed a new sequential aggregate signature scheme and a new synchronized aggregate signature scheme using a newly devised “public key sharing” technique, and we proved their security under the LRSW assumption. Our two aggregate signature schemes in this paper sufficiently satisfy the efficiency properties of aggregate signatures such that the size of public keys should be short, the size of aggregate signatures should be short, and the aggregate verification should be efficient.

An interesting problem is to prove the security of our schemes under static assumptions instead of

the interactive LRSW assumption. Recently, Gerbush et al. proposed a modified CL signature scheme in composite order bilinear groups and proved its security under static assumptions [20]. One may consider to use the modified CL signature scheme of Gerbush et al. for aggregate signature schemes, but it is not easy to apply our techniques to the modified CL signature scheme in composite order bilinear groups.
