# The Double-Hash Transform: From Identification to (Double-Authentication-Preventing) Signatures, Tightly 

Mihir Bellare ${ }^{1} \quad$ Douglas Stebila ${ }^{2}$

December 2015

#### Abstract

We give a new method to turn identification schemes into signature schemes with two advantages over the Fiat-Shamir transform: (1) Security is proven with tight reductions to standard assumptions, and (2) We obtain not just ordinary signatures, but ones with extra properties, specifically double-authentication prevention. The method consists of defining a new goal for identification called security against constrained impersonation that, unlike standard goals, can be shown via tight reductions from standard assumptions, and then using a double-hashing transform to turn identification schemes that meet this notion, and have an additional syntactic property we call being trapdoor, into double-authentication-preventing signature (DAPS) schemes, again with a tight reduction. Our implementations, using OpenSSL's crypto library on an Intel Core i7, show that our DAPS schemes are not only significantly more efficient than prior ones, but competitive with in-use signature schemes that lack the double authentication preventing property. DAPS are of potential interest in deterring mass surveillance.

## 1 Introduction

Identification-based signatures are attractive because they are efficient. This paper offers a new way to obtain them that (1) Unlike the Fiat-Shamir transform, has a tight reduction to standard underlying algebraic problems, so that security is justified for smaller parameter sizes, thereby increasing speed, and (2) Yields not just ordinary signatures but ones with extra properties. The key is to rely on a new, weak notion of security of identification against constrained impersonation that is established with a tight reduction.
Background. By an identification scheme we mean a three-move Sigma protocol ${ }^{1}$ in which the prover sends a commitment $Y$ computed using private randomness $y$, the verifier sends a random challenge $c$, the prover returns a response $z$ computed using $y$ and its secret key isk, and the verifier computes a boolean decision from the conversation transcript $Y\|c\| z$ and public key ivk (see Fig. 3). The most basic goal is security against impersonation under passive attack (imp) which requires that an adversary given transcripts of honest protocol executions still fails to make the honest verifier accept in an interaction where it plays the role of the prover, itself picking $Y$ any way it likes, receiving a random $c$, and then producing $z$. Imp-security can be established by reduction to the hardness of the algebraic problem underlying the identification scheme (eg. one-wayness of RSA for GQ [17], factoring for FS [14], discrete log for Schnorr [26], ...). However a given imp adversary with advantage $\epsilon_{\text {imp }}$ must be twice successful in order to extract the secret key, so, via the reset lemma of $[6], \epsilon_{\mathrm{imp}} \approx \sqrt{\epsilon_{\text {alg }}}$ where $\epsilon_{\text {alg }}$ is the advantage in breaking the algebraic problem, meaning the reduction is very loose.

The Fiat-Shamir transform [14] derives from an identification scheme the signature scheme in which a signature of a message $m$ is a pair $(Y, z)$ such that the transcript $Y\|c\| z$ is accepting for $c=\mathrm{H}(Y \| m)$. AABN [1] reduce security of the signature scheme to the imp security of the identification scheme, with the hash function H modeled as a random oracle [7]. A $q$-query forger will have advantage $\epsilon_{\mathrm{sig}} \approx q \epsilon_{\mathrm{imp}}$ against the signature scheme, which, combined with the above, means $\epsilon_{\text {sig }} \approx q \sqrt{\epsilon_{\text {alg }}}$. There are thus two sources of loss in the reduction, namely the square-root and the factor of $q$. We aim to do away with both. Our approach relies crucially on some (new) definitions.

Constrained impersonation. We return to the identification scheme and provide an alternative definition of security. We continue, as with imp, to allow a passive attack in which the adversary against the identification scheme can obtain transcripts $Y_{1}\left\|c_{1}\right\| z_{1}, Y_{2}\left\|c_{2}\right\| z_{2} \ldots$ of interactions between the honest prover and verifier. Recall that in imp, this is followed by letting the adversary play the role of cheating prover, where it can send a commitment $Y$ of its choice to the verifier, and succeeds if it finds a correct response to the random challenge it receives. In constrained impersonation (cimp), there are two changes. First, the adversary may not select its own $Y$. It must use (is constrained to use) a commitment from one of the transcripts it received in its passive attack. Second, it is allowed multiple impersonation attempts. Each one consists of pointing at some transcript $i$, receiving a (fresh) random challenge $c$, and then, providing a response $z$, with success meaning that the transcript $Y_{i}\|c\| z$ is accepting for at least one of the impersonation attempts. ${ }^{2}$

Relations between cimp, imp and the algebraic problem alg are depicted in Fig. 1. (Ignore kr for now.) A dotted line is a loose reduction and a full line is a tight reduction. We see that the

[^1]

| Transform | Signature | Where ID.Vf $(i v k, Y\\|c\\| z)$ and | ID security | Reduction |
| :---: | :---: | :---: | :---: | :---: |
| FS | $(Y, z)$ | $c=\mathrm{H}(Y \\| m)$ | imp | loose |
| Swap | $(c, z)$ | $Y=\mathrm{H}(c \\| m)$ | N/A | tight |
| H2 | $(z, s)$ | $Y=\mathrm{H}_{1}(m), \quad c=\mathrm{H}_{2}(m \\| s)$ | cimp | tight |

| Transform | DAPS | Where ID.Vf $($ ivk,$Y\\|c\\| z)$ and | ID security | Reduction |
| :---: | :---: | :---: | :---: | :---: |
| $\mathbf{H 2}{ }_{+}$ | $(z, s)$ | $Y=\mathrm{H}_{1}(a), \quad c=\mathrm{H}_{2}(a\\|p\\| s)$ | cimp, kr | tight |

Figure 1: Top: Relations between notions of security for an identification scheme ID. Dotted lines denote loose reductions and full lines denote tight reductions. Middle: Transforms of identification schemes into signature schemes. A signature as shown in the 2nd column defines an accepting transcript $Y\|c\| z$ with quantities as determined in the third column where $\mathrm{H}, \mathrm{H}_{1}, \mathrm{H}_{2}$ are random oracles and where $s$ for $\mathbf{H} \mathbf{2}$ is a randomly-chosen seed. The 4th column shows the assumption made on the identification scheme to prove security of the signature scheme. The last column indicates tightness of the signature reduction all the way down to the underlying algebraic assumption. The Swap and H2 transforms require the identification scheme to be trapdoor. Bottom: Our transform generalized to yield DAPS rather than ordinary signatures.
reduction from the algebraic problem to cimp, unlike the one to imp, is tight. Imp does imply cimp, but there is a factor of loss equal to the number of impersonation attempts, so this reduction is loose. Besides being tight, the reduction of cimp to the algebraic problem has the advantage of being easy and direct to establish. Theorems 4 and 5 detail instances of it, showing smaller terms we have omitted in this discussion.

Now the question we pose is, can we take advantage of this by devising a transform of identification into signatures that relies only on the cimp security of the identification? Furthermore, we must ensure that our transform itself incurs no losses, meaning security of the signature reduces tightly to cimp. If so, we would get signatures tightly from the algebraic problem. Our H2 transform does this. First we need another definition.

Trapdoor identification. Recall that in an identification scheme, the prover uses private randomness $y$ to generate its commitment $Y$. The $\mathbf{H} 2$ transform will not work with an arbitrary identification scheme. It requires the latter to be trapdoor. This means the prover can pick the commitment $Y$ directly at random from the space of commitments and then compute the associated private randomness $y$ using its secret key via a prescribed algorithm. A formal definition is in Section 3.

Many existing identification schemes will meet our definition of being trapdoor modulo possibly some changes to the key structure. Thus the GQ-ID of [17] is trapdoor if we add the decryption
exponent $d$ to the secret key. With similar changes to the keys, the Fiat-Shamir [14] and OngSchnorr [22] identification schemes are trapdoor. The MR-ID factoring-based identification scheme of [20] is trivially trapdoor. We also define and work with a trapdoor identification scheme CF-ID based on claw-free permutations that generalizes MR-ID. But not all identification schemes are trapdoor. A prominent one that is not is Schnorr's (discrete-log based) scheme [26].
Basic double-hash transform H2. The construction and its attributes are summarized in the 3rd row of the first table in Fig. 1. The signer specifies the commitment as a hash $Y=\mathrm{H}_{1}(\mathrm{~m})$ of the message under a hash function $\mathrm{H}_{1}$. Then it picks a random seed $s$, of some seed length s associated to the scheme, and obtains a challenge $c=\mathrm{H}_{2}(m \| s)$ by hashing the message and seed under another hash function $\mathrm{H}_{2}$. Using the trapdoor property of the identification scheme and the secret key, it computes a response $z$, returning $(z, s)$ as the signature. Verification consists of checking that the transcript $Y\|c\| z$ is accepting with $Y, c$ specified as above. Theorem 1 shows unforgeability with a tight reduction to the cimp security of the identification scheme, meaning $\epsilon_{\text {sig }} \approx \epsilon_{\text {cimp }}$. This, by the above fact that cimp is itself obtained tightly from the algebraic problem, results in a tight reduction of unforgeability to the latter, meaning $\epsilon_{\text {sig }} \approx \epsilon_{\text {alg }}$.

We stress that the algebraic assumptions we use are the same standard and classical ones used historically to show imp of the identification scheme and security of the FS-derived signature scheme. For example, when the base identification scheme is GQ-ID, the assumption is one-wayness of RSA. When it is the Fiat-Shamir or MR-ID, it is factoring, and so on.
DAPS. Double-authentication-preventing signature (DAPS) schemes were introduced by Poettering and Stebila (PS) [23]. In such a signature scheme, the message being signed is a pair $m=(a, p)$ consisting of an "address" $a$ and a "payload" $p$. Let us say that messages ( $a_{0}, p_{0}$ ), ( $a_{1}, p_{1}$ ) are colliding if $a_{0}=a_{1}$ but $p_{0} \neq p_{1}$. The double-authentication prevention requirement is that there is an efficient extraction algorithm that given a public key $P K$ and valid signatures $\sigma_{0}, \sigma_{1}$ on colliding messages $\left(a, p_{0}\right),\left(a, p_{1}\right)$, respectively, returns the secret signing key $S K$ underlying $P K$. Additonally, the scheme must satisfy standard unforgeability under a chosen-message attack [16], but in light of the first property we must make the restriction that the address components of all messages signed in the attack are different.

Why DAPS? PS [23] discuss several potential applications. For completeness, let us briefly recall one. The Snowden revelations have shown that the NSA may coerce corporations into measures that compromise security. PS [23] consider, in this light, the subversion of certificate authorities (CAs) and the use of DAPS as a deterrent. Thus, suppose example.com has a (legitimate) certificate cert $_{1}=$ (example.com, $p k_{1}, \sigma_{1}$ ) from a particular CA such as Comodo, where $p k_{1}$ is the public key of example.com and $\sigma_{1}$ is the CA's signature on the pair (example.com, $p k_{1}$ ), computed under the secret key $S K$ of the CA. Big brother induces the CA to issue another certificate cert $_{0}=$ (example.com, $p k_{0}, \sigma_{0}$ ) in the name of example.com where $p k_{0}$ is a public key supplied by big brother, so that it knows the corresponding secret key $s k_{0}$, and $\sigma_{0}$ is the CA's signature on the pair (example.com, $p k_{0}$ ), again computed under the secret key $S K$ of the CA. With this rogue certificate in hand, big brother could impersonate example.com in a TLS session with a client, compromising security of the latter. But if the CAs signatures are produced with a DAPS, then $\sigma_{1}, \sigma_{2}$ are valid signatures on the colliding messages (example.com, $p k_{0}$ ), (example.com, $p k_{1}$ ), respectively, which means that anyone can extract the CA's signing key SK. This would lead to public loss of reputation and business for the CA, increasing the CA's incentive, or giving it an argument, to not comply with big brother's request to create the rogue certificate.
Prior schemes. PS [23] give a factoring-based DAPS that we call PS-DAPS. Its signature contains $n+1$ elements in the group $\mathbb{Z}_{N}^{*}$, where $n$ is the length of a hash of the address and $N$ is
the modulus in the public key. Specifically, for 80 -bit security (1024-bit modulus, 160 -bit hash), a signature contains 161 group elements, for a length of 164,864 bits or about 20 Kbytes. This is a factor 161 times longer than a 1024 bit RSA PKCS\#1 signature, more than enough to preclude use of the scheme in practice. Furthermore, signing and verifying times are significantly greater than for signature schemes currently used for certificates such as RSA PKCS\#1 (cf. Fig. 17.)

If we want DAPS to be a viable practical option, we need DAPS schemes that are competitive with current non-DAPS schemes on all cost parameters, meaning signature size, key size, signing time and verifying time. This is what we deliver. We will show that H2 naturally and easily extends to obtain DAPS schemes that are secure and efficient.
Extended double-hash transform $\mathbf{H} 2_{+}$. We obtain a DAPS from a trapdoor identification scheme via $\mathbf{H} 2_{+}$as summarized in the last table in Fig. 1. The signer specifies the commitment as a hash $Y=\mathrm{H}_{1}(a)$ of the address, picks a random seed $s$ of length sl, obtains a challenge $c=\mathrm{H}_{2}(a\|p\| s)$, uses the trapdoor property of the identification scheme and the secret key to compute a response $z$, and returns $(z, s)$ as the signature. Additionally the public key is enhanced so that recovery of the secret identification key allows recovery of the full DAPS secret key (cf. Fig. 10). Theorem 2 establishes the double-authentication prevention property via the extractability property of the identification Sigma protocol. For unforgeability we need to consider the additionally property kr that the identification scheme is secure against recovery of the secret key under passive attack. As Fig. 1 and Theorems 4,5 indicate, however, this is also easily and tightly established under the algebraic problem. Theorem 3 shows unforgeability with a tight reduction to the cimp +kr security of the identification scheme, meaning $\epsilon_{\mathrm{sig}} \approx \epsilon_{\mathrm{cimp}}+\epsilon_{\mathrm{kr}}$. This results in a tight reduction of unforgeability of the DAPS to the algebraic problem, meaning $\epsilon_{\mathrm{sig}} \approx 2 \epsilon_{\text {alg }}$.
GQ-DAPS. As an example, applying our extended $\mathbf{H} 2_{+}$transform to the GQ identification scheme results in the following GQ-DAPS scheme. The public key is ( $N, e, X, T K$ ) and the secret key is $(x, d)$ where $N=p q$ is an RSA modulus, $e$ is an encryption exponent, $d$ is the corresponding decryption exponent, $x, X \in \mathbb{Z}_{N}^{*}$ satisfy $X=x^{e} \bmod N$, and $T K=\mathrm{H}_{3}(x) \oplus d$. The keys are thus as in the GQ identification scheme [17] except that we add $d$ to the secret key and $T K$ to the public key. To sign message $(a, p)$, pick a random sl-bit $s$-the seed length sl is a parameter of the scheme - let $Y=\mathrm{H}_{1}(a)$-the commitment is not picked at random but determined uniquely by the addresslet $y=Y^{d} \bmod N$, let $c=\mathrm{H}_{2}(a\|p\| s) \in\{0,1\}^{l}$ - the challenge - let $z=y x^{c} \bmod N$ and return $(z, s)$ as the signature. We omit describing verification; see Fig. 15 for a full description of the scheme. Given valid signatures $\left(z_{0}, p_{0}\right),\left(z_{1}, p_{1}\right)$ on colliding messages $\left(a, p_{0}\right),\left(a, p_{1}\right)$, respectively, one has GQ [17] conversation transcripts with the same commitment and different challenges - this is why we set the commitment to a hash of the address - and can use the GQ-ID Sigma protocol extractability property to extract $x$. This is not quite enough for double-authentication-prevention because we must also extract $d$. It was for this that $T K$ was put in the public key: from $x$ we can recover $d=\mathrm{H}_{3}(x) \oplus T K$. We prove unforgeability tightly under one-wayness of RSA, and efficiency is again good on all fronts (cf. Fig. 17). Many other DAPS can be similarly obtained.

Implementation. In theoretical cryptography, "efficient" often just means "polynomial time," which is quite divorced from efficiency in practice. Some works measure "efficiency" by counting modular exponentiations or hash operations. Even these estimates can, in our experience, be moot. Implementation is key to gauge and show efficiency. We implement GQ-DAPS, MR-DAPS and the prior PS-DAPS using OpenSSL's BIGNUM library on an Intel Core i7 machine for both 1024-bit and 2048-bit modulii. (The latter is what commercial CA's currently use.) Fig. 17 shows the signing time, verifying time, signature size and key sizes for all schemes. GQ-DAPS, MR-DAPS emerge as around 150 times faster than PS-DAPS for signing and verifying while also having signatures
about 140 times shorter. In fact the Figure shows that GQ-DAPS, MR-DAPS are close to RSA PKCS \#1v1.5 in all parameters and runtimes. This means that DAPS can replace the signatures currently used for certificates with minimal loss in performance.
Necessity of our assumption. Trapdoor identification schemes may seem a very particular assumption from which to obtain DAPS. However we show in Section 8 that from any DAPS satisfying double-authentication-prevention and unforgeability, one can build a trapdoor identification scheme that is mimp-secure and satisfies the Sigma protocol extractability property. This shows that the assumption we make is effectively necessary for DAPS.

Applicability of DAPS. As a reader may justifiably point out, various issues must be addressed for PS's application of DAPS to the deterrence of certificate subversion, that we sketched above, to be a full solution. For example, there may be legitimate reasons for a CA to issue a new certificate in the name of example.com (the old one may have expired or been revoked) which at first glance is precluded by DAPS. Or, big brother might approach a different CA. (Indeed, the DAPS idea is inherently restricted to a single CA environment.) There are various answers to these questions which in particular are discussed to some extent by PS [23]. One might also ask why a CA would want, or agree, to use DAPS. Recently, we have seen Internet corporations taking steps to make subversion harder. Google's push for end-to-end encryption following the Snowden revelations is one instance. In another, Apple "reworked its encryption in a way that prevents the company ... from getting access to the ... user data stored on smartphones and tablet computers" [27]. A CA might similarly see espousing DAPS. We will not however attempt to address application issues in full here. Our motivation for this work has been theoretical interest (we find the primitive and problem technically intriguing) and the perspective that efficient, secure schemes are a necessary, even if not sufficient, condition for application. Whether DAPS as a concept has true practical utility remains to be seen, but, if it does, our schemes are better choices than prior ones.
Swap. Micali and Reyzin [20] give a signature scheme with a tight reduction to factoring. It is obtained from their MR-ID identification scheme via a method they call "swap." ABN [2] say that the method generalizes to other factoring-based schemes. However, "swap" has never been stated as a general transform of an identification scheme into a signature scheme; it appears rather as an ad hoc technique to go directly and tightly from the algebraic problem to the signature. This lack of abstraction is perhaps due in part to a lack of definitions, and our notion of a trapdoor identification scheme allows us to partially fill the gap. We claim -formalizing discussion in ABN [2]- that this is the syntactic condition allowing swap to operate. The 2 nd row of the first table of Fig. 1 summarizes what we now call the Swap transform to turn a trapdoor identification scheme into a signature scheme. However, it continues to be that security is reduced directly to the algebraic problem rather than to a goal of the identification scheme, explaining the "N/A" entry in the table.

How do Swap and H2 compare? They apply to the same class of identification schemes (trapdoor) and both result in tight reductions of the signature to the underlying algebraic problem. However, H2 answers what we believe is the compelling question we posed above, namely to obtain a signature scheme whose security reduces tightly to the cimp security of an underlying identification scheme, motivated by the fact that this notion, unlike classical imp, is easily and tightly established in turn under the algebraic assumption. Swap does not do this: cimp security of the identification scheme demonstrably does not suffice to establish security of Swap signatures. The other difference is that, unlike either the FS or the Swap transforms, H2 extends easily to yield DAPS, and we obtain thereby the most efficient such signatures to date, as discussed above.
Further related work and open questions. ABP [2] show a tight reduction of FS-derived GQ signatures to the $\Phi$-hiding assumption of [10]. In contrast, both H2-derived and Swap-derived

GQ signatures have a tight reduction to the standard one-wayness of RSA. AFLT [3] use a slight variant of the Fiat-Shamir transform to turn lossy identification schemes into signature schemes with security based tightly on key indistinguishability, resulting in signature schemes with tight reductions to the decisional short discrete logarithm problem, the shortest vector problem in ideal lattices and subset sum.

The first proofs of unforgeability for FS-derived signatures [24] were direct, meaning they reduced security of the signature scheme directly to the hardness of the algebraic problem underlying the identification scheme. This was done using forking lemmas [24, 5, 4]. Indirect proofs begin with $[21,1]$. As indicated above, AABN [1] reduce security of the signature scheme to the imp security of the identification scheme. However, both the direct and the indirect approach result in reductions of the same looseness we discussed above. The advantage of working with cimp and H2 as opposed to imp and FS is to remove this looseness while retaining the modular structure of the AABN approach. The benefits of the latter are that the identification schemes can be analyzed separately, and the use of random oracles is confined to the transform.

Both our DAPS and that of PS [23] are proven in the random oracle model. This raises the foundational question of what are the minimal assumptions under which DAPS can be built in the standard model. Ordinary signatures are possible from any one-way function [25]. Is it possible to obtain DAPS from any one-way function? Or, can one give some evidence that this will not be true, for example by showing that DAPS implies a primitive like secret-key exchange that is not likely to be possible based on one-way functions [18]?

The DAPS property that the secret key is recoverable from signatures of colliding messages is conceptually similar to the recoverability of the spender's identity from double-spending of an e-coin in offline e-cash [11]. Whether this connection can be exploited to obtain new DAPS schemes is an interesting open question.

## 2 Notation and some standard definitions

Notation. We let $\varepsilon$ denote the empty string. If $X$ is a finite set, we let $x \leftarrow \$ X$ denote picking an element of $X$ uniformly at random and assigning it to $x$. Algorithms may be randomized unless otherwise indicated. Running time is worst case. If $A$ is an algorithm, we let $y \leftarrow A\left(x_{1}, \ldots ; r\right)$ denote running $A$ with random coins $r$ on inputs $x_{1}, \ldots$ and assigning the output to $y$. We let $y \leftarrow A\left(x_{1}, \ldots\right)$ be the result of picking $r$ at random and letting $y \leftarrow A\left(x_{1}, \ldots ; r\right)$. We let $\left[A\left(x_{1}, \ldots\right)\right]$ denote the set of all possible outputs of $A$ when invoked with inputs $x_{1}, \ldots$. We use the code based game playing framework of [8]. (See Fig. 2 for an example.) By $\operatorname{Pr}[G]$ we denote the event that the execution of game $G$ results in the game returning true. We also adopt the convention that the running time of an adversary refers to the worst case execution time of the game with the adversary. This means that the time taken for oracles to compute replies to queries is included.

We expand on our notation and treatment of random oracles in these games since it is a bit unusual. In our constructions, we will need random oracles with different ranges. For example we may want one random oracle returning points in a group $\mathbb{Z}_{N}^{*}$ and another returning strings of some length $k$. To provide a single unified definition, we have the procedure H in the games take not just the input $x$ but a description Rng of the set from which outputs are to be drawn at random. Thus $y \leftarrow \mathrm{H}\left(x, \mathbb{Z}_{N}^{*}\right)$ will return a random element of $\mathbb{Z}_{N}^{*}$, and so on. If $\mathrm{Rng}_{1}, \mathrm{Rng}_{2}$ are different sets then $\mathrm{H}\left(\cdot, \mathrm{Rng}_{1}\right)$ and $\mathrm{H}\left(\cdot, \mathrm{Rng}_{2}\right)$ are independent random oracles with the indicated range sets.
Signatures. In a signature scheme DS, the signer generates signing key sk and verifying key vk via $(v k, s k) \leftarrow \Phi D S . \mathrm{Kg}^{\mathrm{H}}$ where H is the random oracle, with syntax is as discussed above. Now it can compute a signature $\sigma \leftarrow \mathrm{DS} . \mathrm{Sig}^{\mathrm{H}}(\mathrm{vk}, \mathrm{sk}, \mathrm{m})$ on any message $m \in\{0,1\}^{*}$. A verifier can

| Game $\mathrm{UF}_{\text {DS }}^{\mathcal{A}}$ | $\underline{\operatorname{Sign}(m)}$ |
| :---: | :---: |
| $\begin{aligned} & (v k, s k) \leftarrow \mathrm{DS} . \mathrm{Kg}^{\mathrm{H}} ; M \leftarrow \emptyset \\ & (m, \sigma) \leftarrow \mathcal{A}^{\text {SIGN,H}}(v k) \end{aligned}$ | $\overline{M \leftarrow M} \cup\{m\} ; \sigma \leftarrow \& \mathrm{DS}^{\mathrm{Sig}}{ }^{\mathrm{H}}(v k, s k, m)$ <br> Return $\sigma$ |
| Return $\left(\mathrm{DS} . \mathrm{Vf}^{\mathrm{H}}(v k, m, \sigma) \wedge(m \notin M)\right)$ | $\begin{aligned} & \frac{\mathrm{H}(x, \mathrm{Rng})}{\text { If not } \mathrm{HT}[x, \mathrm{Rng}] \text { then } \mathrm{HT}[x, \mathrm{Rng}] \leftarrow \& \mathrm{Rng}} \\ & \text { Return HT }[x, \mathrm{Rng}] \end{aligned}$ |

Figure 2: Game defining unforgeability of signature scheme DS.
deterministically compute a boolean $v \leftarrow \mathrm{DS} . \mathrm{Vf}{ }^{\mathrm{H}}(v k, m, \sigma)$ indicating whether or not $\sigma$ is a valid signature of $m$ relative to $v k$. Correctness as usual requires that $\operatorname{DS} . V f^{H}\left(v k, m, D S . S i g{ }^{H}(v k, s k\right.$, $m))=$ true with probability one. Unforgeability is measured via the advantage $\operatorname{Adv}_{\mathrm{DS}}^{\mathrm{uf}}(\mathcal{A})=$ $\operatorname{Pr}\left[\mathrm{UF}_{\mathrm{DS}}^{\mathcal{A}}\right]$ of adversary $\mathcal{A}$, where game $\mathrm{UF}_{\mathrm{DS}}^{\mathcal{A}}$ is in Fig. 2. This is the classical notion of [16], lifted to the ROM as per [7].

## 3 Cimp-secure Identification

We define security of identification schemes against constrained impersonation. Later we will show how any trapdoor identification scheme with this property can be transformed into a DAPS with a tight reduction.
Identification. An identification (ID) scheme ID operates as depicted in Fig. 3. First, via (isk, ivk, $t k$ ) $\leftarrow$ ID. Kg , the prover generates a private identification key isk, public verification key ivk and auxiliary information $t k$. Via $(Y, y) \leftarrow$ ID.Cmt $(i v k)$ it generates commitment $Y$ and corresponding private state $y$. The verifier sends a random challenge of length ID.cl. The prover's response $z$ and the verifier's boolean decision $v$ are deterministically computed. An example is the GQ scheme of Fig. 15. We require the obvious correctness condition. We also require the Sigma Protocol [12] extractability condition, which says there is an algorithm ID.Ex such that if $Y_{1}\left\|c_{1}\right\| z_{1}, Y_{2}\left\|c_{2}\right\| z_{2}$ are accepting transcripts under ivk with $Y_{1}=Y_{2}$ but $c_{1} \neq c_{2}$ then ID.Ex given ivk and the transcripts returns isk. Formally we ask that $\operatorname{Pr}\left[\mathrm{EX}_{\mathrm{iD}}^{\mathcal{A}}\right]=0$ for all adversaries $\mathcal{A}$, where the game is in Fig. 3. Finally we require a key-verification algorithm ID.KVf such that $\operatorname{ID} . \operatorname{KVf}(i v k, i s k)=$ true if $(i s k, i v k, t k) \in[I D . K g]$ for some $t k$, and false otherwise.

The auxiliary information $t k$ is not used in a basic ID scheme. We use it when we say what it means for the scheme to be trapdoor. Namely there is an algorithm ID.Cmt ${ }^{-1}$ that produces $y$ from $Y$ with the aid of the trapdoor tk. Formally, the outputs of the following two processes are identically distributed. Both processes generate (isk, ivk, $t k$ ) $\leftarrow \&$ ID. Kg . The first process then lets $(Y, y) \leftarrow \&$ ID.Cmt $(i v k)$. The second process picks $Y \leftarrow \&$ ID.CmtSp $(i v k)$ and lets $y \leftarrow \&$ ID.Cmt ${ }^{-1}$ (ivk, $t k, Y$ ). Both processes return (isk, ivk, $t k, Y, y$ ). Here ID.CmtSp $(i v k)$ is a space of commitments associated to ID. We let ID.tl denote the length of $t k$.
Security of ID schemes. Recall that security of an identification scheme ID under impersonation $[13,1]$ considers an adversary who, given ivk but not isk, first attacks the honest, isk-using prover and then, using the information it gathers, attempts to impersonate the real prover by successfully identifying itself to the verifier. In this impersonation attempt, the adversary, in the role of malicious prover, submits a commitment $Y$ of its choice, receives an honest verifier challenge $c$, submits a response $z$ of its choice, and wins if ID. $\mathrm{Vf}(\mathrm{ivk}, Y \| c z)=$ true. A hierarchy of possible firstphase attacks is defined in [6]. We are interested only in the weakest, namely passive attacks, where the adversary is just an eavesdropper and gets honestly-generated protocol transcripts. (Active and

| Prover |  | Verifier |
| :---: | :---: | :---: |
| Input: ivk, isk |  | Input: ivk |

Figure 4: Games defining security of identification scheme ID against constrained impersonation under passive attack and against key recovery.
even concurrent attacks are relevant in other contexts [6].)
We suggest a new constrained impersonation goal that weakens the classic impersonation goal. We will be in the setting where the adversary has a passive attack, allowing it to obtain transcripts. When it makes its impersonation attempt, it is no longer allowed to choose the commitment. Rather, it is required (constrained) to use a commitment from the transcripts. The formalization considers game cIMP $\mathcal{I N}_{\mathrm{ID}}^{\mathcal{P}}$ of Fig. 4 associated to identification scheme ID and cimp adversary $\mathcal{P}$. The transcript oracle TR returns upon each invocation a transcript of an interaction between the honest prover and verifier, allowing $\mathcal{P}$ to mount its passive attack. Adversary $\mathcal{P}$ can mount an impersonation attempt through its CH and DEC oracles. It would first have to give CH the index $l$ of an existing transcript. It would get back a fresh challenge $c$ and a session $\mathrm{id} j$. To win it would have to call DEC with $j$ and a correct response relative to the commitment from the $l$-th transcript and challenge $c$. Note that unlike the conventional definitions, we allow multiple impersonation attempts, not just one, reflected in the adversary being able to call oracles Ch, DEC as often as it

likes and winning if any attempt is successful. We let $\operatorname{Adv}_{\mathrm{ID}}^{\text {cimp }}(\mathcal{P})=\operatorname{Pr}\left[\operatorname{cIMP}_{\mathrm{ID}}^{\mathcal{P}}\right]$.
A scheme meeting this goal is not necessarily useful for actual identification in practice because in the latter we cannot constrain the adversary to use only existing commitments. However we do not wish to use it directly in this way. We use identification only as a tool. The benefits are (1) it will suffice for our application, but (2) as indicated by Theorems 4 and 5 , it can be achieved with tight reductions to standard assumptions, as opposed to the stronger impersonation goals.

We also define and use the security of the identification scheme against key recovery under passive attack. The formalization considers game $\mathrm{KR}_{\mathrm{ID}}^{\mathcal{D}}$ of Fig. 4 associated to identification scheme ID and kr adversary $\mathcal{P}$. The transcript oracle TR is as before. Adversary $\mathcal{P}$ aims simply to recover isk. We let $\operatorname{Adv}_{\mathrm{ID}}^{\mathrm{kr}}(\mathcal{P})=\operatorname{Pr}\left[\mathrm{KR}_{\mathrm{ID}}^{\mathcal{P}}\right]$ be the probability that it succeeds, where success means recovering the secret key. Again Theorems 4 and 5 show that this form of security is easily proven under standard assumptions with a tight reduction.

## 4 Basic double-hash transform

We specify the basic transform and prove it works.
The construction. Let ID be a trapdoor identification scheme. Our H2 (double hash) transform associates to it and a seed length sl $\in \mathbb{N}$ a signature scheme $\mathrm{DS}=\mathbf{H 2}[\mathrm{ID}$, sll]. The algorithms of DS are defined in Fig. 5. Recall that in the Fiat-Shamir transform [14], the signer picks $(Y, y) \leftarrow s$ ID.Cmt(ivk) as per the ID scheme and commits to these values by hashing $Y$ with the message to create a challenge. We instead specify the commitment $Y$ as a hash of the message alone. However, doing this means that it is not clear how in general to obtain $y$. This is where the trapdoor property comes in, allowing our signer to obtain it as $y \leftarrow \& \mathrm{ID} . \mathrm{Cmt}^{-1}(i v k, t k, Y)$. We then specify the challenge as a randomized hash of the message. (Unlike in the FS transform, the commitment is not hashed along with the message.) The randomization is captured by the seed $s$ whose length sl was a parameter of our transform.

Unforgeability of our construction. The following shows that the unforgeability of our signature tightly reduces to the cimp security of the underlying ID scheme. Recall that as per our conventions, the number of queries by $\mathcal{A}$ to some oracle includes the number made in the game, and similarly the running time of an adversary is the total execution time of the game, the time used by oracles included.
Theorem 1 Let signature scheme $\mathrm{DS}=\mathbf{H} \mathbf{2}[\mathrm{ID}, \mathrm{sl}]$ be obtained from trapdoor identification scheme ID and seed length sl as in Fig. 5. Let $\mathcal{A}$ be a uf-adversary against DS. Suppose the number of

|  | $\sigma \leftarrow(z, s) ;$ Return $\sigma$ |

Figure 6: Games for proof of Theorem 1. Game $G_{1}$ includes the boxed code and game $G_{0}$ does not.
queries that $\mathcal{A}$ makes to its $\mathrm{H}(\cdot, \mathrm{ID} . \operatorname{CmtSp}(i v k)), \mathrm{H}\left(\cdot,\{0,1\}^{\mathrm{ID} . \mathrm{cl}}\right)$, SIGN oracles are, respectively, $q_{2}, q_{3}, q_{s}$, where ivk is as in game $\mathrm{UF}_{\mathrm{DS}}^{\mathcal{A}}$. Then from $\mathcal{A}$ we can construct cimp adversary $\mathcal{P}$ such that

$$
\begin{equation*}
\operatorname{Adv}_{\mathrm{DS}}^{\mathrm{uf}}(\mathcal{A}) \leq \operatorname{Adv}_{\mathrm{ID}}^{\mathrm{cimp}}(\mathcal{P})+\frac{q_{s}\left(2 q_{3}+q_{s}-1\right)}{2^{\text {sl}+1}} \tag{1}
\end{equation*}
$$

Adversary $\mathcal{P}$ make $q_{2}+q_{s}+1$ queries to Tr . It makes $q_{3}$ queries to Ch and one query to Dec. It has running time about that of $\mathcal{A}$.

Proof of of Theorem 1: We assume that $\mathcal{A}$ avoids certain pointless behavior that would only cause it to lose. Thus, we assume it did not query to Sign the message $m$ in the forgery ( $m, \sigma$ ) that it eventually outputs. This means that the set $M$ in game UF $\mathcal{D S}_{\mathrm{DS}}^{\mathcal{A}}$, and the code and checks associated with it, are redundant and can be removed. We will work with this simplified form of the game.

When procedure Sign is replying to signing query $m$, it first computes $Y$ and picks $s$. We would like that, at this point, it can define the table entry $\operatorname{HT}\left[m \| s,\{0,1\}^{\text {ID.cl }}\right]$ without caring whether it was already defined. (This is to allow an eventual impersonation adversary to program this RO response with a challenge emanating from a transcript obtained from the transcript oracle.) In general, of course, this would be wrong, but intuitively the random choice of $s$ means it is usually right. (This indeed is why we have the seed in the scheme.) To show this formally we consider the games $\mathrm{G}_{0}, \mathrm{G}_{1}$ of Fig. 6. Game $\mathrm{G}_{0}$ excludes the boxed code, so that its Sign procedure defines $\mathrm{HT}[\mathrm{m}$ $\left.\| s,\{0,1\}^{\text {ID.cl }}\right]$ only when this entry was not already defined, but game $\mathrm{G}_{1}$ includes the boxed code, so that Sign defines this entry always, as we would like. But these games are identical-until-bad [8], meaning differ only in code that follows the setting of the boolean flag bad to true. So we have

$$
\begin{align*}
\operatorname{Adv}_{\mathrm{DS}}^{\mathrm{uf}}(\mathcal{A})=\operatorname{Pr}\left[\mathrm{G}_{0}\right] & =\operatorname{Pr}\left[\mathrm{G}_{1}\right]+\operatorname{Pr}\left[\mathrm{G}_{0}\right]-\operatorname{Pr}\left[\mathrm{G}_{1}\right] \\
& \leq \operatorname{Pr}\left[\mathrm{G}_{1}\right]+\operatorname{Pr}\left[\mathrm{G}_{0} \text { sets bad }\right], \tag{2}
\end{align*}
$$

where the inequality is by the Fundamental Lemma of Game Playing of [8]. The random choice of $s$ made by procedure Sign ensures

$$
\begin{equation*}
\operatorname{Pr}\left[\mathrm{G}_{0} \text { sets bad }\right] \leq \sum_{i=0}^{q_{s}-1} \frac{q_{3}+i}{2^{\mathrm{sl}}}=\frac{q_{s}\left(2 q_{3}+q_{s}-1\right)}{2^{\mathrm{sl}+1}} \tag{3}
\end{equation*}
$$

Figure 8: Adversary for proof of Theorem 1.

Now we need to bound $\operatorname{Pr}\left[\mathrm{G}_{1}\right]$. Consider game $\mathrm{G}_{2}$ of Fig. 7. Towards using cimp, this game refrains from using isk directly in procedure Sign. Instead, it begins by generating conversation transcripts $Y_{i}\left\|c_{i}\right\| z_{i}$ and has SIGN use these. To make this possible, H( $\left.\cdot, \mathrm{ID} . \mathrm{CmtSp}(\mathrm{ivk})\right)$ values are set to the transcript commitments. Then Sign retrieves the corresponding commitment $Y$, sets $\operatorname{HT}\left[m \| s,\{0,1\}^{\text {ID.cl }}\right]$ to the challenge from the same transcript, and puts the corresponding response in the signature. Since the signatures are correctly distributed we have

$$
\begin{equation*}
\operatorname{Pr}\left[\mathrm{G}_{1}\right]=\operatorname{Pr}\left[\mathrm{G}_{2}\right] . \tag{4}
\end{equation*}
$$

We build cimp adversary $\mathcal{P}$ so that

$$
\begin{equation*}
\operatorname{Pr}\left[\mathrm{G}_{2}\right] \leq \operatorname{Adv}_{\mathrm{ID}}^{\text {cimp }}(\mathcal{P}) . \tag{5}
\end{equation*}
$$

Game $\mathrm{G}_{2}$ was crafted exactly to make the construction of adversary $\mathcal{P}$ quite direct. The construction is described in detail in Fig. 8. Adversary $\mathcal{P}$ has access to oracles Tr, Ch, Dec as per game cIMP ${ }_{\mathrm{ID}}^{\mathcal{P}}$ in which it is executing. It runs $\mathcal{A}$, simulating answers to $\mathcal{A}$ 's queries to Sign and H as shown. It obtains conversation transcripts using its Tr oracle to play the role of the ones generated in

```

Figure 9: Games defining unforgeability and extractability conditions of DAPS DS. The Sign procedure is invoked by game RUF while H is invoked by both games.
$\mathrm{G}_{2}$. Using these, Sign can be simulated as per game $\mathrm{G}_{2}$. Oracle $\mathrm{H}(\cdot, \mathrm{Rng})$ is simulated as in $\mathrm{G}_{2}$ when Rng $=\operatorname{ID} . \operatorname{CmtSp}(i v k)$. When a query $x$ is made to $\mathrm{H}\left(\cdot,\{0,1\}^{\text {ID.cl }}\right)$, adversary $\mathcal{P}$ parses $x$ as $m \| s$. It then retrieves the index $l$ corresponding to $m$ in the list of transcripts and submits this to its challenge oracle CH to get back a session id $j$ and a challenge, and returns this challenge as the response to the oracle query. Finally when $\mathcal{A}$ produces a forgery, the session id corresponding to the message and seed in the forgery is retrieved via Ind $_{3}$. Now this session is completed by querying the response in the forged signature to the decision oracle DEc. We need to show that the impersonation is successful as long as the forgery was valid. A somewhat delicate point is that we use the fact that the message $m$ in the forgery was not a Sign query. This is what ensures that a session corresponding to the forgery conversation exists.

## 5 DAPS definitions

Let DS be a signature scheme. In a DAPS [23], a message $m=(a, p)$ is a pair consisting of an address $a$ and a payload $p$. We require the DAP property and a restricted form of unforgeability.
The DAP property. Let us say that messages $m_{1}=\left(a_{1}, p_{1}\right)$ and $m_{2}=\left(a_{2}, p_{2}\right)$ are colliding if $a_{1}=a_{2}$ but $p_{1} \neq p_{2}$. Double authentication prevention [23] requires that signatures on colliding messages allow anyone to extract the signing key. It is captured formally by the advantage $\operatorname{Adv}_{\mathrm{DS}}^{\text {dap }}(\mathcal{A})=\operatorname{Pr}\left[\mathrm{DAP}_{\mathrm{DS}}^{\mathcal{A}}\right]$ associated to adversary $\mathcal{A}$, where game $\mathrm{DAP}_{\mathrm{DS}}^{\mathcal{A}}$ is in Fig. 9. The adversary produces messages $m_{1}, m_{2}$ and signatures $\sigma_{1}, \sigma_{2}$, and an extraction algorithm DS.Ex ${ }^{\mathrm{H}}$ associated to the scheme then attempts to compute sk. The adversary wins if the key $s k^{*}$ produced
by DS.Ex is different from sk yet extraction should have succeeded, meaning the messages were colliding and their signatures were valid. If $G$ is a game, we are denoting by $\operatorname{Pr}[\mathrm{G}]$ - here and in the rest of the paper - the probability that the game returns true. The argument Rng to the random oracle H allows the caller to specify the set from which responses are drawn in a particular scheme, for example $\mathbb{Z}_{N}^{*}$. The adversary has $s k$ as input to cover the fact that the signer is the one attempting - due to coercion and subversion, but nonetheless - to produce signatures on colliding messages. (And thus it does not need access to a Sign oracle.) We note that we are not saying it is hard to produce signatures on colliding messages - it isn't, given sk - but rather that doing so will reveal sk. We also stress that extraction is not required just for honestly-generated signatures, but for any, even adversarially generated signatures that are valid, again because the signer is the adversary here.
Unforgeability. We also require restricted unforgeability, captured formally by the advantage $\operatorname{Adv}_{\mathrm{DS}}^{\mathrm{ruf}}(\mathcal{A})=\operatorname{Pr}\left[\mathrm{RUF}_{\mathrm{DS}}^{\mathcal{A}}\right]$ associated to adversary $\mathcal{A}$, where game RUF $\mathcal{D S}_{\mathcal{A}}^{\mathcal{A}}$ is in Fig. 9 [23]. This is the classical notion except that addresses of the messages the signer signs must be all different, as captured through the set $A$ in the game. This is necessary because the double authentication prevention requirement precludes security if the signer releases signatures of two messages with the same address. In practice it means that the signer must maintain a log of all messages it has signed and make sure that it does not sign two messages with the same address. A CA is likely to maintain such a log in any case so this is unlikely to be an extra burden.
Discussion. Asking that the key $s k^{*}$ returned by the extractor DS.Ex ${ }^{H}$ be equal to $s k$ may seem unnecessarily strong. It would suffice if $s k^{*}$ was "functionally equivalent" to $s k$, meaning allowed computation of signatures indistinguishable from real ones. Indeed, such a property is formalized in PS [23]. However our schemes achieve the stronger property we have defined, so we adopt it in our definition.

The DAP game chooses the keys $v k, s k$ honestly. Allowing these to be adversarially chosen would result in a stronger requirement, also formalized in PS [23]. Our view is that our requirement is reasonable because the coercion happens after the CA and its keys are established. If the choice of keys is considered a potential source of vulnerability, one might generate them via secure computation between a few different parties.

## 6 The extended double-hash transform

We show how any trapdoor identification scheme can be transformed into a DAPS. We prove both that our DAPS is double authentication preventing and unforgeable. In the next section we will instantiate this general construction to get specific, efficient DAPS.

The construction. Let ID be a trapdoor identification scheme. Our H2 (extended double hash) transform associates to it and a seed length $s l \in \mathbb{N}$ a DAPS DS $=\mathbf{H} 2_{+}[I D$, sl]. The algorithms of DS are defined in Fig. 10. We instead specify the commitment $Y$ as a hash of the address rather than of the full message as in H2. This is done so that messages with the same address result in transcripts with the same commitment, putting us in a position to use the extractability of ID to achieve double authentication prevention. We then specify the challenge $c$ as a randomized hash of the message and seed, as in basic $\mathbf{H} \mathbf{2}_{+}$. The introduction of the trapdoor tk however creates a new difficulty, namely that extraction under the ID scheme will only recover isk and to achieve double authentication prevention we must recover the entire secret key $s k=(i s k, t k)$. We resolve this by putting in the verification key a particular encryption, denoted $T K$, of $t k$, under isk.
DAP-SECURITY of our construction. The following confirms that double authentication pre-

| DS. $\mathrm{Kg}^{\mathrm{H}}$ | DS.Sig ${ }^{\mathrm{H}}(v k, s k, m)$ |
| :---: | :---: |

Figure 10: Our construction of a DAPS DS $=\mathbf{H} 2_{+}[I D, s l]$ from a trapdoor identification scheme ID and a seed length $s l \in \mathbb{N}$.
vention is achieved. This is relatively straightforward given the construction; the bigger challenge will be showing unforgeability. As per out conventions, the number of (distinct) queries $q$ of the adversary to $\mathrm{H}\left(\cdot,\{0,1\}^{\text {ID.cl }}\right)$, referred to below, is, formally, the number of queries made to this oracle in the execution of the game $\mathrm{DAP}_{\mathrm{DS}}^{\mathcal{A}}$, so that queries made not directly by $\mathcal{A}$ but by game procedures are also counted. As a result it will always be the case that $q \geq 2$.

Theorem 2 Let $D A P S$ DS $=\mathbf{H} 2_{+}[I D, s l]$ be obtained from trapdoor identification scheme ID and seed length sl as above. Let $\mathcal{A}$ be an adversary making $q \geq 2$ distinct $\mathrm{H}\left(\cdot,\{0,1\}^{\text {ID.cl }}\right)$ queries. Then $\operatorname{Adv}_{\mathrm{DS}}^{\mathrm{dap}}(\mathcal{A}) \leq q(q-1) / 2^{\text {ID.cl+1 }}$.

Proof of of Theorem 2: Consider the $\mathrm{DAP}_{\mathrm{DS}}^{\mathcal{A}}$ game of Fig. 9. Within this, consider the execution of the algorithm DS.Ex ${ }^{\mathrm{H}}$ of Fig. 10 on $v k, m_{1}, m_{2}, \sigma_{2}, \sigma_{2}$ where $\left(m_{1}, m_{2}, \sigma_{1}, \sigma_{2}\right) \leftarrow \$ \mathcal{A}^{\mathrm{H}}(v k$, sk). Let $Y_{1}\left\|c_{1}\right\| z_{1}, Y_{2}\left\|c_{2}\right\| z_{2}$ be the transcripts computed within. Assume $\sigma_{1}, \sigma_{2}$ are valid signatures of $m_{1}, m_{2}$, respectively, relative to $\mathrm{vk}=(\mathrm{ivk}, T K)$. As per the verification algorithm $\mathrm{DS} . \mathrm{Vf}^{\mathrm{H}}$ of Fig. 10 this means that the transcripts $Y_{1}\left\|c_{1}\right\| z_{1}, Y_{2}\left\|c_{2}\right\| z_{2}$ are valid under the ID scheme, meaning ID. $\operatorname{Vf}\left(\right.$ ivk, $\left.Y_{1}\left\|c_{1}\right\| z_{1}\right)=\operatorname{ID} . \operatorname{Vf}\left(\operatorname{ivk}, Y_{2}\left\|c_{2}\right\| z_{2}\right)=$ true. If the messages $m_{1}=\left(a_{1}, p_{1}\right)$ and $m_{2}=\left(a_{2}, p_{2}\right)$ output by $\mathcal{A}$ are colliding then we also have $Y_{1}=Y_{2}$. This is because verification ensures that $Y_{1}=\mathrm{H}\left(a_{1}\right.$, ID.CmtSp(ivk)) and $Y_{2}=\mathrm{H}\left(a_{2}, \operatorname{ID} \cdot \operatorname{CmtSp}(i v k)\right)$. So if $c_{1} \neq c_{2}$ then the extraction property of ID ensures that isk ${ }^{*}=i s k$. If so, we also have $t k^{*}=t k$, so that the full secret key $s k=($ isk, $t k)$ is recovered. So $\operatorname{Adv}_{\mathrm{DS}}^{\mathrm{dap}}(\mathcal{A})$ is at most the probability that the challenges are equal even though the payloads are not. But the challenges are outputs of $\mathrm{H}\left(\cdot,\{0,1\}^{\text {ID.cl }}\right)$, to which the game makes at most $q$ queries. So the probability that these challenges collide is at most $q(q-1) / 2^{\text {ID.cl+1 }}$.

Restricted unforgeability of our construction. The following shows that the restricted unforgeability of our DAPS tightly reduces to the cimp plus kr security of the underlying ID scheme.

Theorem 3 Let DAPS DS $=\mathbf{H 2}{ }_{+}[\mathrm{ID}, \mathrm{sl}]$ be obtained from trapdoor identification scheme ID and seed length sl as in Fig. 10. Let $\mathcal{A}$ be a ruf-adversary against DS. Suppose the number of queries that $\mathcal{A}$ makes to its $\mathrm{H}\left(\cdot,\{0,1\}^{\mathrm{ID} . \mathrm{tI}}\right), \mathrm{H}(\cdot, \mathrm{ID} . \operatorname{CmtSp}(\mathrm{ivk})), \mathrm{H}\left(\cdot,\{0,1\}^{\mathrm{ID} . \mathrm{cl}}\right)$, SigN oracles are, respectively,

Figure 11: Games for proof of Theorem 3. Games $\mathrm{G}_{1}, \mathrm{G}_{2}$ include the boxed code and games $\mathrm{G}_{0}, \mathrm{G}_{3}$ do not.
$q_{1}, q_{2}, q_{3}, q_{s}$, where ivk is as in game $\operatorname{RUF}_{\mathrm{DS}}^{\mathcal{A}}$. Then from $\mathcal{A}$ we can construct cimp adversary $\mathcal{P}_{1}$ and kr adversary $\mathcal{P}_{2}$ such that

$$
\begin{align*}
& \operatorname{Adv}_{\mathrm{DS}}^{\mathrm{ruf}}(\mathcal{A}) \\
& \quad \leq \operatorname{Adv}_{\mathrm{ID}}^{\operatorname{cimp}}\left(\mathcal{P}_{1}\right)+\operatorname{Adv}_{\mathrm{ID}}^{\mathrm{kr}}\left(\mathcal{P}_{2}\right)+\frac{q_{s}\left(2 q_{3}+q_{s}-1\right)}{2^{\mathrm{sl}+1}} . \tag{6}
\end{align*}
$$

Adversaries $\mathcal{P}_{1}, \mathcal{P}_{2}$ make $q_{2}+q_{s}+1$ queries to Tr. Adversary $\mathcal{P}_{1}$ makes $q_{3}$ queries to CH and one query to DEc. The running time of adversaries $\mathcal{P}_{1}$ is about that of $\mathcal{A}$. The running time of adversary $\mathcal{P}_{2}$ is that of $\mathcal{A}$ plus the time for $q_{1}$ executions of ID.KVf.

Proof of of Theorem 3: We assume that $\mathcal{A}$ avoids certain pointless behavior that would only cause it to lose. Thus, we assume that, in the messages it queries to Sign, the addresses are all different. Also we assume it did not query to Sign the message $m$ in the forgery ( $m, \sigma$ ) that it eventually outputs. The two together mean that the sets $A, M$ in game RUF $\mathcal{D}_{\mathrm{DS}}^{\mathcal{A}}$, and the code and checks associated with them, are redundant and can be removed. We will work with this simplified form of the game.
Identical-until-bad games $\mathrm{G}_{0}, \mathrm{G}_{1}$ of Fig. 11, as in the proof of Theorem 1, move us to allow picking a random seed in responding to a Sign query, regardless of whether the corresponding hash table
entry was defined or not. We have

$$
\begin{align*}
\operatorname{Adv}_{\mathrm{DS}}^{\mathrm{ruf}}(\mathcal{A})=\operatorname{Pr}\left[\mathrm{G}_{0}\right] & =\operatorname{Pr}\left[\mathrm{G}_{1}\right]+\operatorname{Pr}\left[\mathrm{G}_{0}\right]-\operatorname{Pr}\left[\mathrm{G}_{1}\right] \\
& \leq \operatorname{Pr}\left[\mathrm{G}_{1}\right]+\operatorname{Pr}\left[\mathrm{G}_{0} \text { sets bad }\right], \tag{7}
\end{align*}
$$

where the inequality is by the Fundamental Lemma of Game Playing of [8]. The random choice of $s$ made by procedure Sign ensures

$$
\begin{equation*}
\operatorname{Pr}\left[\mathrm{G}_{0} \text { sets bad }\right] \leq \sum_{i=0}^{q_{s}-1} \frac{q_{3}+i}{2^{\text {sl }}}=\frac{q_{s}\left(2 q_{3}+q_{s}-1\right)}{2^{\text {sl}+1}} \tag{8}
\end{equation*}
$$

Now we need to bound $\operatorname{Pr}\left[\mathrm{G}_{1}\right]$. We start by considering whether the ciphertext $T K \leftarrow t k \oplus$ $\mathrm{H}\left(\right.$ isk, $\{0,1\}^{\text {ID.tI }}$ ) helps $\mathcal{A}$ over and above access to Sign. Consider the games $\mathrm{G}_{2}, \mathrm{G}_{3}$ of Fig. 11. They pick $T K$ directly at random rather than as prescribed in the scheme. However, via the boxed code that it contains, game $\mathrm{G}_{2}$ compensates, replying to $\mathrm{H}\left(\cdot,\{0,1\}^{\mathrm{D} . \mathrm{tI}}\right)$ queries in such a way that $T K=t k \oplus \mathrm{H}\left(\right.$ isk, $\left.\{0,1\}^{\mathrm{ID} . \mathrm{t}}\right)$. Thus $\mathrm{G}_{2}$ is equivalent to $\mathrm{G}_{1}$. Game $\mathrm{G}_{3}$ omits the boxed code, but the games are identical-until-bad. So we have

$$
\begin{align*}
\operatorname{Pr}\left[\mathrm{G}_{1}\right]=\operatorname{Pr}\left[\mathrm{G}_{2}\right] & =\operatorname{Pr}\left[\mathrm{G}_{3}\right]+\operatorname{Pr}\left[\mathrm{G}_{2}\right]-\operatorname{Pr}\left[\mathrm{G}_{3}\right] \\
& \leq \operatorname{Pr}\left[\mathrm{G}_{3}\right]+\operatorname{Pr}\left[\mathrm{G}_{3} \text { sets bad }\right], \tag{9}
\end{align*}
$$

where again the inequality is by the Fundamental Lemma of Game Playing of [8]. Now we have two tasks, namely to bound $\operatorname{Pr}\left[\mathrm{G}_{3}\right]$ and to bound $\operatorname{Pr}\left[\mathrm{G}_{3}\right.$ sets bad $]$. The first corresponds to showing that $\mathcal{A}$ cannot forge if the ciphertext $T K$ is random, and the second corresponds to showing that changing the ciphertext to random makes little difference. The first relies on the assumed cimp security of ID, the second on its assumed kr security.
To bound $\operatorname{Pr}\left[\mathrm{G}_{3}\right]$, consider game $\mathrm{G}_{4}$ of Fig. 12. It mimics game $\mathrm{G}_{2}$ in the proof of Theorem 1 , moving us towards using cimp by generating conversation transcripts $Y_{i}\left\|c_{i}\right\| z_{i}$ and having SigN use these. We have

$$
\begin{equation*}
\operatorname{Pr}\left[\mathrm{G}_{3}\right]=\operatorname{Pr}\left[\mathrm{G}_{4}\right] . \tag{10}
\end{equation*}
$$

We build cimp adversary $\mathcal{P}_{1}$ so that

$$
\begin{equation*}
\operatorname{Pr}\left[\mathrm{G}_{4}\right] \leq \operatorname{Adv}_{\mathrm{ID}}^{\text {cimp }}\left(\mathcal{P}_{1}\right) . \tag{11}
\end{equation*}
$$

The construction of $\mathcal{P}_{1}$ mimics the construction of $\mathcal{P}$ in the proof of Theorem 1, and is described in detail in Fig. 13.
To bound $\operatorname{Pr}\left[\mathrm{G}_{3}\right.$ sets bad], consider game $\mathrm{G}_{5}$ of Fig. 12. It answers Sign queries just like $\mathrm{G}_{4}$, and the only modification in answering H queries is to keep track of queries to $\mathrm{H}\left(\cdot,\{0,1\}^{\text {ID.tI }}\right)$ in the set $T$. The game ignores the forgery, returning true if isk was queried to $\mathrm{H}\left(\cdot,\{0,1\}^{\text {ID.tI }}\right)$. We have

$$
\begin{equation*}
\operatorname{Pr}\left[\mathrm{G}_{3} \text { sets bad }\right]=\operatorname{Pr}\left[\mathrm{G}_{5}\right] . \tag{12}
\end{equation*}
$$

We build $\mathcal{P}_{2}$ so that

$$
\begin{equation*}
\operatorname{Pr}\left[\mathrm{G}_{5}\right] \leq \operatorname{Adv}_{\mathrm{ID}}^{\mathrm{kr}}\left(\mathcal{P}_{2}\right) . \tag{13}
\end{equation*}
$$

The idea is simple, namely that if the adversary queries isk to $\mathrm{H}\left(\cdot,\{0,1\}^{\text {ID.tI }}\right)$ then we can obtain isk by watching the oracle queries of $\mathcal{A}$. The difficulty is that, to run $\mathcal{A}$, one first has to simulate answers to Sign queries using transcripts, and it is to enable this that we moved to $\mathrm{G}_{5}$. Again the game was crafted to make the construction of adversary $\mathcal{P}_{2}$, described in detail Fig. 13, quite direct. The simulation of the SIGN oracle is as before. The simulation of H is more direct, following

Figure 12: More games for the proof of Theorem 3.
game $\mathrm{G}_{5}$ rather than invoking the CH oracle. When $\mathcal{A}$ returns its forgery, the set $T$ contains candidates for the identification secret key isk. Adversary $\mathcal{P}_{2}$ now verifies each candidate using the key-verification algorithm of the identification scheme, returning a successful candidate if one exists in its list.

Necessity of trapdoor ID schemes for DAPS. Trapdoor identification may seem a very particular assumption as a starting point for DAPS. However in Section 8 we show that from any DAPS satisfying double-authentication-prevention and unforgeability we can build a simple trapdoor identification scheme satisfying mimp-security and Sigma-protocol extractability. These being exactly the assumptions for our transform, it shows that these sufficient assumptions are in fact also necessary. The link between trapdoor identification and DAPS is thus quite strong.

## 7 Instantiation and implementation

We instantiate our general transform of Section 6 to obtain GQ-DAPS and CF-DAPS. We then make parameter choices and discuss our implementation and performance results.

### 7.1 GQ-ID and GQ-DAPS

GQ-ID. An RSA generator with modulus length $k$ is an algorithm RSA that returns a tuple $(N, p, q, e, d)$ where $p, q$ are distinct, odd primes, $N=p q$ is the modulus, in the range $2^{k-1}<$

Figure 14: Games defining one-wayness of RSA generator RSA, claw-freeness of claw-free TDF generator FG and factoring security of modulus generator MOD.
$N<2^{k}$, encryption and decryption exponents $e, d$ are in $\mathbb{Z}_{\varphi(N)}^{*}$ and $e d \equiv 1(\bmod \varphi(N))$. The assumption is one-wayness, formalized by defining the ow-advantage of an adversary $\mathcal{A}$ against RSA by $\operatorname{Adv}_{\text {RSA }}^{\mathrm{ow}}(\mathcal{A})=\operatorname{Pr}\left[\mathrm{OW}_{\text {RSA }}^{\mathcal{A}}\right]$ where the game is in Fig. 14 .

Fig. 15 shows the GQ-ID identification scheme associated to RSA and a challenge length $l<k$ such that $\operatorname{gcd}(e, c)=1$ for all $c \in\{0,1\}^{l}$ and all $(N, p, q, e, d) \in[\mathrm{RSA}]$. The commitment space is $\mathbb{Z}_{N}^{*}$. By egcd we denote the extended gcd algorithm that given relatively-prime inputs $e, c$ returns $a, b$ such that $a e+b c=1$. Algorithm GQ-ID.Cmt ${ }^{-1}$ shows that this scheme is trapdoor.

If we want to establish cimp security, the first and natural route is to use known results.

Figure 15: Identification scheme GQ-ID associated to RSA generator RSA with modulus length $k$, and challenge length $l$, and GQ-DAPS $=\mathbf{H} \mathbf{2}_{+}[$GQ-ID, sl] derived via our transform from GQ-ID.

Thus let $\operatorname{Adv}_{\mathrm{ID}}^{\mathrm{imp}}(\mathcal{Q})$ denote the advantage of an adversary $\mathcal{Q}$ in violating the standard security against impersonation under passive attack as formalized in [1]. If $\mathcal{P}$ is a cimp adversary making $q$ queries each to its CH and DEC oracles then a standard hybrid argument shows how to build $\mathcal{Q}$ using the same number of Tr queries as $\mathcal{P}$ and with about the same running time so that $\operatorname{Adv}_{\text {ID }}^{\text {cimp }}(\mathcal{P}) \leq q \cdot \operatorname{Adv}_{\text {ID }}^{\text {imp }}(\mathcal{Q})$. The imp advantage is well studied, and using the standard bound and proof based on the reset lemma of [6] we would get a ow adversary $\mathcal{A}$ of comparable resources such that

$$
\begin{equation*}
\operatorname{Adv}_{\mathrm{GQ}-\mathrm{ID}}^{\operatorname{cimp}}\left(\mathcal{P}_{1}\right) \leq q \cdot\left(\sqrt{\mathbf{A d v}_{\mathrm{RSA}}^{\mathrm{ow}}(\mathcal{A})}+\frac{1}{2^{l}}\right) . \tag{14}
\end{equation*}
$$

The term in parentheses is from the reset lemma. This bound is poor, both due to the square root and due to the multiplication by $q$ in the first term. The following says that we can do much better with a direct analysis, establishing both cimp and kr security with tight bounds.

Theorem 4 Let GQ-ID be the identification scheme associated to RSA generator RSA with modulus length $k$ and challenge length $l$ as above. Let $\mathcal{P}_{1}$ be a cimp adversary making $q$ queries each to its CH and DEC oracles. Then from $\mathcal{P}_{1}$ we can construct ow adversary $\mathcal{A}$ such that

$$
\begin{equation*}
\operatorname{Adv}_{\mathrm{GQ}-\mathrm{ID}}^{\operatorname{cimp}}\left(\mathcal{P}_{1}\right) \leq \operatorname{Adv}_{\mathrm{RSA}}^{\mathrm{ow}}(\mathcal{A})+\frac{q}{2^{l}} \tag{15}
\end{equation*}
$$

The running time of $\mathcal{A}$ is that of $\mathcal{P}_{1}$ plus the overhead of one execution of the GQ-ID.Ex algorithm. Also let $\mathcal{P}_{2}$ be a $k r$ adversary. Then from $\mathcal{P}_{2}$ we can construct ow adversary $\mathcal{A}$ such that

$$
\begin{equation*}
\operatorname{Adv}_{\mathrm{GQ}-\mathrm{ID}}^{\mathrm{kr}}\left(\mathcal{P}_{2}\right) \leq \operatorname{Adv}_{\mathrm{RSA}}^{\mathrm{ow}}(\mathcal{A}) \tag{16}
\end{equation*}
$$

The running time of $\mathcal{A}$ is that of $\mathcal{P}_{2}$.
The proof of Equation (15) is simple. In the execution of $\mathcal{P}_{1}$, if the impersonation is successful with a challenge different from the one in the transcript, then we can use GQ-ID.Ex to extract the secret key. The transcript queries can be simulated using the honest-verifier zero-knowledge property of GQ-ID. This doesn't add to the time overhead because by our convention running time refers to the execution of the adversary with the game, and in the real case the transcript oracle uses comparable time. The proof of Equation (16) is even more trivial since $\mathcal{P}_{2}$ returns the secret key directly. Thus we see that for these weaker goals we can not only establish tighter security but the proofs are much simpler.
GQ-DAPS. Fig. 15 shows the algorithms of our GQ-DAPS DAPS scheme derived by applying our transform to the trapdoor GQ-ID identification scheme of Fig. 15, where the latter is based on an RSA generator RSA with modulus length $k$ and a challenge length $l<k$. It is thus parameterized by RSA, $l$ and seed length sl. To estimate security for a given modulus length $k$ we use Theorem 3 and Theorem 4. The reductions are tight in both cases and so we need to estimate the advantage of a time $t$ adversary against the one-wayness of RSA. We do this under the assumption that the NFS is the best factoring method. Then taking into account Theorem 3 and Theorem 4, our implementation uses a 1024 -bit modulus, a 160 -bit hash and a seed length of 160 for the usual expected 80 bits of security. Since CA's now use 2048-bit modulii, we also implement the scheme with a 2048 -bit modulus and 256 -bit hashes and seeds. See below and Fig. 17 for implementation and performance information.

### 7.2 CF-ID and CF-DAPS

CF-ID. Our definition of a claw-free function generator extends the one of [16]. To be able to work with generators where membership in the domain cannot be efficiently tested, we have a superset of this domain in which such testing is possible. We also include a key-verification algorithm. Proceeding to the details, the generator FG specifies the following. Key-generation algorithm FG.Kg returns a tuple ( $e k, i k$ ) consisting of an evaluation key ek and an inversion key ik. Associated to $e k$ are finite sets $\mathrm{FG} . \mathrm{D}_{1}(e k) \subseteq \mathrm{FG} . \mathrm{D}_{2}(e k)$. Also specified are deterministic evaluation and inversion algorithms FG.Ev and FG.Ev ${ }^{-1}$. For $d \in\{0,1\}$, these in turn specify functions FG.Evek,d: FG.D ${ }_{2}(e k)$ $\rightarrow$ FG.D ${ }_{1}(e k)$ such that the restriction $\mathrm{FG}^{\mathrm{E}} \mathrm{Ev}_{\text {ek,d }}: \mathrm{FG}^{\mathrm{D}} \mathrm{D}_{1}(e k) \rightarrow$ FG. $\mathrm{D}_{1}(e k)$ is a permutation with inverse FG.Ev $\mathrm{Ev}_{\mathrm{ik}, \mathrm{d}}^{-1}$ : FG. $\mathrm{D}_{1}(e k) \rightarrow$ FG. $\mathrm{D}_{1}(e k)$. Membership in FG. $\mathrm{D}_{2}(e k)$ must be efficiently testable given $e k$. Membership in FG. $D_{1}(e k)$ may not be efficiently testable given ek, but it should be possible to efficiently pick random elements from the set given ek. The assumption is claw-freeness, formalized by defining the cf-advantage of an adversary $\mathcal{A}$ against FG by $\operatorname{Adv}_{\mathrm{FG}}^{\mathrm{cf}}(\mathcal{A})=\operatorname{Pr}\left[\mathrm{CF}_{\mathrm{FG}}^{\mathcal{A}}\right]$ where the game is in Fig. 14. The game tests membership in FG.D $D_{1}(e k)$ and hence may not be efficient but that's ok. There is an extraction algorithm FG.Ex that takes ek, $x_{0}, x_{1}$ such that $\mathrm{FG} \cdot \mathrm{Ev}_{\text {ek }, 0}\left(x_{0}\right)=\mathrm{FG} . \mathrm{Ev}_{e k, 1}\left(x_{1}\right)-x_{0}, x_{1}$ is referred to as a claw- and returns ik. There is a key verification algorithm FG.KVf that takes $e k, x$ and returns true iff $(e k, x) \in[F G . K g]$.

For a string $w=w[1] \ldots w[n] \in\{0,1\}^{n}$, let FG.Ev ${ }_{e k, w}$ : FG.D ${ }_{2}(e k) \rightarrow$ FG.D ${ }_{1}(e k)$ and FG.Ev $_{i k}{ }^{-1} w$ $:$ FG. $\mathrm{D}_{1}(e k) \rightarrow$ FG.D $\mathrm{D}_{1}(e k)$ be defined for $x \in \mathrm{FG} . \mathrm{D}_{2}(e k)$ and $y \in \mathrm{FG} . \mathrm{D}_{1}(e k)$ by

| Return $x$ | Return $y$ |

Fig. 16 shows the CF-ID identification scheme associated to FG and a challenge length $l$. The commitment space is $\mathrm{FG} . \mathrm{D}_{1}(e k)$. By $0 c$ we denote the challenge $c$ prefixed with a 0 bit. This is done following [20] because the verifier may not be able to test membership of $z$ in FG. $\mathrm{D}_{1}(e k)$, but now it can test membership in FG.D $\mathrm{D}_{2}(e k)$ and use the fact that $\mathrm{FG}_{\mathrm{E}} \mathrm{Ev}_{\text {ek }, 0}(z) \in \mathrm{FG}_{\mathrm{D}} \mathrm{D}_{1}(e k)$. The scheme is trivially trapdoor, with CF-ID.Cmt ${ }^{-1}$ returning $\varepsilon$. The key verification algorithm is the same as that of FG. The following summarizes the security properties of the scheme.

Theorem 5 Let CF-ID be the identification scheme associated to function generator FG and challenge length $l$ as above. Let $\mathcal{P}_{1}$ be a cimp adversary making $q$ queries each to its CH and DEC oracles. Then from $\mathcal{P}_{1}$ we can construct cf adversary $\mathcal{A}$ such that

$$
\begin{equation*}
\operatorname{Adv}_{\mathrm{CF}-\mathrm{D}}^{\operatorname{cimp}}\left(\mathcal{P}_{1}\right) \leq \operatorname{Adv}_{\mathrm{FG}}^{\mathrm{cf}}(\mathcal{A})+\frac{q}{2^{l}} \tag{17}
\end{equation*}
$$

The running time of $\mathcal{A}$ is that of $\mathcal{P}_{1}$ plus the overhead of one execution of the CF-ID.Ex algorithm. Also let $\mathcal{P}_{2}$ be a kr adversary. Then from $\mathcal{P}_{2}$ we can construct of adversary $\mathcal{A}$ such that

$$
\begin{equation*}
\operatorname{Adv}_{\mathrm{CF}-\mathrm{ID}}^{\mathrm{kr}}\left(\mathcal{P}_{2}\right) \leq \operatorname{Adv}_{\mathrm{FG}}^{\mathrm{cf}}(\mathcal{A}) . \tag{18}
\end{equation*}
$$

The running time of $\mathcal{A}$ is that of $\mathcal{P}_{2}$.
Again the value here is that the reductions for these weaker security goals are tight. For the classical imp goal, the reductions are analogous to Equation (14). The proof of Theorem 5 is again simple. The identification protocol is honest-verifier zero-knowledge and this together with extractability establishes Equation (17). Equation (18) is even more direct.
CF-DAPS. Fig. 16 shows the algorithms of our CF-DAPS DAPS scheme derived by applying our transform to the trapdoor CF-ID identification scheme of Fig. 15, where the latter is based on an function generator FG and a challenge length $l$. It is thus parameterized by FG, $l$ and seed length sl. Due to the tight reductions in Theorem 3 and Theorem 5, security will amount to that of the function generator. Our implementation will use a particular choice of the latter for speed, and we now discuss the schemes based on this choice.

MR-ID and MR-DAPS. A modulus generator with security parameter $k$ is an algorithm MOD that returns a tuple $(N, p, q)$ where $p, q$ are primes satisfying $p \equiv 3(\bmod 8)$ and $q \equiv 7(\bmod 8)$, and $N=p q$ is the modulus, in the range $2^{k-1}<N<2^{k}$. The assumption is hardness of factoring, formalized by defining the factoring-advantage of an adversary $\mathcal{A}$ against MOD by $\operatorname{Adv}_{\mathrm{MOD}}^{\mathrm{fac}}(\mathcal{A})=$ $\operatorname{Pr}\left[\mathrm{FAC}_{\mathrm{MOD}}^{\mathcal{A}}\right]$ where the game is in Fig. 14.

We associate to a modulus generator MOD the particular function generator $\mathrm{FG}=\mathrm{FG}[\mathrm{MOD}]$ defined as follows. FG.Kg runs MOD to get $(N, p, q)$ and then returns $(N,(N, p, q))$. We let FG. $\mathrm{D}_{2}(N)=\mathbb{Z}_{N}^{*}$, in which membership is efficiently testable given $N$. We let FG. $\mathrm{D}_{1}(N)=\mathrm{QR}(N)=$ $\left\{z^{2} \bmod N: z \in \mathbb{Z}_{N}^{*}\right\}$ be the subset of quadratic residues. Membership in $\operatorname{QR}(N)$ is not known to be efficiently testable given only $N$, but one can sample a random point in it by picking $z \leftarrow \& \mathbb{Z}_{N}^{*}$
 Note that, since $p \equiv 3(\bmod 8)$ and $q \equiv 7(\bmod 8)$, we have that neither 2 nor -2 is a quadratic residue $\bmod N$. For $y \in \operatorname{QR}(N)$ the inverses are defined as

$$
\operatorname{FG}^{\operatorname{E}} \mathrm{E}_{(N, p, q), 0}^{-1}(y)=\sqrt{y} \quad \bmod N \quad \text { and } \quad \operatorname{FG} \cdot \operatorname{Ev}_{(N, p, q), 1}^{-1}(y)=\sqrt{4^{-1} y} \quad \bmod N
$$

where $\sqrt{z}$ denotes the square root of $z$ that is itself a quadratic residue $\bmod N$. This can be efficiently computed given $p, q$. Extraction algorithm FG.Ex takes $N, x_{0}, x_{1}$ such that $x_{0}, x_{1} \in$ $\mathrm{QR}(N)$ and $x_{0}^{2} \equiv 4 x_{1}^{2} \bmod N$, which means $r=\operatorname{gcd}\left(x_{0}-2 x_{1}, N\right)$ divides $N$. However $x_{0}, x_{1} \in$ $\mathrm{QR}(N)$ and hence $x_{0} \not \equiv \pm 2 x_{1}(\bmod N)$, so $r$ is a non-trivial factor of $N$, and the algorithm can thus return $(N, p, q)$. Key verification algorithm $\operatorname{FG} \cdot \operatorname{KVf}(N,(N, p, q))$ returns true if $N=p q$. Clawfreeness tightly reduces to factoring, so the latter is the basis of security.

When $F G=F G[M O D]$, identification scheme CF-ID is an identification scheme specified by MR [20] as underlying the signature scheme of [19]. We denote this identification scheme by MR-ID. The corresponding CF-DAPS is denoted by MR-DAPS. This is the choice for our implementation. Given the tightness of the reduction of Theorem 3 and Theorem 5 we can again pick the modulus based on the assumption that the NFS is the best factoring method.

### 7.3 Implementation and performance

We implemented the MR-DAPS and GQ-DAPS schemes. For comparison purposes we also implemented the original PS-DAPS and used an implementation of the standard RSA PKCS\#1v. 5
currently used for signing certificates. Our implementation is in C, using OpenSSL's BIGNUM library for number theoretic operations. ${ }^{3}$

For the implementation of the claw-free TDF for MR-DAPS, we need to compute FG.Ev ${ }_{(N, p, q), c}^{-1}(x)$ for a $c$ of length $l$. The naive approach requires computing $l$ square roots modulo $N$, which takes $O\left(l k^{3}\right)$ time. Instead, we use the following technique suggested by Goldreich [15] which computes FG.Ev ${ }_{(N, p, q), c}^{-1}(x)$ with a constant number of exponentiations (assuming a small amount of precomputation which can be reused), thereby achieving an overall runtime of $O\left(k^{3}\right)$. Compute

$$
{\operatorname{FG} \cdot \mathrm{Ev}_{(N, p, q), c}^{-1}}_{-1}(x)=\frac{R_{N}\left(2^{l}, x\right)}{\left(R_{N}\left(2^{l}, 4\right)\right)^{i(c)}} \quad \bmod N
$$

where $R_{N}\left(2^{l}, x\right)$ denotes the $2^{l}$-th square root of $x$ modulo $N, l$ is the bit-length of $c$, and $i(c)$ denotes the integer representation of $c . R_{N}\left(2^{l}, x\right)$ can be computed quickly by computing $R_{p}\left(2^{l}, x\right)$ and $R_{q}\left(2^{l}, x\right)$ and using the Chinese remainder theorem. $R_{p}\left(2^{l}, x\right)$ can be computed by precomputing $a=(p+1) / 4$ (the "inverse" of 2 modulo $\varphi(p)$ ) and $b=a^{l} \bmod \varphi(p)$ (the "inverse" of $2^{l}$ modulo $\varphi(p))$, and then computing $R_{p}\left(2^{l}, x\right)$ as $x^{b} \bmod p$.

To hash onto quadratic residues we follow the framework of Brier et al. for indifferentiable hashing [9] as described by Poettering and Stebila [23]: we first hash onto $\mathbb{Z}_{N}$ to obtain an element $r$. With high probability, randomly chosen elements of $\mathbb{Z}_{N}$ are also in $\mathbb{Z}_{N}^{*}$. If $r$ has Jacobi symbol -1 , we set $r \leftarrow r t \bmod N$ where $t$ is a fixed element with Jacobi symbol -1 , in our case $t=2$ always suffices. Exactly one of $r$ and $N-r$ will be a quadratic residue $\bmod N$.

For the implementation of GQ-DAPS, we use encryption exponent $e=65537$ as this is the default RSA public key exponent in OpenSSL, allowing for fair comparisons with RSA PKCS\#1v1.5.

Timings were run on an Intel Core i7 ( 3720 QM ) with 4 cores each running at 2.6 GHz ; the tests were run on a single core with TurboBoost and hyper-threading disabled. Software was compiled for the x86_64 architecture with -03 optimizations using 11 vm 6.0 (clang 600.0.56). The OpenSSL version used was v1.0.2.

Table 17 shows average runtimes and key sizes using 1024-bit modulii and 160-bit hashes and using 2048-bit modulii and 256 -bit hashes. For DAPS schemes, address is 15 bytes and payload is 33 bytes; for RSA PKCS\#1v1.5, message is 48 bytes. Times reported are an average over 30 seconds. For RSA sign and verify operations, standard deviation was between $3 \%$ and $44 \%$. For all other operations, standard deviation was less than $4 \%$.

The table omits runtimes for key generation, as this is a one-time operation. Key generation times are fairly similar across schemes, as for all schemes the main cost is the generation of an RSA modulus. For all schemes with 1024-bit keys, key generation times, from the top row to the bottom row, are $29.9 \mathrm{~ms}, 24.2 \mathrm{~ms}, 31.5 \mathrm{~ms}$, and 23.7 ms ; with 2048 -bit keys, generation times are 156.5 ms , $135.6 \mathrm{~ms}, 167.8 \mathrm{~ms}$, and 125.5 ms . For all key generation operations, standard deviation was between $64 \%$ and $74 \%$ (this is to be expected, as key generation involves generating primes, a probabilistic process with high variance in runtime). While key generation is substantially more expensive than signing or verification, it is still less than a second, and each signer needs to do it only once.

Compared with the existing PS-DAPS, our MR-DAPS and GQ-DAPS are several orders of magnitude faster for both signing and verification. When using 2048-bit modulii, MR-DAPS signatures can be generated $336 \times$ and verified $116 \times$ faster, and GQ-DAPS signatures can be generated $198 \times$ and verified $399 \times$ faster; moreover our signatures are much smaller, both just 2304 bits, compared with 528384 bits for PS-DAPS, and nearly the same size as RSA PKCS\#1v1.5 signatures. Signing times for our schemes are competitive with RSA PKCS\#1v1.5 signatures. Using MR-DAPS or GQ-

Figure 18: Our construction of a trapdoor identification scheme $\mathrm{ID}=\mathbf{H} \mathbf{2}_{+}^{-\mathbf{1}}[\mathrm{DS}, \mathrm{sl}]$ from a DAPS DS and a seed length $s \mid \in \mathbb{N}$. ID.CmtSp $(i v k)=\{0,1\}^{\text {sl }}$ for all ivk.

DAPS for signatures in digital certificates would incur little computational or size overhead relative to currently used signatures.

## 8 From DAPS to trapdoor ID

Here we show that DAPS implies trapdoor identification. Given any DAPS satisfying double-authentication-prevention and unforgeability, we build a trapdoor identification scheme, via the construction $\mathbf{H 2}_{+}^{-1}$ in Fig. 18, that is mimp-secure and satisfies the Sigma protocol extractability condition. This shows that the assumption we make to obtain DAPS is effectively necessary. All proofs are omitted.

The basic idea of the construction is as follows. The ID scheme's keys are just the keys of a DAPS. A commitment is a random string, as is a challenge; the response is generated as a DAPS signature with the commitment as the address and challenge as the payload. Verification in the ID scheme is just verification in the DAPS. The ID scheme is trapdoor because the commitment "secret" is just the commitment itself, and the extractability of the Sigma protocol comes from the double-signature extractability of the DAPS.

We now make and prove three claims about the identification scheme: (1) it is trapdoor (2) It

| $\underline{\text { Adversary } \mathcal{A}_{1}^{\text {Sign }}(v k)}$ | $\underline{\mathrm{ChS}(Y)}$ |
| :---: | :---: |
| $d \leftarrow s \mathcal{A}^{\text {TrS,ChS, DecS }}(v k)$ | $i \leftarrow i+1 ; U \leftarrow U \cup\{i\} ; c \leftarrow ¢\{0,1\}^{\text {ID.cl }}$ |
| $\underline{\operatorname{TrS}}()$ | $\mathrm{TT}[i] \leftarrow Y \\| c$ |
| $Y \leftarrow$ ID. $\mathrm{CmtSp}(v k)$ | Return ( $i, c$ ) |
| $c \leftarrow s\{0,1\}^{\text {s }}$ | $\underline{\operatorname{DECS}(j, z)}$ |
| $z \leftarrow ¢ \operatorname{SigN}((Y, c))$ | If $(j \notin U)$ then return $\perp$ |
| Return $Y\\|c\\| z$ | $\begin{aligned} & U \leftarrow U \backslash\{j\} ; Y \\| c \leftarrow \mathrm{TT}[j] \\ & v \leftarrow \operatorname{DS} . \operatorname{Vf}(\mathrm{vk},(Y, c), z) \end{aligned}$ |
|  | If $v$ then $\mathcal{A}_{1}$ returns $((Y, c), z)$ to its uf-challenger Return $v$ (to $\mathcal{A}$ ) |

Figure 19: Adversary for proof of Theorem 7.
is mimp-secure, and (3) It satisfies Sigma-protocol extractability as defined in Appendix 3. These are exactly the properties assumed of the identification scheme for our transform to work, so that our result here shows that the sufficient assumptions we make in Section 6 on the identification scheme to obtain DAPS are in fact also necessary.

Theorem 6 Let DS be a DAPS and let $\mathrm{sl} \in \mathbb{N}$. Then $\mathrm{ID}=\mathbf{H} \mathbf{2}_{+}^{-\mathbf{1}}[\mathrm{DS}, \mathrm{sl}]$ is trapdoor.

Proof: Recall that for an ID scheme to be trapdoor, the following two processes must be identically distributed:

1. (isk, ivk, $t \mathrm{k}) \leftarrow \mathrm{s}$ ID. $\mathrm{Kg} ;(Y, y) \leftarrow \mathrm{I}$ ID.Cmt $(i v k) ; \operatorname{Return}(i s k, i v k, t k, Y, y)$.
2. (isk, ivk, $t \mathrm{k}) \leftarrow \mathrm{s}$ ID. $\mathrm{Kg} ; ~ Y \leftarrow \& \mathrm{ID} . \mathrm{CmtSp}(i v k) ; y \leftarrow \& \mathrm{ID} . \mathrm{Cmt}^{-1}$ (ivk, $\mathrm{tk}, Y$ ) ; Return (isk, ivk, $t k, Y, y)$.

For ID $=\mathbf{H 2}{ }_{+}^{-1}[\mathrm{DS}, \mathrm{sl}]$, since ID.Cmt $(i v k)$ simply selects $Y \leftarrow \& \mathrm{ID} . \mathrm{CmtSp}(i v k)$ and $Y=y$, we have that both processes above are equivalent to:

$$
(i s k, i v k, t k) \leftarrow \& \text { ID.Kg } ; Y \leftarrow \& \text { ID.CmtSp }(i v k) ; \text { Return (isk, ivk, } t k, Y, Y)
$$

This completes the proof.
Next we show that our constructed identification scheme is mimp secure.
Theorem 7 Let DS be a DAPS and let $\mathrm{sl} \in \mathbb{N}$. Let $\mathcal{A}$ be a mimp-adversary against $\mathrm{ID}=$ $\mathbf{H} \mathbf{2}_{+}^{-\mathbf{1}}[\mathrm{DS}, \mathrm{sl}]$ making $q$ queries to its Tr oracle. Then from $\mathcal{A}$ we can construct uf-adversary $\mathcal{A}_{1}$ such that $\operatorname{Adv}_{\mathrm{ID}}^{\text {cimp }}(\mathcal{A}) \leq \operatorname{Adv}_{\mathrm{DS}}^{\mathrm{ruf}}\left(\mathcal{A}_{1}\right)$. $\mathcal{A}_{1}$ makes $q$ queries to its Sign oracle and the running time of $\mathcal{A}_{1}$ is that of $\mathcal{A}$ plus some small overhead, including one execution of DS.Vf for each call by $\mathcal{A}$ to its Dec oracle.

Proof: Adversary $\mathcal{A}_{1}$ is shown in Fig. 19. $\mathcal{A}_{1}$ directly simulates the mimp experiment for $\mathcal{A}$; to create transcripts, $\mathcal{A}_{1}$ uses its SIGN oracle. If $\mathcal{A}$ submits an accepting transcript to its DECS oracle, this immediately gives $\mathcal{A}_{1}$ a forgery for DS. $\mathcal{A}_{1}$ 's simulation of game RUF $\mathcal{D S}_{\mathrm{DS}}^{\mathcal{A}}$ is perfect. The bound follows.

Finally we show that our constructed identification scheme satisfies Sigma-protocol extractability.

```
Adversary }\mp@subsup{\mathcal{A}}{1}{}(vk,sk) (Y,\mp@subsup{c}{1}{},\mp@subsup{z}{1}{},\mp@subsup{c}{2}{},\mp@subsup{z}{2}{})\leftarrow\mathcal{A}(vk,sk,\varepsilon
Return ((Y, c) ),(Y,\mp@subsup{c}{2}{}),\mp@subsup{z}{1}{},\mp@subsup{z}{2}{})
```

Figure 20: Adversary for proof of Theorem 8.

Theorem 8 Let DS be a DAPS and let $\mathrm{s} \mid \in \mathbb{N}$. Let $\mathcal{A}$ be a ex-adversary against $\mathrm{ID}=\mathbf{H} 2_{+}^{-\mathbf{1}}[\mathrm{DS}$, sl]. From $\mathcal{A}$ we can construct dap-adversary $\mathcal{A}_{1}$ such that $\operatorname{Adv}_{\mathrm{ID}}^{\mathrm{ex}}(\mathcal{A}) \leq \operatorname{Adv}_{\mathrm{DS}}^{\mathrm{dap}}\left(\mathcal{A}_{1}\right)$. The running time of $\mathcal{A}_{1}$ is that of $\mathcal{A}$.

Proof: Adversary $\mathcal{A}_{1}$ is shown in Fig. 20. $\mathcal{A}_{1}$ directly calls $\mathcal{A}$ which is an ex adversary against the identification scheme ID. Note that, for $\mathrm{ID}=\mathbf{H} 2_{+}^{-\mathbf{1}}[\mathrm{DS}, \mathrm{sl}]$, the trapdoor key $t \mathrm{k}=\varepsilon$, so this is a perfect simulation of $\mathrm{EX}_{\mathrm{ID}}^{\mathcal{A}}$. If $\mathcal{A}$ returns two accepting transcripts $Y\left\|c_{1}\right\| z_{1}$ and $Y\left\|c_{2}\right\| z_{2}$ with $c_{1} \neq c_{2}$, then $\left(Y, c_{1}\right)$ and $\left(Y, c_{2}\right)$ are a pair of colliding messages for DS and $z_{1}$ and $z_{2}$, respectively, are valid signatures. ID.Ex fails to return the correct secret key from this part of transcripts exactly when DS.Ex fails. The bound in the theorem statement follows.

[^1]:    ${ }^{1}$ This means it is honest-verifier zero knowledge, and from two accepting transcripts with the same commitment but different challenges, one can extract the secret key.
    ${ }^{2}$ One might note that cimp is quite useless from the point of view of the use in practice of the identification scheme for actual identification, because in that setting we may not be able to constrain the adversary to use only prior commitments. However we are interested in identification only as a tool, not as an end goal. Cimp will work well for us in the former regard.
