# Computationally binding quantum commitments

Dominique Unruh University of Tartu

February 3, 2016

**Abstract.** We present a new definition of computationally binding commitment schemes in the quantum setting, which we call "collapse-binding". The definition applies to string commitments, composes in parallel, and works well with rewinding-based proofs. We give simple constructions of collapse-binding commitments in the random oracle model, giving evidence that they can be realized from hash functions like SHA-3. We evidence the usefulness of our definition by constructing three-round statistical zero-knowledge quantum arguments of knowledge for all NP languages.

### 1 Introduction

We study the definition and construction of computationally binding string commitment schemes in the quantum setting. A commitment scheme is a two-party protocol consisting of two phases, the commit and the open phase. The goal of the commitment is to allow the sender to transmit information related to a message m during the commit phase in such a way that the recipient learns nothing about the message (hiding property). But at the same time, the sender cannot change his mind later about the message (binding property). Later, in the open phase, the sender reveals the message m and proves that this was indeed the message that he had in mind earlier. We will focus on non-interactive classical commitments, that is, the commit and open phase consists of a single classical message. However, the adversary who tries to break the binding or hiding property will be a quantum-polynomial-time algorithm. At the first glance, it seems that the definition of the binding property in this setting is straightforward; we just take the classical definition but consider quantum adversaries instead of classical ones:

**Definition 1 (Classical-style binding** – **informal)** No quantum-polynomial-time algorithm A can output, except with negligible probability, a commitment c (i.e., the message sent during the commit phase) as well as two openings u, u' that open c to two different messages m, m'.

(Formal definition in Section 2.) Unfortunately, this definition turns out to be inadequate in the quantum setting. Ambainis, Rosmanis, and Unruh [ARU14] show the existence of a commitment scheme (relative to a special oracle) such that: The commitment is classical-style binding. Yet there exists a quantum-polynomial-time adversary A that outputs a commitment c, then expects a message m as input, and then provides valid opening information for c and m. That is, the adversary can open the commitment c to any message of his choosing, even if he learns that message only after committing. This is in clear contradiction to the intuition of the binding property. How is this possible, as Definition 1 says that the adversary cannot produce two different openings for the same commitment? In the construction from [ARU14], the adversary has a quantum state  $|\Psi\rangle$  that allows him to compute one opening for a message of his choosing, however, this computation will destroy the state  $|\Psi\rangle$ . Thus, the adversary cannot compute two openings simultaneously, hence the commitment is classically-binding. But he can open the commitment to an arbitrary message once, which shows that the commitment scheme is basically useless despite being classically-binding.

### 1.1 Prior definitions

We now discuss various definitions that appeared in the literature and that circumvent the above limitation of the classical-binding property. (We do not discuss the hiding property here, because that one does not have any comparable problems. See Definition 10 below

<sup>&</sup>lt;sup>1</sup>Note that for classical adversaries, the classical-binding property gives useful guarantees: If an adversary can produce an opening for any message m using some classical algorithm, he can also produce two openings for different messages m, m' by running that algorithm twice.

for the definition of hiding.) In each case, we discuss some limitations of the definitions to motivate the need for a new definition for computationally binding commitments. The reader only interested in our results can safely skip this section.

**Sum-binding.** The most obvious solution is to simply require that the adversary cannot open successfully to each of two messages: That is:

**Definition 2 (Sum-binding** – **informal)** Consider a bit commitment scheme. (I.e., one can only commit to m = 0 or m = 1.)

Given an adversary A, let  $p_b$  be the probability that the recipient accepts in the following execution: A commits, then A is given b, and then A provides opening information for message b.

A commitment is sum-binding iff for any quantum-polynomial-time adversary A,  $p_0 + p_1 \le 1 + negligible$ .

Note that even with an ideal commitment,  $p_0 + p_1 = 1$  is possible (the adversary just picks b := 0 in the commit phase with probability  $p_0$ , and b := 1 else). So  $p_0 + p_1 \le 1 + negligible$  is the best we can expect if we allow for a negligible probability of an attack. The sum-binding definition has occurred implicitly and explicitly in different variants in [BCJL93, May97, DMS00, CDMS04, CSST11]. We use the name sum-binding here to distinguish it from the other definitions of binding discussed here since it does not have an established name.

Although it avoids the attack described above, the sum-binding definition has a number of disadvantages:

- It is specific to the bit commitment case. There is no straightforward generalization to the the string commitment case (i.e., where the message m does not have to be a single bit). See [CDMS04] for discussion why obvious approaches fail.<sup>2</sup>
- It is unclear how the definition behaves when we use the commitment several times. (I.e., it is not clear how it behaves under composition.) For example, given bits  $m_1, \ldots, m_n$ , what are the security guarantees if we commit to each of the  $m_i$ ? (Be it in parallel, or sequentially.) Basically, we would expect that all commitments together form a binding commitment on the string  $m = m_1 \ldots m_n$ , but this is something we cannot even express using the sum-binding definition.
- It is not clear how useful sum-binding commitments are as subprotocols in larger protocols. That is, is the sum-binding property strong enough to allow to prove the security of complex protocols using commitments? While there are constructions of sum-binding in the literature (e.g., [DMS00]), we are not aware of research where (computational) sum-binding commitments are used as subprotocols.

<sup>&</sup>lt;sup>2</sup>One obvious attempt would be: Let  $p_m$  be the probability that A opens the commitment as m when given m after the commit phase. Then for all  $m_0, m_1$ , we have  $p_{m_0} + p_{m_1} \le 1 + negligible$ .

However, this leaves the possibility that the adversary A achieves the following: In the commit phase, A outputs  $c, m_0, m_1$  where  $m_0, m_1$  are uniformly distributed. Then A gets a bit b. Then A opens c with message  $m_b$ . This should not be possible if c is binding, yet for this A,  $p_m$  is negligible for any fixed m. (Since  $\Pr[m \in \{m_0, m_1\}]$  is negligible.)

**CDMS-binding.** Crépeau, Dumais, Mayers, and Salvail [CDMS04] suggest a generalization of the sum-binding property to string commitments. The basic idea is: Instead of bounding  $p_0 + p_1 \le 1 + negligible$  where  $p_m$  is the probability that the adversary open his commitment as  $m \in \{0,1\}$ , we could bound  $\sum_m p_m \le 1 + negligible$  where m ranges over all bitstrings. However, as discussed in [CDMS04], this would be too strong a requirement. (Basically, this is because the sum  $\sum_m p_m$  has exponentially many summands, so even negligible attack probabilities can add up to large probabilities.) Instead, they proposed the following definition:

**Definition 3 (CDMS-binding – informal)** Let F be a family of functions. Fix a string commitment scheme. For  $f \in F$ , let  $\tilde{p}_y^f$  be the probability that the recipient accepts in the following execution: A commits. A gets y. A tries to open the commitment to some m with f(m) = y.

We call the commitment scheme F-CDMS-binding iff for all adversaries A and all  $f \in F$ , we have  $\sum_{y} \tilde{p}_{y}^{f} \leq 1 + negligible$ .

Now if all  $f \in F$  have a polynomial-size range, the sum  $\sum_y \tilde{p}_y^f$  will have polynomially many summands. The intuition behind this definition is that every function  $f \in F$  represents some property of the committed message m (e.g., f(m) is the parity of m). Then, if a commitment scheme is F-CDMS-binding, this intuitively means that the although the adversary might be able to change his mind about the message m, he cannot change his mind about f(m). (E.g., if the parity function is in F, this means that the adversary will be committed to the parity of the message m.) [CDMS04] successfully used this definition (for a specific class F) to show that using quantum communication and a commitment, we can construct an oblivious transfer protocol. (Note however that their protocol is different and more complex than the original OT protocol from [BBCS91].)

Although the CDMS-binding definition generalizes the sum-binding definition to the case of string commitments, it comes with its own challenges:

- The definition is parametrized by a specific family F of functions that specifies in which way the commitment should be binding. This function family has to be chosen dependent on the particular use case. This makes the definition less universal and canonical.
- To the best of our knowledge, no construction of CDMS-binding commitments is known. Crépeau et al. [CDMS04] conjecture that the protocol from [CLS01] can be extended to a CDMS-binding one for functions F with small range, but no proof or construction is given.
- It is not known whether the definition is composable. If we commit to messages  $m_1, \ldots, m_n$  individually using F-CDMS-binding commitments, does this constitute an F'-CDMS-binding commitment on  $m := m_1 \| \ldots \| m_n$ ? If so, for which F'?
- While CDMS-binding commitments have successfully been used in a larger protocol (namely, the OT protocol from [CDMS04]), we believe that in many contexts, the definition is still not very easy to use. At least in classical cryptography, one often uses the fact that it is possible to extract the committed message by rewinding (basically, one runs the open phase, saves the opened message, and rewinds to before

the opening phase). It is not clear how to do that with CDMS-binding commitments. For example, it is not clear how one could use CDMS-binding commitments in the construction of sigma-protocols that are quantum arguments of knowledge (as done in Section 7 below using our definition of binding commitments).

**Perfectly-binding commitments.** One possibility to solve all the problems mentioned so far is simply to use perfectly-binding commitments.

**Definition 4 (Perfectly-binding – informal)** A commitment scheme is perfectly-binding if there exists no tuple (c, m, u, m', u') with  $m \neq m'$  such that u is a valid opening for c with message m, and u' is a valid opening for c with message m'.

However, if we restrict ourselves to perfectly-binding commitments, we get the following disadvantages:

- A perfectly-binding commitment cannot be statistically hiding [May97]. That is, the hiding property cannot hold against computationally unlimited adversaries. That means that we give up on information-theoretical security for one party just because we do not have a suitable definition for the computationally-binding property. For example, the constructions in [Unr12] are only computational zero-knowledge (not statistical zero-knowledge) because perfectly-binding commitments are used.
- Perfectly-binding commitments cannot be short. That is, the length of the commitment must be as long as the length of the committed message. So by using only perfectly-binding commitments, we may lose efficiency.

UC commitments. One further possibility is to use commitments that are UC-secure [Unr10]. Since the security of a protocol using a UC-secure commitment can be reduced to the security of the same protocol using an ideal (in particular perfectly-binding) commitment, UC-secure commitments are easy to use. Yet, this solution again comes with disadvantages:

- UC-commitments do not exist without the use of additional setup such as, e.g., a common reference strings (CRS). It is possible to chose the CRS in a precomputation phase using a coin-toss protocol [DL09]. But that increases the round complexity of the resulting protocol (and, incidentally, loses the UC security and possibly even the concurrent composability of the resulting protocol).
- In the construction of UC-secure commitment schemes, trapdoors are used that allow the simulator to extract the committed message. This implies that constructions of UC-secure commitment are usually more complex, less efficient, and use stronger computational assumptions.
- At least when using a CRS, UC commitments cannot be short.

Damgård, Fehr, Lunemann, Salvail, and Schaffner [DFL<sup>+</sup>09] use so-called dual-mode commitments, these are somewhat weaker than UC commitments. Yet, they also use extraction using a trapdoor in the CRS. Hence the disadvantages of UC commitments apply to dual-mode commitments as well.

**Q-binding.** Damgård, Fehr, and Salvail [DFS52] give another definition for computationally binding string commitments. Intuitively, the definition says that an adversary who uses the commitment has negligible advantage in a "betting game" over an adversary that has to use perfect commitments. Here, a betting game is represented as an arbitrary predicate on the opened values in the commitments, and on some random input that the adversary learns only after committing. (E.g., a bet could be: the sum of all opened values equals the random value u that the adversary learns just before opening.) Somewhat more formally:

**Definition 5 (Q-binding** – **informal)** For an adversary A and an predicate Q, consider the following game: A outputs commitments  $C_1, \ldots, C_N$ . Then A gets a random bitstring u. Then A opens a subset  $\mathbf{A}$  of the commitments, let  $(s_i)_{i \in \mathbf{A}}$  be the contents. A wins if  $Q(\mathbf{A}, (s_i)_{i \in \mathbf{A}}, u) = 1$ .

A commitment scheme is Q-binding iff for any quantum-polynomial-time A and any predicate Q, the adversary A wins with probability at most  $p_{\mathsf{IDEAL}} + negl$ , where  $p_{\mathsf{IDEAL}}$  is the maximum winning probability when using a perfectly binding commitment.

The definition overcomes some of the problems of the CDMS-binding definition. In particular, there is no need to parametrize the definition with a class F of functions, specifically chosen to fit the use case at hand. Also, the Q-binding definition composes in parallel: if a commitment scheme is Q-binding, then the commitment scheme resulting from committing to each of  $m_1, \ldots, m_n$  individually is Q-binding, too. (This should come as no surprise, since the Q-binding definition itself explicitly refers to a polynomial number of parallel copies of the commitment scheme.) The definition seems particularly well-suited for commit-and-choose constructions (i.e., where one party commits to a set of values, and the other party selects which of them should be opened), since security when opening a specific subset is built into the definition. [DFS52] give a generic construction for unconditionally hiding Q-binding equivocal trapdoor commitments from a certain class of sigma-protocols. They show that using such commitments, sigma-protocols can be converted into statistical quantum zero-knowledge arguments in the CRS model.

However, their definition also comes with a number of challenges:

- The only construction of unconditionally hiding Q-binding commitments known is actually an equivocal trapdoor commitment. Trapdoor commitments usually need stronger assumptions. Note also that no protocols using non-equivocal Q-binding commitments are known (the zero-knowledge protocols in [DFS52] need the trapdoor because they are constructed following the "no quantum rewinding paradigm"). And, due to the absence of rewinding, the zero-knowledge protocols only work in the CRS model.
- The possibility for parallel composition might be limited: It follows directly from the definition that Q-binding commitments on  $m_1, \ldots, m_n$  are a Q-binding commitment on  $m = m_1 \ldots m_n$ . However, it is not clear what happens if we commit to  $m_1, \ldots, m_n$  using different Q-binding commitments. (Or the same Q-binding commitment, but using different public keys.)
- The definition is specialized for the commit-and-choose paradigm. It is unclear how it can be used in rewinding-based proofs. (On the other hand, in commit-and-choose

situations, Q-binding commitments might be more suitable than those we propose; whether this is the case constitutes future work.)

Summarizing, Q-binding commitments seem to be well suited for commit-and-choose constructions, but for proofs involving rewinding, we need another definition.

**DFRSS-binding.** Damgård, Fehr, Renner, Salvail, and Schaffner [DFR<sup>+</sup>07] presented a definition for the unconditional binding property, targeted mainly for the bounded quantum storage model; the following is a direct adaptation of their definition to the computational setting:

**Definition 6 (DFRSS-binding – adapted)** In a commitment, let V denote the recipient's classical state, and Z the sender's classical state.

A bit commitment is DFRSS-binding iff for any quantum-polynomial-time sender  $\tilde{C}$ , there exists a randomized function B' such that the following holds:

Let  $\tilde{C}$  and the honest recipient execute the commit phase. Compute b' := B'(V, Z). Let  $\tilde{C}(b')$  and the honest recipient execute the open phase. Let b denote the opened bit (or  $\bot$  if the recipient does not accept). Then  $\Pr[b' \neq b]$  is negligible.

In other words, given the classical part of the state of the recipient *and* the sender, it is possible to extract what bit the sender will open to. (The extraction does not have to be efficiently feasible.)

The definition can be extended to string commitments by letting B' range over bitstrings.

We have changed the original definition from [DFR<sup>+</sup>07] to refer to quantum-polynomial-time adversaries. (We also reformulated it for easier readability, changing a number of technical details in the process. However, the current definition is in the spirit of the original. And our discussion also applies to the original formulation.)

The definition was originally intended for protocols in the bounded quantum storage model. What happens if we use it in the standard model, i.e., with no limit on the quantum memory of the sender? In this case, it is always possible for the malicious sender to perform all his operations in superposition, and only the recipient will perform measurements. Then, in Definition 6, the register Z will be empty. Hence the definition requires that the committed bit b' can be computed from the recipient's state V alone. This immediately implies that the scheme cannot be statistically hiding, and that the commitments cannot be shorter than the message.

Hence the DFRSS-binding definition shares the drawbacks of the perfectly binding definition, unless we are in the bounded quantum storage model. (We stress that  $[\mathrm{DFR}^+07]$  never claimed that the definition should be used outside the bounded quantum storage model.)

### 1.2 Our contribution

We give a new definition for the computational-binding property for commitment schemes, called "collapse-binding" (Section 2). This definition is composable (several collapse-binding commitments are also collapse-binding together), works well with quantum

rewinding (see below), does not conflict with statistical hiding (as perfectly-binding commitments would), allows for short commitments (i.e., the commitment can be shorter than the committed message, in contrast to perfectly-binding commitments, and to extractable commitments in the CRS model). Basically, collapse-binding commitments seem to be in the quantum setting what computationally-binding commitments are in the classical setting.

We show that collision-resistant hash functions are not sufficient for getting collapsebinding or even just sum-binding commitments (Section 3), at least when using standard constructions, and relative to an oracle. We present a strengthening of collision-resistant hash functions, "collapsing hash functions" that can serve as a drop-in replacement for collision-resistant hash functions (Section 4). Using collapsing hash functions, we show several standard constructions of commitments to be collapse-binding (Section 5).

We conjecture that standard cryptographic hash functions such as SHA-3 [NIS14] are collapsing (and thus lead to collapse-binding commitments). We give evidence for this conjecture by proving that the random oracle is a collapsing hash function.

We show that the definition of collapse-binding commitments is usable by extending the construction of quantum proofs of knowledge from [Unr12] (Section 7). Their construction uses perfectly-binding commitments (actually, strict-binding, which is slightly stronger) to get proofs of knowledge. We show that when replacing the perfectly-binding commitments with collapse-binding ones, we get statistical zero-knowledge quantum arguments of knowledge. In particular, this shows that collapse-binding commitments work well together with rewinding.

### 1.3 Our techniques

Collapse-binding commitments. To explain the definition of collapse-binding commitments, first consider a perfectly-binding commitment. That is, when an adversary A outputs a commitment c, there is only one possible message  $m_c$  that A can open c to. Hence, if the adversary A outputs a superposition of messages that he can open c to, that superposition will necessarily be in the state  $|m_c\rangle$ . Hence, we can characterize perfectly-binding commitments by requiring: when an adversary outputs a superposition of messages that he can open the commitment c to, that superposition will necessarily be a single computational basis vector (i.e., no non-trivial superposition).

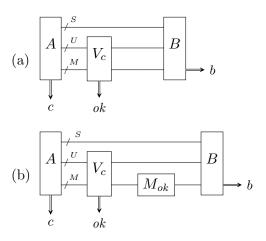

Figure 1: Games from the definition of collapse-binding commitments.

To express this more formally, consider the circuit in Figure 1 (a). Here the adversary A outputs a commitment c (classical message). Furthermore, he outputs three quantum registers S, U, M. S contains his state. M is supposed to contain a superposition of messages, U a superposition of corresponding opening informations. Then we apply the measurement  $V_c$ . This measurement measures

whether U, M contain matching opening information/message. More formally,  $V_c$  measures whether U, M is a superposition of states  $|u, m\rangle$  such that u is valid opening information for message m and commitment c. Let ok = 1 if the measurement succeeds. Then we feed the registers S, U, M back to the second part B of the adversary. B outputs a classical bit b. As discussed before, a commitment is perfectly-binding iff for all adversaries A, the state of M after measuring ok = 1 is a computational basis vector.

The state of a register is a computational basis vector (or, synonymously: is in a collapsed state) iff measuring that register in the computational basis does not change that state. Consider the circuit in Figure 1 (b). Here we added a measurement  $M_{ok}$  on M after  $V_c$ .  $M_{ok}$  is a complete measurement in the computational basis, but is executed only if ok = 1. Since  $M_{ok}$  disturbs the state of M iff that state is not a computational basis vector, we can rephrase the definition of perfectly-binding commitments:

A commitment is perfectly-binding iff, for all computationally unlimited adversaries  $A, B, \Pr[b=1]$  is equal in Figures 1 (a) and 1 (b) where b is the output (i.e., guess) of B.<sup>3</sup> Now we are ready to weaken this characterization to get a computational binding prop-

Now we are ready to weaken this characterization to get a computational binding property. Basically, we require that the same holds for quantum-polynomial-time adversaries:

**Definition 7 (Collapse-binding – informal)** A commitment is collapse-binding iff, for all quantum-polynomial-time adversaries  $A, B, \Pr[b=1]$  in Figure 1 (a) is negligibly close to  $\Pr[b=1]$  in Figure 1 (b).

In other words, with a perfectly-binding commitment, the adversary cannot produce a superposition of different messages that are contained in the commitment. But with a collapse-binding commitment, the adversary is forced to produce a state that looks like it is not a superposition of different messages. For the purpose of computational security, this will often be as good.

We quickly explain why collapse-binding commitments work well with quantum rewinding. In the case of quantum rewinding (e.g., in the analysis of proofs of knowledge [Unr12]), one problem is that we might need to run an adversary until he opens a commitment c, then to measure the opened message, and then to go back to an earlier state by applying the inverse of the adversary. The problem is that measuring the opened message will disturb the state of the adversary, and thus make rewinding impossible. Except: if the opened message cannot be distinguished from being already in a collapsed state (as guaranteed by collapse-binding), then measuring the opened message does not disturb the state in a noticeable way and we can rewind. (See the discussion on arguments of knowledge below.)

Constructing collapse-binding commitments. Collapse-binding commitments are useful only if they exist. Perfectly-binding commitments are easily seen to be collapse-binding, but then we cannot have statistically hiding or short commitments. In the classical setting, we get practical computationally-binding commitments from a collision-resistant hash function H. The most obvious construction is to send c := H(m||u) for

<sup>&</sup>lt;sup>3</sup>Our exposition above was not very rigorous, but it is easy to see that this is indeed an "if and only if".

uniformly random u of suitable length. We call this the "canonical commitment". The canonical commitment is easily seen to be classical-style binding if H is collision-resistant, and it is statistically hiding if H is a random oracle. To get rid of the random-oracle requirement, we can use a somewhat more complex constructions by Halevi and Micali [HM96] instead. Unfortunately, both the canonical commitment and the Halevi-Micali commitments are not collapse-binding if H is merely collision-resistant. In fact, relative to a specific oracle and using a specific collision-resistant hash function, there is a total break where the adversary can unveil the commitment to any message of his chosing. To show this, we tweak the technique from [ARU14] to construct a hash function H such that the adversary can sample an image c of d together with a quantum state  $|\Psi\rangle$  such that: Given the state  $|\Psi\rangle$ , for any d, the adversary can find a random d with d with d and d is the process destroys d is the canonical commitment, based on this d is trivially broken. Similar constructions break the Halevi-Micali commitments.

Since collision-resistance seems too weak a property in the quantum setting (at least for our purposes), we give a strengthening of collision-resistance: collapsing hash functions:

**Definition 8 (Collapsing hash function** – **informal)** An adversary is valid if he outputs a classical value c, and a register M containing a superposition of messages m with H(m) = c. We call H collapsing iff no quantum-polynomial-time adversary can distinguish whether we measure M in the computational basis or not, before giving the register M back to the adversary. (This is formalized with games similar to those in Figure 1.)

We can show that collapsing hash functions are collision-resistant, and they share a number of structural properties with collision-resistant functions. E.g., injective functions are collapsing, and the composition  $H \circ H'$  of collapsing functions is collapsing.

Due to the similarity between the definition of collapsing hash functions and collapse-binding commitments, we can show that the canonical commitment and the Halevi-Micali commitments are collapse-binding if H is collapsing.

However, this leaves the question: do collapsing functions exist in the first place? We conjecture that common industrial hash function like SHA3 [NIS14] are actually collapsing (not only collision-resistant). In fact, we argue that the collapsing property should be a requirement for the design of future hash functions (in the sense that a hash function where the collapsing property is in doubt should not be selected for industry standards), since collision-resistance is not sufficient if we wish to achieve post-quantum secure cryptography. We support our conjecture that sufficiently unstructured functions are collapsing by proving that the random oracle is collapsing:

Random oracles are collapsing. We now sketch on a high level our proof that random oracles are collapsing, or, equivalently, that a random function is collapsing with high probability. In our analysis, we assume that the adversary can query the random oracle on the superposition of different inputs; this is necessary for having a

realistic modeling of hash functions [BDF<sup>+</sup>11]. As a first step, we identify a new property, "half-collision resistance":

**Definition 9 (Half-collision resistance** – **informal)** A half-collision of H is a string x such that there exists an  $x' \neq x$  with H(x') = H(x). A hash function H is half-collision resistant if no adversary does the following: He outputs a half-collision with non-negligible probability. And he never outputs a non-half-collision. (The adversary may output  $\bot$  though.)

That is, half-collision resistance says that the adversary cannot find non-injective inputs to H without sometimes accidentally outputting injective inputs. We show: if H is half-collision resistant, it is collapsing.

The proof idea is: if H is not collapsing, the adversary can produce a superposition M of messages m with H(m) = c and notice whether M is being measured. The latter implies that M must be a superposition of at least two messages m with H(m) = c. Hence by measuring M, the adversary gets a half-collision. Much additional work is needed to make sure that the adversary does not accidentally measure the register M when it is not a nontrivial superposition.

(The half-collision resistance property might be useful independent of the proof that the random oracle is collapsing. When trying to construct collapsing hash functions based on other assumptions, half-collision resistance might be easier to verify since its definition consists of purely classical games.)

Next we construct a random function  $H^*: X \to Y$  with  $|Y| = \frac{2}{3}|X|$ . That is,  $H^*$  is slightly compressing. The domain of  $H^*$  is partitioned into two sets  $X_1, X_2$  with  $|X_1| = 2|X_2|$ .  $H^*$  is injective on  $X_2$ , and 2-to-1 on  $X_1$ . Besides those constraints,  $H^*$  is uniformly random. We can then show that  $H^*$  is half-collision resistant. (Basically, this means that the adversary cannot identify the subset  $X_1$ .) Furthermore, we can show that  $H^*$  is indistinguishable from a random function  $H: X \to Y$ . The latter fact is shown by step-wise rewriting of the definition of  $H^*$  until we reach H (crucially using the fact that random functions and random injections are indistinguishable [Zha15]). Since  $H^*$  is half-collision resistant, it is collapsing. And since H is indistinguishable from  $H^*$ , H is collapsing.

We now know that random functions  $H: X \to Y$  are collapsing if  $|Y| = \frac{2}{3}|X|$  (i.e., if they are slightly compressing). However, we want that H is collapsing for arbitrary X and Y, as long as Y has superpolynomial size. For  $|X| \le |Y|$ , H is indistinguishable from a random injection, which in turn is collapsing. The interesting case is |X| > |Y| (namely, when H is compressing). In this case, we show (following an idea from [Zha15]) that H can be written as  $H = f_n \circ \cdots \circ f_1$  where all  $f_i$  are slightly compressing. (Some technical care is needed when |Y|/|X| is not a power of  $\frac{2}{3}$ .) Since all  $f_i$  are collapsing, so is H. This shows that a random function H is collapsing, in other words, that the random oracle is collapsing (if its range has superpolynomial size).

Quantum arguments of knowledge. We illustrate the use of collapse-binding commitments by revisiting the construction of proofs of knowledge from Unruh [Unr12].

Unruh showed that a sigma-protocol (i.e., a particular kind of three round proof system) is a quantum proof of knowledge if it has two properties: special soundness (from two interactions with the same first and different second messages one can efficiently compute a witness) and strict soundness (the first and second message of a valid interaction determine the third). In the classical setting, only special soundness is needed. In the quantum setting, strict soundness is additionally required to allow for quantum rewinding: In the proof from [Unr12], we run the malicious prover to get his response (the third message). Then we measure the response. Then we rewind the prover (by applying the inverse of the unitary transformation representing the prover). Then we run the prover again to get a second answer. Special soundness then implies that from the two responses, we get a witness. However, we need to make sure that measuring the prover's response before rewinding does not disturb the state (too much). In [Unr12], this follows from strict soundness: strict soundness guarantees that the response is uniquely determined, and thus measuring the response does not disturb the state. To achieve strict soundness, [Unr12] lets the prover commit to all possible responses in the first message using perfectly-binding commitments.<sup>4</sup> The drawback of this solution is that the commitments cannot be statistically hiding, so we cannot get statistical zero-knowledge proofs using the method from [Unr12].

What happens if we replace the perfectly-binding commitments by collapse-binding commitments containing the response? In that case, the response will not necessarily be information-theoretically determined by the first two messages. However, the definition of collapse-binding commitments guarantees that measuring that response will be indistinguishable from not measuring it. Thus, if we measure the response, the state might be disturbed, but it will be computationally indistinguishable from not being disturbed. This is enough for the proof technique from [Unr12] to go through when using collapse-binding commitments, assuming the prover is computationally limited. The resulting protocol will not be a quantum proof of knowledge, but a quantum argument of knowledge (i.e., secure only against computationally limited provers). But in contrast to [Unr12], the proof system will be statistical zero-knowledge.

To summarize: from collapse-binding commitments (or from collapsing hash functions), we get three-round statistical zero-knowledge quantum arguments of knowledge for all languages in NP (with inverse polynomial knowledge error). To the best of our knowledge, not even three-round statistical zero-knowledge quantum arguments were known before.

### 1.4 Related work.

Commitments. Brassard, Crépeau, Jozsa, and Langlois [BCJL93] presented an information-theoretically hiding and binding commitment scheme using quantum communication. However, the protocol was flawed, Mayers [May97] showed that information-theoretically hiding and binding commitments are impossible. (This is no contradiction to our results, because our commitments are not information-theoretically binding.) Dumais, Mayers, and Salvail [DMS00] and Crépeau, Légaré, and Salvail [CLS01] constructed

<sup>&</sup>lt;sup>4</sup>Actually, "strict-binding commitments" but this distinction is not relevant for this exposition.

statistically hiding commitments from quantum one-way permutations/functions, respectively. Their protocols use quantum communication, and are sum-binding. Crépeau, Dumais, Mayers, and Salvail [CDMS04] generalized the sum-binding definition to string commitments and constructed an OT protocol based on that definition. (However, it is not known whether the protocol composes even sequentially.) Damgård, Fehr, Lunemann, Salvail, and Schaffner [DFL+09] and Unruh [Unr10] showed a much simpler OT protocol to be secure, assuming much stronger commitment definitions in the CRS model, but achieving stronger security notions (sequential composability/UC). Ambainis, Rosmanis, and Unruh [ARU14] show that classical-style binding commitments are not necessarily even sum-binding.

Quantum random oracles. Random oracles were first explicitly considered in a quantum cryptographic context by Boneh, Dagdelen, Fischlin, Lehmann, Schaffner, and Zhandry [BDF+11] who stressed that the adversary should have superposition access to the random oracle. Zhandry [Zha15] showed that the random oracle is collision-resistant. In contrast, we show (based on his result) that the random oracle is collapsing (a stronger property).

Quantum rewinding and proof systems. Watrous [Wat09] showed how quantum rewinding can be used to prove the security of quantum zero-knowledge protocols. Unruh [Unr12] showed how a different flavor of quantum rewinding can be used for proving the security of quantum proofs of knowledge; we extend their technique to quantum arguments of knowledge. Unruh [Unr15a] constructs non-interactive computational zero-knowledge quantum arguments of knowledge in the random oracle model.

# 2 Definitions and basic properties

**Preliminaries.** For the necessary background in quantum computing, see, e.g., [NC10]. By  $|i\rangle$  with  $i\in I$  we denote the vectors of the computational basis of the Hilbert space with dimension |I|. We also use the symbol  $|\cdot\rangle$  to refer to other (non-basis) vectors (e.g.,  $|\Psi\rangle$ ). And  $\langle\Psi|$  is the conjugate transpose of  $|\Psi\rangle$ . ||x|| refers to the Euclidean or  $\ell^2$ -norm. We only consider finite dimensional Hilbert spaces. We denote  $|+\rangle:=\frac{1}{\sqrt{2}}|0\rangle+\frac{1}{\sqrt{2}}|1\rangle$  and  $|-\rangle:=\frac{1}{\sqrt{2}}|0\rangle-\frac{1}{\sqrt{2}}|1\rangle$ . For a linear operator A on a Hilbert space, we denote by  $A^{\dagger}$  its conjugate transpose. We denote by I the identity. We call an operator A on a Hilbert space a projector iff it is an orthogonal projector, i.e., a linear map with  $P^2=P$  and  $P=P^{\dagger}$ . By  $\mathrm{TD}(\rho,\rho')$  we denote the trace distance between  $\rho$  and  $\rho'$ , and by  $F(\rho,\rho')$  the fidelity.

Given an algorithm A, let  $x \leftarrow A(y)$  denote the result of running A with inputs y, and assigning the output to x. Let  $x \stackrel{\$}{\leftarrow} M$  denote assigning a uniformly random element of M to x. We will use  $\eta$  to denote the security parameter, that is a positive integer that will be passed to all algorithms and adversaries and that indicates the required security level. By  $a \parallel b$  we denote the concatenation of bitstrings a and b.

We call an algorithm quantum-polynomial-time if it is a quantum algorithm and its runtime is bounded by a polynomial in its input length with probability 1. We call an algorithm classical-polynomial-time if it performs only classical operations and its runtime is bounded by a polynomial in its input length with probability 1. We write  $1^{\eta}$  for a bitstring (of 1's) of length  $\eta$ . (The latter is useful for making algorithms run in polynomial-time in the length of the security parameter, e.g.,  $A(1^{\eta})$  will run polynomial-time in  $\eta$ .)

Commitments. A commitment scheme (com, verify) consists of a quantum-polynomial-time algorithm com and a deterministic quantum-polynomial-time algorithm verify.  $(c,u) \leftarrow com(1^{\eta},m)$  returns a commitment c and the opening information u for the message m and security parameter  $\eta$ . c alone is supposed not to reveal anything about m (hiding). To open, we send (m,u) to the recipient who checks whether  $verify(1^{\eta},c,m,u)=1$ . Both com and verify have classical input and output. com has a well-defined message space  $MSP_{\eta}$  that also depends on the security parameter  $\eta$  (e.g.,  $\{0,1\}^{\eta}$ ). Furthermore, for technical reasons, we assume that it is possible to find triples (c,m,u) with  $verify(1^{\eta},c,m,u)=1$  with probability 1 in quantum-polynomial-time in  $\eta$ . We first state some standard properties of commitments.

**Definition 10** Let (com, verify) be a commitment scheme. We define:

- **Perfect completeness:** (com, verify) has perfect completeness iff for all  $m \in MSP_{\eta}$ ,  $Pr[verify(1^{\eta}, c, m, u) = 1 : (c, u) \leftarrow com(1^{\eta}, m)] = 1$ .
- Computational hiding: (com, verify) is computationally hiding iff for any quantum-polynomial-time A and any polynomial  $\ell$ , there is a negligible  $\mu$  such that for any  $\eta$ , any  $m_0, m_1 \in \mathsf{MSP}_{\eta}$  with  $|m_0|, |m_1| \leq \ell(\eta)$ , and any  $|\Psi\rangle$ ,  $|P_0 P_1| \leq \mu(\eta)$  where  $P_i := \Pr[b = 1 : (c, u) \leftarrow com(1^{\eta}, m_i), b \leftarrow A(1^{\eta}, |\Psi\rangle, c)]$ .
- Statistical hiding: Like computational hiding, except that we quantify over all A (not just quantum-polynomial-time A).

**Definition 11 (Classical-style binding)** A commitment scheme is classical-style binding iff for any quantum-polynomial-time algorithm A, the following is negligible in  $\eta$ :

$$\Pr[verify(1^{\eta}, c, m, u) = 1 \land verify(1^{\eta}, c, m', u') = 1 \land m \neq m' : (c, m, u, m', u') \leftarrow A(1^{\eta})]$$

<sup>&</sup>lt;sup>5</sup>To be practical, those algorithms should of course be classical. We allow quantum-polynomial-time algorithms here to state our results in greater generality.

<sup>&</sup>lt;sup>6</sup>This technical condition is necessary, e.g., for Definition 13 below. Without this condition, it is not clear that "valid" adversaries exist at all. Note that a commitment scheme with quantum-polynomial-time com and perfect completeness will always satisfies this technical condition: to find c, m, u, simply set m := 0 and compute  $(m, u) \leftarrow com(1^{\eta}, m)$ .

 $<sup>^{7}|\</sup>Psi\rangle$  is the auxiliary input of A that represents knowledge of A acquired, e.g., in prior protocol runs. One could use a mixed state instead, this would lead to an equivalent definition.

**Definition 12 (Collapse-binding)** For algorithms A, B, consider the following games:

$$\begin{aligned} \mathsf{Game}_1: \quad & (S,M,U,c) \leftarrow A(1^\eta), \ ok \leftarrow V_c(M,U), \ m \leftarrow M_{ok}(M), \ b \leftarrow B(1^\eta,S,M,U) \\ \mathsf{Game}_2: \quad & (S,M,U,c) \leftarrow A(1^\eta), \ ok \leftarrow V_c(M,U), \\ \end{aligned}$$

Here S, M, U are quantum registers.  $V_c$  is a measurement whether M, U contains a valid opening, formally  $V_c$  is defined through the projector  $\sum_{\substack{m,u \ verify(1^\eta,c,m,u)=1}} |m\rangle\langle m|\otimes |u\rangle\langle u|$ .  $M_{ok}$  is a measurement of M in the computational basis if ok=1, and does nothing if ok=0 (i.e., it sets  $m:=\bot$  and does not touch the register M).

A commitment scheme is collapse-binding iff for any quantum-polynomial-time algorithms A, B, the difference  $|\Pr[b=1:\mathsf{Game}_1] - \Pr[b=1:\mathsf{Game}_2]|$  is negligible.

Instead of measuring using  $V_c$  whether the adversary outputs a correct opening information, we can quantify only over adversaries that always output correct opening information. This leads to the following equivalent definition of collapse-binding commitments. This definition is often easier to handle when proving that a given scheme is collapse-binding.

**Definition 13 (Collapse-binding** – variant) For algorithms A, B, consider the following games:

$$\begin{aligned} \mathsf{Game}_1: \quad & (S,M,U,c) \leftarrow A(1^{\eta}), \ m \leftarrow M_{comp}(M), \ b \leftarrow B(1^{\eta},S,M,U) \\ \mathsf{Game}_2: \quad & (S,M,U,c) \leftarrow A(1^{\eta}), \qquad \qquad b \leftarrow B(1^{\eta},S,M,U) \end{aligned}$$

Here S, M, U are quantum registers.  $M_{comp}(M)$  is a measurement of M in the computational basis.

We call an adversary (A, B) valid if  $\Pr[verify(c, m, u) = 1] = 1$  when running  $(S, M, U, c) \leftarrow A(1^{\eta})$  and measuring M, U in the computational basis to obtain m, u.

A commitment scheme is collapse-binding iff for any quantum-polynomial-time valid adversary (A,B), the difference  $\left|\Pr[b=1:\mathsf{Game}_1]-\Pr[b=1:\mathsf{Game}_2]\right|$  is negligible.

**Lemma 14** A commitment scheme (com, verify) is collapse-binding with respect to Definition 12 iff it is collapse-binding with respect to Definition 13.

*Proof.* To avoid confusion, we call the games from Definition 12  $\mathsf{Game}_1$ ,  $\mathsf{Game}_2$ , while we call those from Definition 13  $\mathsf{Game}_1'$ ,  $\mathsf{Game}_2'$ . And the adversary in Definition 13 (that is used in  $\mathsf{Game}_1'$ ,  $\mathsf{Game}_2'$ ) we call (A', B').

First, assume that there is an adversary (A', B') breaking Definition 13, i.e.,  $\mu := |\Pr[b=1:\mathsf{Game}_1'] - \Pr[b=1:\mathsf{Game}_2']|$  is non-negligible. Let (A,B) := (A',B'). By definition of validity, the measurement  $V_c$  from Definition 12 will succeed with probability 1 in  $\mathsf{Game}_1$  and  $\mathsf{Game}_2$ . Hence that measurement has no effect, and thus  $\Pr[b=1:\mathsf{Game}_1] = \Pr[b=1:\mathsf{Game}_1']$  and  $\Pr[b=1:\mathsf{Game}_2] = \Pr[b=1:\mathsf{Game}_2']$ . Thus  $|\Pr[b=1:\mathsf{Game}_1'] - \Pr[b=1:\mathsf{Game}_2']| = \mu$  is non-negligible. Thus (A,B) also breaks Definition 12.

Now, consider an adversary (A,B) breaking Definition 12, i.e.,  $\nu := |\Pr[b=1: \mathsf{Game}_1] - \Pr[b=1: \mathsf{Game}_2]|$  is non-negligible. Construct (A',B') as follows:  $A'(1^\eta)$  runs  $(S,M,U,c) \leftarrow A(1^\eta)$ . Then it applies  $ok \leftarrow V_c(M,U)$ . If ok=1, A' returns (S,M,U,c). Otherwise, A' picks (c,m,u) with  $verify(1^\eta,c,m,u)=1$ ,8 initializes M,U with  $|m\rangle|u\rangle$ , and S with  $|\bot\rangle$ , and outputs c. (We assume that  $|\bot\rangle$  is orthogonal to any state that A would produce.) And B' does the following: If ok=0, then B' outputs 0. If ok=1, B' executes B.

A' is valid by construction: If ok = 1,  $verify(1^{\eta}, c, m, u) = 1$  with probability 1 when measuring M, U as m, u, because M, U is in the image of  $V_c$ . And if ok = 0,  $verify(1^{\eta}, c, m, u) = 1$  by choice of c, m, u.

We easily see that

$$\begin{split} 0 &= \Pr[b = 1 : \mathsf{Game}_1'|ok = 0] = \Pr[b = 1 : \mathsf{Game}_2'|ok = 0] = 0 \\ \alpha &:= \Pr[b = 1 : \mathsf{Game}_1|ok = 0] = \Pr[b = 1 : \mathsf{Game}_2|ok = 0] \\ \beta &:= \Pr[b = 1 : \mathsf{Game}_1|ok = 1] = \Pr[b = 1 : \mathsf{Game}_1'|ok = 1] \\ \gamma &:= \Pr[b = 1 : \mathsf{Game}_2|ok = 1] = \Pr[b = 1 : \mathsf{Game}_2'|ok = 1] \\ \delta &:= \Pr[ok = 1 : \mathsf{Game}_1] = \Pr[ok = 1 : \mathsf{Game}_1'] \\ &= \Pr[ok = 1 : \mathsf{Game}_2] = \Pr[ok = 1 : \mathsf{Game}_2'] \end{split}$$

and from this we calculate

$$\begin{split} \left| \Pr[b = 1 : \mathsf{Game}_1'] - \Pr[b = 1 : \mathsf{Game}_2'] \right| \\ &= \left| \left( 0(1 - \delta) + \beta \delta \right) - \left( 0(1 - \delta) + \gamma \delta \right) \right| = \left| \left( \alpha(1 - \delta) + \beta \delta \right) - \left( \alpha(1 - \delta) + \gamma \delta \right) \right| \\ &= \left| \Pr[b = 1 : \mathsf{Game}_1] - \Pr[b = 1 : \mathsf{Game}_2] \right| = \nu \end{split}$$

which is non-negligible. Thus (A', B') breaks Definition 13.

Definition 12 guarantees that the adversary cannot distinguish whether the register M is measured or not. However, it is not immediately obvious what happens when we measure M partially (e.g., we measure just one qubit). Could it be that such a partial measurement will be noticed? We expect that this is not the case, since a partial measurement lies half-way between no measurement and a complete measurement. The following lemma confirms that intuition: If a commitment scheme is collapse-binding, then Definition 12 also holds for partial measurements. (Assuming that the partial measurement is performed in the computational basis and can be implemented by a polynomial-time circuit.)

Lemma 15 (Collapse-binding w.r.t. partial measurements) For a commitment scheme (com, verify), and for algorithms A, B, consider the following games:

$$\begin{aligned} \mathsf{Game}_1: \quad & (S,M,U,c,f) \leftarrow A(1^\eta), \ ok \leftarrow V_c(M,U), \ x \leftarrow M_{ok}^f(M), \ b \leftarrow B(1^\eta,S,M,U) \\ \mathsf{Game}_2: \quad & (S,M,U,c,f) \leftarrow A(1^\eta), \ ok \leftarrow V_c(M,U), \\ \end{aligned}$$

<sup>&</sup>lt;sup>8</sup>This is efficiently possible with probability 1 by assumption, see page 14.

Here f is a Boolean circuit (with multiple-bit output).  $V_c$  is as in Definition 12.  $M_{ok}^f$  is a measurement of M that returns f(m) where m is the content of M if ok = 1, and does nothing if ok = 0 (i.e., it sets  $m := \bot$  and does not touch the register M). More formally, if ok = 1,  $M_f$  is the measurement defined by the projectors  $P_x := \sum_{m: f(m) = x} |m\rangle\langle m|$  for all x in the range of f, and if ok = 0,  $M_f$  is defined by the single projector  $P_\bot := I$ .

If (com, verify) is collapse-binding, then for any quantum-polynomial-time adversary (A, B), the difference  $|\Pr[b = 1 : \mathsf{Game}_1] - \Pr[b = 1 : \mathsf{Game}_2]|$  is negligible.

*Proof.* We start with  $\mathsf{Game}_1$ . It is easy to see that  $V_c$  and  $M_{ok}^f$  commute, and that  $V_c$  is idempotent. Thus  $\Pr[b=1:\mathsf{Game}_1]=\Pr[b=1:\mathsf{Game}_3]$  with:

$$\mathsf{Game}_3: \quad (S, M, U, c, f) \leftarrow A, \ ok' \leftarrow V_c, \ x \leftarrow M_{ok'}^f, \ ok \leftarrow V_c, \ b \leftarrow B$$

(We omit the inputs of the various algorithms and measurements since they are unchanged throughout the proof.) If we consider the first three operations  $(A, V_c, M_{ok'}^f)$  as a single adversary, we can apply the collapse-binding property of com. Thus  $|\Pr[b=1:\mathsf{Game}_3] - \Pr[b=1:\mathsf{Game}_4]| = \varepsilon_1$  for some negligible  $\varepsilon_1$  with:

$$\mathsf{Game}_4: \quad (S, M, U, c, f) \leftarrow A, \ ok' \leftarrow V_c, \ x \leftarrow M_{ok'}^f, \ ok \leftarrow V_c, \ m \leftarrow M_{ok}, \ b \leftarrow B$$

We can see that  $V_c, M_{ok'}^f, M_{ok}$  all commute. Furthermore  $V_c$  is idempotent, so we get  $\Pr[b=1:\mathsf{Game}_4]=\Pr[b=1:\mathsf{Game}_5]$  with:

Game<sub>5</sub>: 
$$(S, M, U, c, f) \leftarrow A$$
,  $ok \leftarrow V_c$ ,  $m \leftarrow M_{ok}$ ,  $x \leftarrow M_{ok}^f$ ,  $b \leftarrow B$ 

(Note that we replace  $M_{ok'}^f$  by  $M_{ok}^f$ .) The outcome of  $M_{ok}^f$  is determined by the outcome of  $M_{ok}$ , we have  $\Pr[b=1:\mathsf{Game}_5]=\Pr[b=1:\mathsf{Game}_6]$  with:

$$\mathsf{Game}_6: \quad (S, M, U, c, f) \leftarrow A, \ ok \leftarrow V_c, \ m \leftarrow M_{ok}, \ b \leftarrow B$$

Since (com, verify) is collapse-binding, we get  $|\Pr[b = 1 : \mathsf{Game}_6] - \Pr[b = 1 : \mathsf{Game}_2]| = \varepsilon_2$  for negligible  $\varepsilon_2$ .

Thus, summarizing, 
$$|\Pr[b=1:\mathsf{Game}_1] - \Pr[b=1:\mathsf{Game}_2]| \leq \varepsilon_1 + \varepsilon_2$$
 is negligible.  $\square$ 

Another question that naturally arises is whether collapse-binding commitments parallel compose. That is, if we commit to values  $m_1, \ldots, m_n$  with n commitments, does this give a collapse-binding commitment on  $m := (m_1, \ldots, m_n)$ ? Note that such a property is not obvious. For example, to the best of our knowledge, no prior definition of a quantum computational binding property in the literature is known to have this property. For collapse-binding commitments, however, the next lemma shows that the parallel composition of several commitments is still collapse-binding.

**Lemma 16 (Parallel composition)** Let (com, verify) be a collapse-binding commitment with message space M. Let  $n = n(\eta)$  be polynomially-bounded and quantum-polynomial-time computable integer.

Let  $(com^n, verify^n)$  be the n-fold parallel composition of (com, verify). That is, its message space is  $M^p$ . And  $com^n(m_1, \ldots, m_n)$  computes  $(c_i, u_i) \leftarrow com(m_i)$  for  $i = 1, \ldots, n$ , and returns (c, u) with  $c := (c_1, \ldots, c_n)$  and  $u := (u_1, \ldots, u_n)$ . And  $verify^n((c_1, \ldots, c_n), (m_1, \ldots, m_n), (u_1, \ldots, u_n)) = 1$  iff  $\forall i. verify(c_i, m_i, u_i) = 1$ . Then  $(com^n, verify^n)$  is collapse-binding.

*Proof.* By Lemma 14, to show that  $(com^n, verify^n)$  is collapse-binding, we need to show that for any valid adversary A against  $(com^n, verify^n)$ ,  $|\Pr[b = 1 : \mathsf{Game}_1] - \Pr[b = 1 : \mathsf{Game}_2]$  is negligible, with  $\mathsf{Game}_1$ ,  $\mathsf{Game}_2$  as follows:

$$\mathsf{Game}_1: \quad (S, M, U, c) \leftarrow A(1^{\eta}), \ m \leftarrow M_{comp}(M), \ b \leftarrow B(1^{\eta}, S, M, U)$$
$$\mathsf{Game}_2: \quad (S, M, U, c) \leftarrow A(1^{\eta}), \qquad b \leftarrow B(1^{\eta}, S, M, U)$$

Using the definition of  $(com^n, verify^n)$ , this is equivalent to:

$$\begin{aligned} \mathsf{Game}_1: & & (S, M_1, \dots, M_n, U_1, \dots, U_n, c_1, \dots, c_n) \leftarrow A(1^{\eta}), \\ & & m_i \leftarrow M_{comp}(M_i) \text{ for } i = 1, \dots, n, \\ & & b \leftarrow B(1^{\eta}, S, M_1, \dots, M_n, U_1, \dots, U_n) \end{aligned}$$
 
$$\mathsf{Game}_2: & & (S, M_1, \dots, M_n, U_1, \dots, U_n, c_1, \dots, c_n) \leftarrow A(1^{\eta}), \\ & & b \leftarrow B(1^{\eta}, S, M_1, \dots, M_n, U_1, \dots, U_n) \end{aligned}$$

And the validity of A implies for all i that measuring  $M_i$ ,  $U_i$  will always return  $m_i$ ,  $u_i$  with  $verify(c_i, m_i, u_i) = 1$ .

We define hybrid games for i = 0, ..., n:

$$\mathsf{Hyb}_j: \quad (S, M_1, \dots, M_n, U_1, \dots, U_n, c_1, \dots, c_n) \leftarrow A(1^{\eta}),$$

$$m_i \leftarrow M_{comp}(M_i) \text{ for } i = 1, \dots, j,$$

$$b \leftarrow B(1^{\eta}, S, M_1, \dots, M_n, U_1, \dots, U_n)$$

Note that in  $\mathsf{Hyb}_j$ , only  $M_1, \ldots, M_j$  are measured.  $M_{j+1}, \ldots, M_n$  are untouched. We immediately have

$$\Pr[b = 1 : \mathsf{Game}_1] = \Pr[b = 1 : \mathsf{Hyb}_n], \qquad \Pr[b = 1 : \mathsf{Game}_2] = \Pr[b = 1 : \mathsf{Hyb}_0].$$
 (1)

We define a new adversary (A', B') for (com, verify) as follows:  $A'(1^{\eta})$  picks  $j \stackrel{\$}{\leftarrow} \{1, \ldots, n\}$ . Then he executes  $(S, M_1, \ldots, M_n, U_1, \ldots, U_n, c_1, \ldots, c_n) \leftarrow A(1^{\eta})$ . He measures  $m_i \leftarrow M_{comp}(M_i)$  for  $i = 1, \ldots, j-1$ , and then sets

$$S' := (j, S, M_1, \dots, M_{j-1}, M_{j+1}, \dots, M_n, U_1, \dots, U_{j-1}, U_{j+1}, \dots, U_n)$$

and  $M:=M_j$  and  $U:=U_j$  and  $c:=c_j$  and returns (S',M,U,c). And  $B'(1^{\eta},S',M,U)$  splits S' again into  $(j,S,M_1,\ldots,M_{j-1},M_{j+1},\ldots,M_n,U_1,\ldots,U_{j-1},U_{j+1},\ldots,U_n)$  and lets  $M_j:=M$  and  $U_j:=U$  and runs  $B(1^{\eta},S,M_1,\ldots,M_n,U_1,\ldots,U_n)$ .

As mentioned above, since A is valid for each i, measuring  $M_i, U_i$  returns  $m_i, u_i$  with  $verify(1^{\eta}, c_i, m_i, u_i) = 1$ . Hence measuring M, U as output by A' returns m, u with  $verify(1^{\eta}, c, m, u) = 1$ . Thus A' is valid for (com, verify).

Thus  $|\Pr[b=1:\mathsf{Game}_1'] - \Pr[b=1:\mathsf{Game}_2']|$  is negligible where  $\mathsf{Game}_1',\mathsf{Game}_2'$  are as follows:

$$\begin{aligned} \mathsf{Game}_1': \quad & (S',M,U,c) \leftarrow A(1^\eta), \ m \leftarrow M_{comp}(M), \ b \leftarrow B(1^\eta,S',M,U) \\ \mathsf{Game}_2': \quad & (S',M,U,c) \leftarrow A(1^\eta), \qquad \qquad b \leftarrow B(1^\eta,S',M,U) \end{aligned}$$

For any fixed choice of j,  $\mathsf{Game}_1'$  is the same as  $\mathsf{Hyb}_j$ , and  $\mathsf{Game}_2'$  is the same as  $\mathsf{Hyb}_{j-1}$ . Thus

$$\begin{split} \Pr[b = 1: \mathsf{Game}_1'] &= \sum_{j=1}^n \frac{1}{n} \Pr[b = 1: \mathsf{Hyb}_j], \\ \Pr[b = 1: \mathsf{Game}_1'] &= \sum_{j=1}^n \frac{1}{n} \Pr[b = 1: \mathsf{Hyb}_{j-1}]. \end{split} \tag{2}$$

Hence

$$\begin{split} &\left|\Pr[b=1:\mathsf{Game}_1'] - \Pr[b=1:\mathsf{Game}_2']\right| \\ &\stackrel{\scriptscriptstyle(2)}{=} \frac{1}{n} \left|\Pr[b=1:\mathsf{Hyb}_n] - \Pr[b=1:\mathsf{Hyb}_0]\right| \\ &\stackrel{\scriptscriptstyle(1)}{=} \frac{1}{n} \left|\Pr[b=1:\mathsf{Game}_1] - \Pr[b=1:\mathsf{Game}_2]\right| \end{split} \tag{3}$$

We showed above that the lhs of (3) is negligible. Thus the rhs of (3) is negligible, too. Since n is polynomially-bounded in  $\eta$ , this implies that  $|\Pr[b=1:\mathsf{Game}_1] - \Pr[b=1:\mathsf{Game}_2]|$  is negligible as well. As stated in the beginning of this proof, this implies that  $(com^n, verify^n)$  is collapse-binding.

## 3 Commitments from collision-resistant hash functions

In the following, we will often refer to hash functions. We will always assume that a hash function depends implicitly on the security parameter (in particular, the size of the range can depend on the security parameter). We also assume that the hash function is quantum-polynomial-time computable (in  $\eta$  and the input length). Besides that, we do not assume any further properties such as collision-resistance unless explicitly mentioned.

**Definition 17 (Canonical commitment scheme)** Given a hash function H and a parameter  $\ell_u = \ell_u(\eta)$ , the canonical commitment scheme for H is:

- Message space  $MSP_{\eta} := \{0, 1\}^*$ .
- $com_{can}(m)$ :  $Pick\ u \stackrel{\$}{\leftarrow} \{0,1\}^{\ell_u}$ .  $Compute\ c := H(m||u)$ .  $Return\ (c,u)$ .
- $verify_{can}(c, m, u)$ : Return 1 iff H(m||u) = c.

 $<sup>^9\</sup>mathrm{When}$  working in the random oracle model: Quantum-polynomial-time computable given access to the random oracle.

It is immediate to see that this scheme is classical-style binding if H is collision-resistant. However, in general it will not be hiding; for example, H(m||u) could leak the first bit of m. However, it is hiding if H is a random oracle:

**Lemma 18** Fix  $\ell_u \geq 0$  and assume that  $|Y| \leq 2^{\ell_u/8}$ . For a random oracle  $H: X \to Y$ , the canonical commitment is statistically hiding.

*Proof.* This lemma was proven in [Pas04, Lemma 9]. The statement of the lemma there additionally assumes that the message space of the canonical commitment is also  $\{0,1\}^{\ell_u}$  (i.e., equal to the space of the randomness u). However, this is never used in the proof. Furthermore, the lemma there assumes that  $|Y| = 2^{\ell_u/8}$ , but the adaption to the case  $|Y| \leq 2^{\ell_u/8}$  is straightforward.

When using a hash function in the standard model, we can use the following commitment scheme instead:

**Definition 19 (Bounded-length Halevi-Micali commitment [HM96])** Fix integers  $\ell = \ell(\eta)$ ,  $n = n(\eta)$ . Let  $L := 4\ell + 2n + 4$ . Let  $H : \{0,1\}^L \to \{0,1\}^\ell$  be a hash function. Let  $F = F(\eta)$  be a family of universal hash functions  $f : \{0,1\}^L \to \{0,1\}^n$ . We define the bounded-length Halevi-Micali commitment  $(com_{HMb}, verify_{HMb})$  with  $MSP_{\eta} = \{0,1\}^n$  as:

- $com_{HMb}(m)$ :  $Pick \ f \in F \ and \ u \in \{0,1\}^L \ uniformly \ at \ random, \ conditioned \ on \ f(u) = m.$  Compute h := H(u). Let c := (h, f). Return (c, u).
- $verify_{HMb}(c, m, u)$  with c = (h, f): Check whether f(u) = m and h = H(u). If so, return 1.

Definition 20 (Unbounded Halevi-Micali commitment [HM96]) Fix an integer  $\ell = \ell(\eta)$ . Let  $H : \{0,1\}^* \to \{0,1\}^{\ell}$  be a hash function. Let  $L := 6\ell + 4$ . Let F be a family of universal hash functions  $f : \{0,1\}^L \to \{0,1\}^{\ell}$ . We define the unbounded Halevi-Micali commitment  $(com_{HMu}, verify_{HMu})$  as:

- $com_{HMu}(m)$ :  $Pick \ f \in F \ and \ u \in \{0,1\}^L \ uniformly \ at \ random, \ conditioned \ on \ f(u) = H(m)$ . Compute h := H(u). Let c := (h, f). Return (c, u).
- $verify_{HMu}(c, m, u)$  with c = (h, f): Check whether f(u) = H(m) and h = H(u). If so, return 1.

**Theorem 21 (Security of Halevi-Micali [HM96])** If  $\ell$  is superlogarithmic, then the Halevi-Micali commitment and the bounded-length Halevi-Micali commitment are statistically hiding. If H is collision-resistant, then the Halevi-Micali commitment and the bounded-length Halevi-Micali commitment are classical-style binding.

Note that [HM96] did not prove the classical-style binding property against quantum adversaries. But the (very simple) proof of binding carries over unchanged to the quantum setting (if H is collision-resistant against quantum adversaries). The statistical hiding property holds against unlimited adversaries anyway, thus also against quantum adversaries.

The following theorem shows that collision-resistance does not seem to be enough to make the above constructions secure in the quantum setting, i.e., classical-style binding is all we get.

**Theorem 22** There is an oracle  $\mathcal{O}$  relative to which there exists a collision-resistant <sup>10</sup> hash function H such that the canonical commitment scheme and both Halevi-Micali commitment schemes using H admit the following attack:

There is a quantum-polynomial-time adversary  $A^{\mathcal{O}}$  that outputs a commitment c, then expects a bit b, and then outputs with overwhelming probability a pair (m, u) such that verify(c, m, u) = 1 and the first bit of m is b.

Clearly, a commitment with that property should not be considered secure. This shows that collision-resistance is too weak a property for constructing commitments in the quantum setting, at least when using standard constructions.

*Proof.* [ARU14, Definition 6] defines a specific oracle  $\mathcal{O}_{all}$  (more precisely, a probability distribution on oracles). We repeat only the parts of the construction that are relevant for our proof: Let  $X := \{0,1\}^{\ell_1}$  and  $Y := \{0,1\}^{\ell_2}$  for some arbitrary polynomially-bounded superlogarithmic  $\ell_1, \ell_2$ . For each  $y \in Y$ , let  $S_y \subseteq X$  be a uniformly random subset of a certain size k. Let  $\mathcal{O}_V$  be an oracle that tests membership in  $S_y$ , more precisely  $\mathcal{O}_V(y,x)=1$  iff  $x\in S_y$ . ( $\mathcal{O}_V$  may be queried in superposition.) Finally,  $\mathcal{O}_{all}$  is defined to be an oracle consisting of  $\mathcal{O}_V$  and several other oracles (some of them implementing unitary transformations).

We use the following important facts about  $\mathcal{O}_{all}$ :

Fact 1 (Hardness of two values) Let A be an algorithm making a polynomial number of oracle queries. Then  $\Pr[x \neq x' \land x, x' \in S_y : (y, x) \leftarrow A^{\mathcal{O}_{all}}(1^{\eta})]$  is negligible.

This fact is a reformulation of [ARU14, Corollary 7 (i)].

Fact 2 (Searching one value) There is a pair  $(E_1, E_2)$  of quantum-polynomial-time oracle algorithms such that:

- $E_1^{\mathcal{O}_{all}}(1^{\eta})$  outputs  $y \in Y$  and a quantum state  $|\Psi(y)\rangle$ . Given a Boolean circuit P with  $|\{x \in S_y : P(x) = 1\}| \geq |S_y|/3$ ,  $E_2^{\mathcal{O}_{all}}(1^{\eta}, y, |\Psi(y)\rangle, P)$  outputs  $x \in S_y$  with P(x) = 1 with overwhelming proba-

This is a special case of [ARU14, Theorem 5].<sup>11</sup>

Informally, Fact 2 tells us that if we choose  $y \in Y$  ourselves, we get a quantum trapdoor  $|\Psi(y)\rangle$  that allows us to search one value  $x \in S_y$  satisfying a predicate of our

 $<sup>^{10}</sup>H$  is collision-resistant iff for any quantum-polynomial-time A,  $\Pr[x \neq x' \land H(x) = H(x') : (x, x') \leftarrow$ 

<sup>&</sup>lt;sup>11</sup>We have fixed  $\delta_{\min} := 1/3$  and n to be the security parameter, and we have removed the argument  $|\Sigma\Psi\rangle$  from  $E_1$  because  $|\Sigma\Psi\rangle$  can be produced by  $E_1$  using the oracle  $\mathcal{O}_{\Psi}$  contained in  $\mathcal{O}_{all}$ .

choice, as long as this predicate is satisfied  $\frac{1}{3}$  of the time. (But note: we cannot get two such x in the same  $S_y$ , as this would violate Fact 1.)

Let  $h_2: \{0,1\}^* \to \{0,1\}^{\ell}$  (for some arbitrary polynomially-bounded superlogarithmic  $\ell$ ) be uniformly random. We can then define the oracle  $\mathcal{O}$  to be the oracle containing  $\mathcal{O}_{all}$  and  $h_2$ . (I.e.,  $\mathcal{O}$  gives access to  $\mathcal{O}_{all}$  and an additional random oracle.) Note that since  $h_2$  and  $\mathcal{O}_{all}$  are independent, Fact 1 still applies when A is given access to  $\mathcal{O}$ .

We now construct a hash function  $H: \{0,1\}^* \to \{0,1\}^{\ell}$ . For  $x \in X$ ,  $y \in Y$  with  $\mathcal{O}_V(y,x) = 1$ , let  $h_1(x||y) := 0||y|$  and let  $h_1(z) := 1||z|$  everywhere else. Let  $H := h_2 \circ h_1$ .

### Claim 1 (Collision-resistance of H) H is collision-resistant (relative to $\mathcal{O}$ ).

To show this, we show that  $h_1$  and  $h_2$  are collision-resistant relative to  $\mathcal{O}$ . This then shows that  $H = h_2 \circ h_1$  is collision-resistant relative to  $\mathcal{O}$ . Any collision of  $h_1$  must be of the form  $h_1(x||y) = h_1(x'||y')$  with  $x||y \neq x'||y'$  and  $\mathcal{O}_V(y',x') = \mathcal{O}_V(y,x) = 1$  since  $h_1$  is injective everywhere else. By definition of  $h_1$ , this implies that 0||y=0||y', thus y=y' and  $x\neq x'$ . And then  $\mathcal{O}_V(y',x')=\mathcal{O}_V(y,x)=1$  implies by definition of  $\mathcal{O}_V$  that  $x, x' \in S_y$ . By Fact 1, a polynomial-time adversary with oracle access to  $\mathcal{O}$  finds such x, x', y only with negligible probability. This shows that  $h_1$  is collision-resistant relative to  $\mathcal{O}$ .

By [Zha15, Theorem 3.1],  $h_2$  is collision-resistant (given oracle access to  $h_2$ ).  $h_2$ Since  $\mathcal{O}_{all}$  is chosen independently of  $h_2$ , it can be simulated with no extra queries to  $h_2$ . I.e., an adversary breaking collision resistance of  $h_2$  using  $\mathcal{O} = (\mathcal{O}_{all}, h_2)$  can be transformed into one breaking collision resistance of  $h_2$  using  $h_2$ . Hence  $h_2$  is also collision-resistant given oracle access to  $\mathcal{O}$ .

Thus  $h_1, h_2$  are collision-resistant relative to  $\mathcal{O}$ , and thus  $H = h_2 \circ h_1$  is collisionresistant relative to  $\mathcal{O}$ .

Attack on the canonical commitment scheme. Let  $\ell_m$  be some arbitrary message length, and  $\ell_u$  the length of the opening information (see Definition 17). For this attack, we assume that the length parameters  $\ell_1, \ell_2$  in the construction of  $\mathcal{O}_{all}$  have been chosen such that  $\ell_m + \ell_u = \ell_1 + \ell_2$ . (This is always possible, since  $\ell_1, \ell_2$  are only required to be superlogarithmic.) The adversary A does the following:

- Let  $E_1, E_2$  be the algorithms from Fact 2.
- $(y, |\Psi(y)\rangle) \leftarrow E_1^{\mathcal{O}_{all}}(1^{\eta})$ . Let  $c := h_2(0||y)$  and send c as the commitment. Upon input b, choose P such that P(x) := 1 iff the first bit of x is b. Run  $x \leftarrow E_2^{\mathcal{O}_{all}}(1^{\eta}, y, |\Psi(y)\rangle, P)$ . Split x||y as m||u| = x||y with  $|m| = \ell_m, |u| = \ell_u$  and send (m, u). (Note: the lengths of m, u do not necessarily match the lengths of x, y, but their combined length does since  $\ell_1 + \ell_2 = \ell_m + \ell_u$ .)

<sup>&</sup>lt;sup>12</sup>Strictly speaking, [Zha15, Theorem 3.1] only applies to random oracles with finite but arbitrary large domain, not to  $h_2$  which has domain  $\{0,1\}^*$ . However, if an adversary finds a collision in  $h_2$  with non-negligible probability  $\mu$ , then there must be a length  $\ell^*$  such that the adversary finds a collision of length at most  $\ell^*$  with probability at least  $\mu/2$ . Thus an adversary breaking collision-resistance of  $h_2$ can be transformed into an adversary breaking collision-resistance of a random oracle with finite domain. [Zha15, Theorem 3.1] then applies.

Since  $S_y \subseteq Y$  is a random set of (superpolynomial) cardinality k, we have that the fraction of  $S_y$  having leading bit b (i.e., satisfying P) is at least  $\frac{1}{3}$  with overwhelming probability. Thus x as returned by  $E_2$  satisfies, by Fact 2, with overwhelming probability  $x \in S_y$  and P(x) = 1. From P(x) = 1 it follows that the first bit of m is b as required. And  $x \in S_y$  implies  $\mathcal{O}_V(y,x) = 1$  which implies  $h_1(x||y) = 0||y$ . Hence  $H(m||u) = h_2(h_1(x||y)) = h_2(0||y) = c$ . Thus  $verify_{can}(c, m, u) = 1$ . This shows that the attack on the canonical commitment is successful with overwhelming probability.

Attack on the bounded-length Halevi-Micali commitment. Let n be the message length, and  $\ell, L$  as in Definition 19. For this attack, we assume that the length parameters  $\ell_1, \ell_2$  have been chosen such that  $\ell_1 + \ell_2 = L$ . (This is always possible, since  $\ell_1, \ell_2$  are only required to be superlogarithmic.) The adversary A does the following:

- Let  $E_1, E_2$  be the algorithms from Fact 2.
- $(y, |\Psi(y)\rangle) \leftarrow E_1^{\mathcal{O}_{all}}(1^{\eta})$ . Pick  $f \in F$  (the family of universal hash functions). Let  $h := h_2(0||y)$  and let c := (h, f) and send c as the commitment.
- Upon input b, choose P such that P(x) := 1 iff the first bit of f(x) is b. Run  $x \leftarrow E_2^{\mathcal{O}_{all}}(1^{\eta}, y, |\Psi(y)\rangle, P)$ . Let u := x and m := f(u) and send (m, u).

Similarly as for the attack on the canonical commitment, we get that A gets with overwhelming probability an  $x \in S_y$  with P(x) = 1 which then implies  $verify_{HMb}(c, m, u) = 1$ .

Attack on the unbounded Halevi-Micali commitment. We describe the attack on the unbounded Halevi-Micali commitment. Let  $\ell_m$  be a superpolynomial message length, and L the length of the opening information (see Definition 20). For this attack, we assume that the length parameters  $\ell_1, \ell_2$  have been chosen such that  $\ell_1 + \ell_2 = \ell_m$ . (This is always possible, since  $\ell_1, \ell_2$  are only required to be superlogarithmic.) The adversary A does the following:

- Let  $E_1, E_2$  be the algorithms from Fact 2.
- $(y, |\Psi(y)\rangle) \leftarrow E_1^{\mathcal{O}_{all}}(1^{\eta})$ . Pick  $f \in F$  and  $u \in \{0, 1\}^L$  such that  $f(u) = h_2(0||y)$ . Compute h := H(u). Let c := (h, f) and send c as the commitment.
- Upon input b, let P(x) := 1 iff the first bit of x is b. Run  $x \leftarrow E_2^{\mathcal{O}_{all}}(1^{\eta}, y, |\Psi(y)\rangle, P)$ . Let m := x || y. Send (m, u).

Similarly as for the attack on the canonical commitment, we get that A gets with overwhelming probability an  $x \in S_y$  with P(x) = 1 which then implies  $verify_{HMu}(c, m, u) = 1$ .

# 4 Collapsing hash functions

As seen in the previous section, for many protocols collision-resistance is not a sufficiently strong property in the quantum setting. In the following, we propose a strengthening of the collision-resistance property that seems more useful in the quantum setting, namely "collapsing" hash functions. We believe that collapsing hash functions are a natural assumption for real-life hash functions such as SHA-3 etc. This belief is supported by the fact that the random oracle is collapsing (see Section 6).

The definition of collapsing hash functions is similar to that of collapsing commitments (Definition 13).

**Definition 23 (Collapsing)** For a function H and algorithms A, B, consider the following games:

$$\begin{aligned} \mathsf{Game}_1: \quad & (S,M,c) \leftarrow A(1^{\eta}), \ m \leftarrow M_{comp}(M), \ b \leftarrow B(1^{\eta},S,M) \\ \mathsf{Game}_2: \quad & (S,M,c) \leftarrow A(1^{\eta}), \qquad \qquad b \leftarrow B(1^{\eta},S,M) \end{aligned}$$

Here S, M are quantum registers.  $M_{comp}(M)$  is a measurement of M in the computational basis.

We call an adversary (A, B) valid if  $\Pr[H(m) = c] = 1$  when we run  $(S, M, c) \leftarrow A(1^{\eta})$  and measure M in the computational basis as m.

A function H is collapsing iff for any quantum-polynomial-time valid adversary (A,B), the difference  $adv := |\Pr[b=1:\mathsf{Game}_1] - \Pr[b=1:\mathsf{Game}_2]|$  is negligible. (We call adv the advantage.)

Notice that the definition of collapsing hash functions is inherently quantum, even though the object we consider (the hash function H) is classical. We know of no classical analogue to collapsing hash functions. However, a collapsing hash function will necessarily be collision-resistant, see Lemma 25 below.

We proceed to give a number of useful properties of collapsing hash functions.

**Lemma 24** An injective function H is collapsing with advantage 0.

*Proof.* Consider an adversary (A, B) against Definition 23. Since (A, B) is valid, by definition we have that  $m \leftarrow M_{comp}(M)$  in  $\mathsf{Game}_1$  returns m with H(m) = c. Since H is injective, this means there is only one such m. Thus M is in state  $|m\rangle$  before applying  $m \leftarrow M_{comp}(M)$ , and the measurement  $M_{comp}(M)$  does not change the state of M. Thus  $\Pr[b=1:\mathsf{Game}_1] = \Pr[b=1:\mathsf{Game}_2]$ .

**Lemma 25** A collapsing hash function is collision resistant.

*Proof.* Assume the hash function H is not collision resistant. Then there is a quantum adversary C that outputs a collision (m, m') with H(x) = H(x') with non-negligible probability  $\mu$ .

We construct a quantum-polynomial-time adversary (A, B) for Definition 23.

Let A be the following quantum algorithm: It runs C to get a collision (m, m'). If (m, m') is a collision, it stores m, m' in the register S, and initializes M with  $|\Psi_{m,m'}\rangle := \frac{1}{\sqrt{2}}|m\rangle + \frac{1}{\sqrt{2}}|m'\rangle$ . It sets c := H(m) = H(m') and returns (S, M, c). If (m, m') is not a collision, A stores  $\bot$  in the register S, initializes M with  $|0\rangle$ , sets c := H(0), and returns (S, M, c).

The algorithm B retrieves m, m' from S. If S contains  $\bot$  instead, B returns b := 0. Otherwise B measures whether M contains  $|\Psi_{m,m'}\rangle$ , i.e., B measures M with the projector  $|\Psi_{m,m'}\rangle\langle\Psi_{m,m'}|$ . If this measurement succeeds, B returns b := 1, else B returns b := 0.

By construction, (A, B) is valid.

In  $\mathsf{Game}_2$ , with probability  $1 - \mu$ , B finds S to contain  $\bot$  and returns b = 0. If S contains a collision m, m', then by construction of A, M contains  $|\Psi_{m,m'}\rangle$ , so B outputs b = 1 with probability 1 in this case. Hence  $\Pr[b = 1 : \mathsf{Game}_2] = \mu$ .

In  $\mathsf{Game}_1$ , with probability  $1-\mu$ , B finds S to contain  $\bot$  and returns b=0. If S contains a collision m,m', then by construction the state of M before  $M_{comp}(M)$  is  $|\Psi_{m,m'}\rangle$ , hence after that measurement it is  $|m\rangle$  or  $|m'\rangle$  (each with probability  $\frac{1}{2}$ ). In each case, the measurement performed by B (projector  $|\Psi_{m,m'}\rangle\langle\Psi_{m,m'}|$ ) succeeds with probability  $\frac{1}{2}$ . Thus, if S contains a collision, B returns b=1 with probability  $\frac{1}{2}$ . Hence  $\Pr[b=1:\mathsf{Game}_1]=\mu/2$ .

Hence  $|\Pr[b=1:\mathsf{Game}_1] - \Pr[b=1:\mathsf{Game}_2]| = \frac{\mu}{2}$  is non-negligible, in contradiction to the assumption that H is collapsing.

Definition 23 guarantees that the adversary cannot distinguish whether the register M is measured or not. Like in the case of commitments (cf. the discussion before Lemma 15) we can ask what happens when a partial measurement is performed. Analogous to Lemma 15 we get that a partial measurement cannot be noticed, either:

**Lemma 26 (Collapsing w.r.t. partial measurements)** For a function H and algorithms A, B, consider the following games:

$$\begin{aligned} \mathsf{Game}_1' : \quad & (S,M,c,f) \leftarrow A(1^\eta), \ x \leftarrow M^f(M), \ b \leftarrow B(1^\eta,S,M) \\ \mathsf{Game}_2 : \quad & (S,M,c,f) \leftarrow A(1^\eta), \qquad \qquad b \leftarrow B(1^\eta,S,M) \end{aligned}$$

Here f is a Boolean circuit (with multiple-bit output).<sup>13</sup> And S, M are quantum registers.  $M^f(M)$  measures f(m) where m is the content of M in the computational basis. Formally,  $M^f(M)$  is the measurement defined by the projectors  $P_x := \sum_{m:f(m)=x} |m\rangle\langle m|$  for all x in the range of f.

If H is collapsing, then for any quantum-polynomial-time valid adversary (A, B), the difference  $|\Pr[b=1:\mathsf{Game}_1'] - \Pr[b=1:\mathsf{Game}_2]|$  is negligible.

*Proof.* The proof is analogous to that of Lemma 15. (The proof actually becomes a bit simpler, because all occurrences of and arguments relating to  $V_c$  may be omitted.)

**Lemma 27** If a valid adversary (A, B) breaks the collapsing property of  $g \circ f$  with advantage  $\varepsilon$ , then there are valid adversaries (A', B') and (A'', B'') with advantages  $\varepsilon', \varepsilon''$  against g, f, respectively, such that  $\varepsilon \leq \varepsilon' + \varepsilon''$ .

(A', B') and (A'', B'') each perform only two additional evaluations of f in comparison to (A, B). (And one additional measurement in the computational basis. But no additional evaluations of g.)

 $<sup>^{13}</sup>$ In the random oracle model, we also allow f to contain gates for evaluating the random oracle.

*Proof.* Consider the following circuits:

Here **M** represents a measurement in the computational basis. (Discarding the outcome.) By definition of  $\varepsilon$ , we have

$$\varepsilon = \Big| \Pr[b = 1 : \text{lhs of } (4)] - \Pr[b = 1 : \text{rhs of } (4)] \Big|.$$

Let  $U_f: |x\rangle |y\rangle \mapsto |x\rangle |y\oplus f(x)\rangle$ . Since  $U_f$  is self-inverse, introducing two consecutive applications of  $U_f$  into the lhs of (4) does not change the outcome probability. That is, with

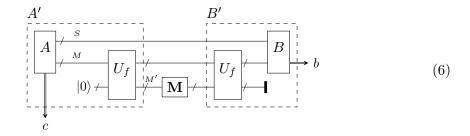

we have

$$Pr[b = 1 : lhs of (4)] = Pr[b = 1 : (5)].$$

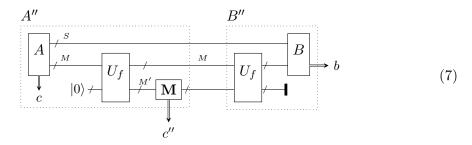

The dashed boxes in (5) define a new adversary (A', B') against g. The top two wires leaving A' contain the state of A', while the bottom wire M' contains the superposition of hashed values. Since A is valid for  $g \circ f$ , M contains a superposition of values m with  $g \circ f(m) = c$ . (By this we mean formally that the projector  $\sum_{m,u:g \circ f(m)=c} |m\rangle\langle m|$  applied to M passes with probability 1.) Hence M' contains a superposition of values m' = f(m) with g(m') = c. Thus A' is valid for g. Let  $\varepsilon'$  be the advantage of A' against g. That is, we have

$$\varepsilon' = |\Pr[b = 1 : (5)] - \Pr[b = 1 : (6)]|$$

with the following circuit (6):

We now change the circuit slightly: Instead of discarding the outcome of the measurement  $\mathbf{M}$ , we assign it to the classical variable c''.

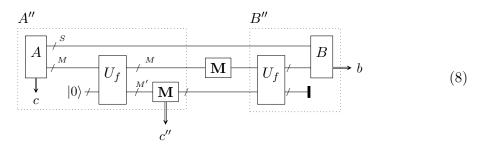

Obviously, not discarding c'' does not change the distribution of b, hence

$$Pr[b = 1 : (6)] = Pr[b = 1 : (7)].$$

The dotted lines in (7) define an adversary (A'', B'') against f. The wires S and M' together form the state of (A'', B''), and the middle wire M is supposed to contain the hashed values. If M contains the value m, then M' contains f(m) and c'' will be f(m). Thus, if we measure a particular value c'', then M contains a superposition of values m with f(m) = c''. Thus, (A'', B'') is valid for f. Let  $\varepsilon''$  be the advantage of (A'', B'') against f. Then we have

$$\varepsilon'' = |\Pr[b = 1 : (7)] - \Pr[b = 1 : (8)]|$$

with the following circuit (8):

The subcircuit consisting of the two  $U_f$  and the two measurements  $\mathbf{M}$  is easily seen to be equivalent to a measurement  $\mathbf{M}$  on the M wire (since we do not use the outcome c''). Thus

$$Pr[b = 1 : (8)] = Pr[b = 1 : rhs of (4)].$$

Collecting all inequalities, we get:

$$\varepsilon = |\Pr[b = 1 : \text{lhs of } (4)] - \Pr[b = 1 : \text{rhs of } (4)]| \le \varepsilon' + \varepsilon''.$$

**Corollary 28** If f and g are collapsing, so is  $g \circ f$ .

Proof. Immediate from Lemma 27.

# 5 Commitments from collapsing hash functions

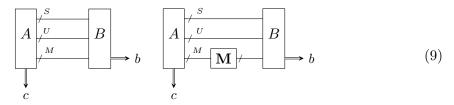

In Section 3 we saw that collision-resistant hash functions are not sufficient for several standard constructions of commitment schemes. We will now show that those same constructions are secure in the quantum setting when using collapsing hash functions instead.

The following lemma (and its Corollary 30 below) allows us to extend the message space of a collapsing commitment by hashing the message with a collapsing hash function. Besides being useful in its own right, we need it in the analysis of the unbounded Halevi-Micali commitment. The proof of the lemma is similar to that of Corollary 28.

**Lemma 29** Let f be a hash function. Let (com, verify) be a commitment scheme. Let  $com_f(1^{\eta}, m) := com(f(m))$  and  $verify_f(1^{\eta}, c, m, u) = verify(1^{\eta}, c, f(m), u)$ . If a valid adversary (A, B) breaks the collapse binding property of  $(com_f, verify_f)$  with advantage  $\varepsilon$  (with respect to Definition 13), then there are valid adversaries (A', B') and (A'', B'') with advantages  $\varepsilon', \varepsilon''$  against the collapse binding property of (com, verify) and the collapsing property of f, respectively, such that  $\varepsilon \leq \varepsilon' + \varepsilon''$ .

(A', B') and (A'', B'') each perform only two additional evaluations of f in comparison to (A, B). (And one additional measurement in the computational basis. But no additional evaluations of com or verify.)

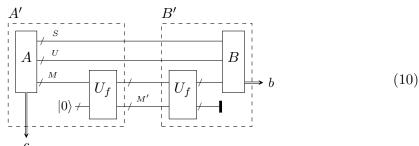

*Proof.* Consider the following circuits:

Here **M** represents a measurement in the computational basis. (Discarding the outcome.) By definition of  $\varepsilon$ , we have

$$\varepsilon = \Big| \Pr[b = 1 : \text{lhs of } (9)] - \Pr[b = 1 : \text{rhs of } (9)] \Big|.$$

Let  $U_f: |x\rangle |y\rangle \mapsto |x\rangle |y \oplus f(x)\rangle$ . Since  $U_f$  is self-inverse, introducing two consecutive applications of  $U_f$  into the lhs of (9) does not change the outcome probability. That is, with

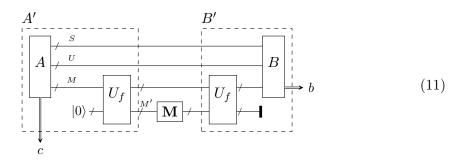

we have

$$\Pr[b = 1 : \text{lhs of } (9)] = \Pr[b = 1 : (10)].$$

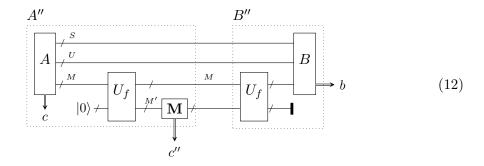

The dashed boxes in (10) define a new adversary (A', B') against  $(com_f, verify_f)$ . The wires S, M leaving A' contain the state of A', the wire M' contains the committed message, and the wire U contains the opening information. Since A is valid for  $(com_f, verify_f)$ , M, U contains a superposition of values m, u with  $verify(1^{\eta}, c, f(m), u) = 1$ . (By this we mean formally that the projector  $\sum_{m,u:verify(1^{\eta},c,f(m),u)=1}|m\rangle\langle m|\otimes |u\rangle\langle u|$  applied to M, U passes with probability 1.) Hence M', U contains a superposition of values m' = f(m) with  $verify(1^{\eta}, c, m', u) = 1$ . Thus A' is valid for (com, verify). Let  $\varepsilon'$  be the advantage of A' against g. That is, we have

$$\varepsilon' = |\Pr[b = 1 : (10)] - \Pr[b = 1 : (11)]|$$

with the following circuit (11):

We now change the circuit slightly: Instead of discarding the outcome of the measurement  $\mathbf{M}$ , we assign it to the classical variable c''.

Obviously, not discarding c'' does not change the distribution of b, hence

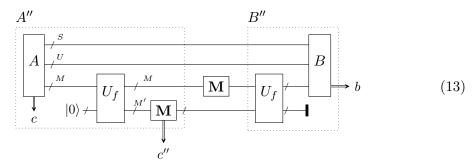

$$Pr[b = 1 : (11)] = Pr[b = 1 : (12)].$$

The dotted lines in (12) define an adversary (A'', B'') against f. The wires S, U, and M' together form the state of (A'', B''), and the middle wire M is supposed to contain the hashed values. If M contains the value m, then M' contains f(m) and c'' will be f(m).

Thus, if we measure a particular value c'', then M contains a superposition of values m with f(m) = c''. Thus, (A'', B'') is valid for f. Let  $\varepsilon''$  be the advantage of (A'', B'') against f. Then we have

$$\varepsilon'' = |\Pr[b = 1 : (12)] - \Pr[b = 1 : (13)]|$$

with the following circuit (13):

The subcircuit consisting of the two  $U_f$  and the two measurements  $\mathbf{M}$  is easily seen to be equivalent to a measurement  $\mathbf{M}$  on the M wire (since we do not use the outcome c''). Thus

$$Pr[b = 1 : (13)] = Pr[b = 1 : rhs of (9)].$$

Collecting all inequalities, we get:

$$\varepsilon = |\Pr[b = 1 : \text{lhs of } (9)] - \Pr[b = 1 : \text{rhs of } (9)]| \le \varepsilon' + \varepsilon''.$$

Corollary 30 Let f be a collapsing function. Let (com, verify) be a collapse binding commitment scheme. Let  $com_f(1^\eta, m) := com(1^\eta, f(m))$  and  $verify_f(1^\eta, c, m, u) = verify(1^\eta, c, f(m), u)$ . Then  $(com_f, verify_f)$  is a collapse-binding commitment scheme.

**Lemma 31** If H is collapsing, then the canonical commitment scheme  $(com_{can}, verify_{can})$ , and the bounded-length Halevi-Micali commitment  $(com_{HMb}, verify_{HMb})$ , and the unbounded Halevi-Micali commitment  $(com_{HMu}, verify_{HMu})$  are collapse-binding. (For any choice of the parameters  $\ell_u, \ell, n$ .)

We give the proof ideafirst. To show that the canonical commitment  $com_{can}$  is collapse-binding, we use the characterization of collapse-binding from Definition 13. We need to show that the adversary cannot distinguish between a measurement on register M and no measurement on register M, assuming the adversary outputs M, U containing a superposition of m, u with  $verify_{can}(c, m, u) = 1$ . The condition  $verify_{can}(c, m, u) = 1$  is equivalent to H(m||u) = c. Hence the adversary outputs in M, U a superposition of preimages of c under H. Since H is collapsing, this implies that the adversary cannot distinguish between a measurement on M, U and no measurement on M, U. This also implies (using some additional work) that the adversary cannot distinguish between a measurement on M and no measurement on M. Hence  $com_{can}$  is collapse-binding. The Halevi-Micali commitments are handled similarly.

*Proof.* We investigate the three commitment schemes one by one:

Canonical commitment. We show that  $(com_{can}, verify_{can})$  is collapse-binding. Fix a valid quantum-polynomial-time adversary (A, B) against the canonical commitment scheme (with respect to Definition 13). By concatenating the registers M, U into a single register M', we get an adversary (A', B') against the hash function H. Written in terms of A', B' (and unfolding the definition of  $verify_{can}$ ), the games from Definition 13 become:

$$\mathsf{Game}_1: \quad (S, M', c) \leftarrow A'(1^{\eta}), \ m \leftarrow M^f(M'), \ b \leftarrow B'(1^{\eta}, S, M')$$
$$\mathsf{Game}_2: \quad (S, M', c) \leftarrow A'(1^{\eta}), \qquad b \leftarrow B'(1^{\eta}, S, M')$$

where f(m||u) := m and  $M^f$  is defined as in Lemma 26.

Since (A, B) is valid, we have  $verify_{can}(1^{\eta}, c, m, u) = 1$  when m, u is the result of measuring M, U. When we define m' := m||u, we have  $verify(1^{\eta}, c, m, u) = 1$  iff H(m') = c by definition of verify. Thus in an execution with (A', B'), we have H(m') = c. Thus (A', B') is valid.

Since (A', B') is valid and quantum-polynomial-time, by Lemma 26,  $|\Pr[b=1: \mathsf{Game}_1] - \Pr[b=1: \mathsf{Game}_2]|$  is negligible. (In Lemma 26, f is chosen by the adversary, but we can transform A' to output f himself.) Since  $\mathsf{Game}_1$  and  $\mathsf{Game}_2$  are equivalent to the games from Definition 13, it follows that  $(com_{can}, verify_{can})$  is collapsing.

Bounded-length Halevi-Micali commitment. We show that  $(com_{HMb}, verify_{HMb})$  is collapse-binding. Fix a valid quantum-polynomial-time adversary (A, B) against the commitment scheme (with respect to Definition 13). By unfolding the definition of  $(com_{HMb}, verify_{HMb})$ , see Definition 19, the games from Definition 13 become:

$$\begin{aligned} \mathsf{Game}_1: \quad & (S, M, U, h, f) \leftarrow A(1^{\eta}), \ m \leftarrow M_{comp}(M), \ b \leftarrow B(1^{\eta}, S, M, U) \\ \mathsf{Game}_2: \quad & (S, M, U, h, f) \leftarrow A(1^{\eta}), \qquad \qquad b \leftarrow B(1^{\eta}, S, M, U) \end{aligned}$$

and validity of A implies that M, U are such that when measuring them, we get m, u with f(u) = m and h = H(u). We need to show that  $|\Pr[b = 1 : \mathsf{Game}_1] - \Pr[b = 1 : \mathsf{Game}_2]|$  is negligible.

Since f(u)=m, measuring M in the computational basis is equivalent to applying the measurement  $M^f$  on U. Here  $M^f$  is as in Lemma 26. Thus we have  $\Pr[b=1:\mathsf{Game}_1]=\Pr[b=1:\mathsf{Game}_1']$  with

$$\mathsf{Game}_1': \quad (S, M, U, h, f) \leftarrow A(1^{\eta}), \ m \leftarrow M^f(U), \ b \leftarrow B(1^{\eta}, S, M, U).$$

By Lemma 26, we get that  $|\Pr[b=1:\mathsf{Game}_1'] - \Pr[b=1:\mathsf{Game}_2]|$  is negligible. (Here we instantiate S, M, c, f in Lemma 26 with S:=(S, M), M:=U, c:=h.)

Thus  $|\Pr[b=1:\mathsf{Game}_1] - \Pr[b=1:\mathsf{Game}_2]|$  is also negligible, hence  $(com_{HMb}, verify_{HMb})$  is collapse-binding.

Unbounded Halevi-Micali commitment. We show that  $(com_{HMu}, verify_{HMu})$  is collapse-binding. Let  $(com, verify) := (com_{HMb}, verify_{HMb})$  and f := H. Then  $(com_f, verify_f)$  as defined in Corollary 30 is the same as  $(com_{HMu}, verify_{HMu})$ . We showed above that  $(com_{HMb}, verify_{HMb})$  is collapse-binding. And f = H is collapsing by assumption. Thus by Corollary 30,  $(com_f, verify_f)$  is collapse binding. Hence  $(com_{HMu}, verify_{HMu})$  is collapse-binding.

# 6 Random oracles are collapsing

In Section 5 we saw that collapsing hash functions imply collapse-binding commitments. In this section, we explore the existence of collapsing hash functions. Specifically, we show that the random oracle is collapsing. This implies that there are simple collapse-binding commitments in the random oracle model. Furthermore, it supports the assumption that real-life hash functions such as SHA-3 etc. could be collapse-binding. Alternatively, we could also directly start with the assumption that SHA-3 is collapsing, in that setting the constructions from Section 5 would not need the random oracle. (In fact, we advocate that a hash function that is not collapsing should not be considered a secure practical hash function, and not recommended for future use.)

For the remainder of this section, X and Y are sets, and  $H: X \to Y$  is a random oracle. Furthermore Y is finite, and  $X \subseteq \{0,1\}^*$  (finite or infinite). And  $q \ge 1$  always refers to an upper bound on the number of oracle queries performed by the adversary.

We start by defining a seemingly unrelated property (half-collision resistance) that will turn out to imply the collapsing property. We will need half-collision resistance in our proof that the random oracle is collapsing. However, the concept of half-collision resistance might be of use for constructions in the standard model, too: since half-collision resistance is defined by a classical game, it might be easier to construct hash functions that are half-collision resistant.<sup>14</sup>

**Definition 32** A half-collision of a hash function  $f: X \to Y$  is a value x such that  $\exists x' \neq x. f(x) = f(x')$ .

An adversary A has advantage  $\varepsilon$  against half-collision resistance iff

- with probability 1, the output of A is a half-collision or  $\bot$ , and
- with probability at  $\varepsilon$ , A outputs a half-collision.

**Lemma 33** If (A, B) is valid and has advantage  $\mu$  against the collapsing property of a hash function f, then there is an adversary D with advantage  $\geq \mu^2/4$  against the half-collision resistance of f. The time-complexity of D is linear in that of (A, B). (If f is given as an oracle, D makes 4q + 4 queries to f when (A, B) makes q queries.)

<sup>&</sup>lt;sup>14</sup>However, half-collision resistance is strictly stronger than collapsing, at least relative to an oracle, as we show next. Consider an oracle  $\mathcal{O}$  picked according to the following distribution: Let  $P_0, P_1 : \{0,1\}^n \to \{0,1\}^n$  be random permutations. Let  $\mathcal{O}(b||x) := P_b(x)$  for  $b \in \{0,1\}, x \in \{0,1\}^n$ . Then every input to  $\mathcal{O}$  is a half-collision, thus  $\mathcal{O}$  cannot be half-collision resistant. However  $P_0$  and  $P_1$  are indistinguishable from a random function (Corollary 34), hence  $\mathcal{O}$  is indistinguishable from  $\mathcal{O}'(b||x) := H_b(x)$  for random functions  $H_0, H_1$ . Note that  $\mathcal{O}'$  is a random function, hence  $\mathcal{O}'$  is collapsing by Theorem 38. Since  $\mathcal{O}$  and  $\mathcal{O}'$  are indistinguishable,  $\mathcal{O}$  is collapsing as well.

Proof sketch: By definition, a valid adversary A will always output in register M a superposition of messages m with H(m) = c (all with the same c). So we have two cases: M contains a superposition of a single message m, or M contains a superposition of several messages that have the same image c, i.e., a superposition of half-collisions. Thus, in the second case, we can find a half-collisions by measuring M. But, an adversary against half-collision resistance must never output a non-half-collision (no false positives). Thus, we need a possibility to test whether M contains only a single message. (In this case, we abort.)

Note that when M contains only a single message, then the adversary B cannot distinguish between a measurement on M and no measurement on M. To exploit this, we run an execution where M is measured and an execution where M is not measured in superposition (roughly speaking), and we make it depend on a control qubit in state  $|+\rangle$  which execution is used. Then, in the case where M contains only a single message, the control qubit stays unentangled with the rest of the circuit. By measuring whether the qubit is still in state  $|+\rangle$ , the half-collision resistance adversary can detect whether M contains one or several messages. (It may err and incorrectly assume that M contains only one message, but an error in that direction is permitted.) Thus we have constructed an adversary against half-collision resistance.

*Proof.* We first construct a slight modification  $B_c$  of the adversary algorithm B.  $B_c$  is parametrized over an image c of f, and  $B_c(S, M)$  first measures its input register M with the projector  $P_c := \sum_{m:f(m)=c} |m\rangle\langle m|$ . That is,  $B_c$  measures whether f applied to the content of M would return c. If so,  $B_c$  executes B and returns the output b of B. If not,  $B_c$  returns b=0.  $B_c$  needs one more query to f than B.

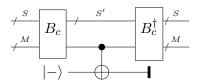

Furthermore, we assume that  $B_c$  is implemented as a unitary circuit. That is, we assume that the input register S (which contains the state of the adversary in the games from Definition 23), contains sufficiently many ancillae for implementing  $B_c$  unitarily, and that  $B_c$  has an output register S' in addition to the register containing b.

In the games from Definition 23, the register M is in the image of  $P_c$  anyway, so in those games,  $B_c$  behaves the same as B. Thus,  $\Pr[b=1]$  differs by  $\mu$  in the following circuits:

M denotes a (single- or multi-bit) measurement in the computational basis. (The first occurrence of M has only an outgoing quantum wire, so it discards the outcome. The second occurrence has only an outgoing classical wire b so it discards the post-measurement state.)

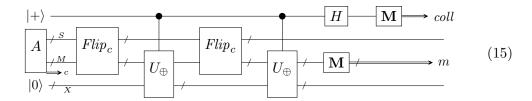

Let  $P_c^B$  be the projector onto the space of all input states where  $B_c$  will output b=1 with probability 1. In particular, since  $B_c$  returns b=0 for  $|s\rangle|m\rangle$  with  $f(m)\neq c$ , we have that im  $P_c\subseteq \operatorname{im}(1-P_c^B)$ , so  $P_c$  and  $P_c^B$  commute. (Strictly speaking, we should

refer to  $I_S \otimes P_c$  here, since  $P_C$  operates on M only. But here and in the remainder of the proof, we implicitly omit tensor products with the identity since for every operator, it is clear on which registers it operates.) Let  $Flip_c := (1 - 2P_c^B)$ . It is easy to verify that  $Flip_c$  is implemented by the following quantum circuit:

We are now ready to define the adversary D against half-collision resistance:

• Execute the following quantum circuit:

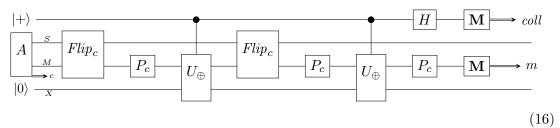

Here **M** is a measurement in the computational basis, and  $U_{\oplus}|x\rangle|y\rangle := |x\rangle|x\oplus y\rangle$  is a unitary operating on registers M, X (where X has the same dimension as M).

- If coll = 0, return  $\perp$ .
- If coll = 1, return m.

Claim 2 With probability 1, D outputs  $\perp$  or a half-collision of f.

To show this claim, first recall that  $P_c$  and  $P_c^B$  commute. Thus also  $P_c$  and  $Flip_c = 1 - 2P_c^B$  commute. Furthermore, since A is a valid adversary, the output of A is in im  $P_c$ . And furthermore  $U_{\oplus}$  and  $P_c$  are easily seen to commute. Thus we can perform the following transformations on the circuit (15) without changing the output probabilities: Add a projector  $P_c$  after A (on the M wire) and commute it until before after the second  $U_{\oplus}$ . Add a projector  $P_c$  after A and commute it until before the second  $U_{\oplus}$ . And add a projector  $P_c$  after A and commute it until before the first  $U_{\oplus}$ . We get the following result:

(Note that this circuit contains projectors, which may in general mean that the final quantum state does not have norm 1 and that thus the output probabilities for coll, m

do not add up to 1. In the present case, however, this is not the case because we argued that the output probabilities are the same as in (15).)

For a fixed value of c (as output by A in the above circuit), we distinguish three cases:

- Case 1 " $c \notin \text{im } f$ ": This never happens because A is valid (and thus the register M contains a superposition of values m with f(m) = c).
- Case 2 "c has exactly one preimage under f": Let  $m_0 := f^{-1}(c)$ . Then  $P_c$  projects onto  $|m_0\rangle$ . Thus after an application of  $P_c$  on the M register,  $U_{\oplus}$  has the same effect as the unitary  $U_{m_0} : |y\rangle \to |y \oplus m_0\rangle$  on X. So we can replace both controlled  $U_{\oplus}$  by controlled  $U_{m_0}$  in circuit (16). But the controlled  $U_{m_0}$  operated only on wires 1 and 4, while  $Flip_c$  and  $P_c$  operate on wires 2 and 3. Thus the first  $U_{m_0}$  can be commuted past  $Flip_c$  and  $P_c$  and then cancels out with the second controlled  $U_{m_0}$ . These transformations have not changed the probability distribution of coll. The first wire of the circuit has become the following:

$$|+\rangle$$
 —  $H$  —  $M$   $\longrightarrow$   $coll$ 

Thus coll = 0 with probability 1. Thus D outputs  $\perp$  with probability 1.

• Case 3 "c has at least two preimages under f": m is the result of measuring the third wire in the computational basis. Just before that measurement,  $P_c = \sum_{m:f(m)=c} |m\rangle\langle m|$  was applied to that wire. Thus f(m)=c with probability 1. Since c has at least two preimages, this implies that m is a half-collision. Thus D outputs a half-collision or  $\bot$  in this case (depending on the value of coll).

This proves Claim 2.

Claim 3 With probability at least  $\mu^2/4$ , D outputs some  $m \neq \bot$ .

To prove this claim, we first define some variables. For fixed c, let  $|\Psi'_c\rangle$  be the output state (in registers S, M) of A when A outputs c. Let  $|\Psi_c\rangle := |\Psi'_c\rangle|0\rangle$  (living in registers S, M, X). Recall that  $P_c^B$  operates on registers S and M, and that  $U_{\oplus} : |x\rangle|y\rangle \to |x\rangle|x\oplus y\rangle$  operates on M and X.

Let

$$\alpha_c := \|P_c^B |\Psi_c\rangle\|$$
 and  $\beta_c := \|P_c^B U_{\oplus} |\Psi_c\rangle\|.$ 

Note that by construction,  $\alpha_c^2$  is the probability that the left circuit in (14) returns b=1, conditioned on the output c, and  $\beta_c^2$  is the probability that the right circuit in (14) outputs b=1, conditioned on c. (For  $\beta_c^2$ , notice that applying  $U_{\oplus}$  has the same effect as measuring M.) Thus

$$\mu = \left| \Pr[b = 1 : \text{left circuit}] - \Pr[b = 1 : \text{right circuit}] \right| = \left| \sum_{c} \Pr[c] \alpha_c^2 - \sum_{c} \Pr[c] \beta_c^2 \right|$$
(17)

where Pr[c] denotes the probability that A yields the classical output c.

Let  $|\Phi_c\rangle$  denote the final state in the execution of the circuit (15) just before measuring coll and m. We have

$$\begin{split} |\Phi_{c}\rangle &= (H \otimes I_{SMX}) \Big(\frac{1}{\sqrt{2}}|0\rangle \otimes \underbrace{Flip_{c}Flip_{c}}|\Psi_{c}\rangle + \frac{1}{\sqrt{2}}|1\rangle \otimes U_{\oplus}Flip_{c}U_{\oplus}Flip_{c}|\Psi_{c}\rangle \Big) \\ &= \frac{1}{2}|0\rangle|\Psi_{c}\rangle + \frac{1}{2}|1\rangle|\Psi_{c}\rangle + \frac{1}{2}|0\rangle \otimes U_{\oplus}Flip_{c}U_{\oplus}Flip_{c}|\Psi_{c}\rangle - \frac{1}{2}|1\rangle \otimes U_{\oplus}Flip_{c}U_{\oplus}Flip_{c}|\Psi_{c}\rangle. \end{split}$$

Let Re x denote the real part of x. Since coll is the result of measuring the first wire in circuit (15), the probability Pr[coll = 1 : c] of having coll = 1 conditioned on a particular value of c is:

$$\begin{aligned} &\Pr[coll = 1:c] \\ &= \left\| \frac{1}{2} |\Psi_c\rangle - \frac{1}{2} U_{\oplus} F lip_c U_{\oplus} F lip_c |\Psi_c\rangle \right\|^2 \\ &= \left\| \frac{1}{2} |\Psi_c\rangle - \frac{1}{2} U_{\oplus} U_{\oplus} |\Psi_c\rangle + U_{\oplus} U_{\oplus} P_c^B |\Psi_c\rangle \qquad (\text{since } F lip_c = I - 2 P_c^B) \\ &\quad + U_{\oplus} P_c^B U_{\oplus} |\Psi_c\rangle - 2 U_{\oplus} P_c^B U_{\oplus} P_c^B |\Psi_c\rangle \right\|^2 \\ &= \left\| P_c^B |\Psi_c\rangle + U_{\oplus} P_c^B U_{\oplus} |\Psi_c\rangle - 2 U_{\oplus} P_c^B U_{\oplus} P_c^B |\Psi_c\rangle \right\|^2 \qquad (\text{since } U_{\oplus} U_{\oplus} = I) \\ &= \underbrace{\left\langle \Psi_c | P_c^B \cdot P_c^B |\Psi_c\rangle + 2 \operatorname{Re} \langle \Psi_c | P_c^B \cdot U_{\oplus} P_c^B U_{\oplus} |\Psi_c\rangle - 4 \operatorname{Re} \langle \Psi_c | P_c^B \cdot U_{\oplus} P_c^B U_{\oplus} P_c^B |\Psi_c\rangle \\ &\quad + \underbrace{\left\langle \Psi_c | U_{\oplus} P_c^B U_{\oplus} \cdot U_{\oplus} P_c^B U_{\oplus} |\Psi_c\rangle - 4 \operatorname{Re} \langle \Psi_c | U_{\oplus} P_c^B U_{\oplus} P_c^B |\Psi_c\rangle \\ &\quad + \underbrace{\left\langle \Psi_c | U_{\oplus} P_c^B U_{\oplus} \cdot U_{\oplus} P_c^B U_{\oplus} |\Psi_c\rangle - 4 \operatorname{Re} \langle \Psi_c | U_{\oplus} P_c^B U_{\oplus} P_c^B |\Psi_c\rangle \\ &\quad = \beta_c^2 \qquad \qquad = 4 \operatorname{Re} \langle \Psi_c | U_{\oplus} P_c^B U_{\oplus} P_c^B |\Psi_c\rangle \\ &\quad + \underbrace{4 \langle \Psi_c | P_c^B U_{\oplus} P_c^B U_{\oplus} P_c^B |\Psi_c\rangle \\ &\quad = \alpha_c^2 + \beta_c^2 - 2 \operatorname{Re} \langle \Psi_c | U_{\oplus} P_c^B U_{\oplus} P_c^B |\Psi_c\rangle \\ &\quad = \alpha_c^2 + \beta_c^2 - 2 \left| \underbrace{\left\langle \Psi_c | U_{\oplus} P_c^B \cdot U_{\oplus} \cdot P_c^B |\Psi_c\rangle \right|}_{\text{norm is } \beta_c} \qquad \text{norm is } \alpha_c^2 \end{aligned}$$

We can now bound the probability Pr[coll = 1] that in circuit (15), we measure coll = 1:

$$\Pr[coll = 1] = \sum_{c} \Pr[c] \Pr[coll = 1 : c] \stackrel{\text{(18)}}{\geq} \sum_{c} \Pr[c] (\alpha_c - \beta_c)^2 \stackrel{\text{(*)}}{\geq} \frac{1}{4} \sum_{c} \Pr[c] (\alpha_c^2 - \beta_c^2)^2 \stackrel{\text{(**)}}{\geq} \frac{1}{4} \left( \sum_{c} \Pr[c] (\alpha_c^2 - \beta_c^2) \right)^2 \stackrel{\text{(17)}}{=} \frac{1}{4} \mu^2.$$

Here (\*) uses the fact that for  $\alpha, \beta \in [0, 1]$ ,  $|\alpha - \beta| \ge \frac{1}{2} |\alpha^2 - \beta^2|$ . And (\*\*) uses Jensen's inequality. Since D outputs  $\bot$  only if coll = 0, it follows that D outputs  $m \ne \bot$  with probability at least  $\frac{1}{4}\mu^2$ . Claim 3 follows.

<sup>15</sup> Proof:  $|\alpha^2 - \beta^2| \le \max_{x \in [0,1]} \frac{\partial x^2}{\partial x} \cdot |\alpha - \beta| = \max_{x \in [0,1]} 2x \cdot |\alpha - \beta| = 2|\alpha - \beta|.$ 

From Claims 2 and 3, it follows that D has advantage  $\geq \mu^2/4$  against the half-collision resistance of f. By inspection of the circuit of D, we see that D invokes one instance of A and four instances of  $B_c$ . And  $B_c$  invokes B and performs at most one more evaluation of f. Thus D performs at most 4q + 4 queries to f, when f is given as an oracle and (A, B) performs q queries.

Corollary 34 (Distinguishing random functions and injections [Zha15]) Assume that  $|X| \leq |Y|$ . Let  $H: X \to Y$  be a uniformly random function. Let  $\hat{H}: X \to Y$  be a uniformly random injection. Then for any q-query adversary A,

$$|\Pr[A^H = 1] - \Pr[A^{\hat{H}} = 1]| \in O(q^3/|Y|).$$

Proof. [Zha15, Section 3.1] shows this lemma for the case |X| = |Y|. For the general case, let  $H': Y \to Y$  be a random function and  $\hat{H}': Y \to Y$  be a random permutation. Then  $H' \circ \hat{H}$  has the same distribution as H, and  $\hat{H}' \circ \hat{H}$  has the same distribution as  $\hat{H}$ . Since the corollary holds for |X| = |Y|, we have that H' and  $\hat{H}'$  can be distinguished with probability at most  $O(q^3/|Y|)$  by a q-query adversary, and thus  $H' \circ \hat{H}$  and  $\hat{H}' \circ \hat{H}$  can be distinguished with probability at most  $O(q^3/|Y|)$ . Thus H and  $\hat{H}$  can be distinguished with probability at most  $O(q^3/|Y|)$ .

**Lemma 35** Assume  $|X| \leq |Y|$ . Then H is collapsing with advantage  $O(q^3/|Y|)$ .

*Proof.* Let  $\hat{H}: X \to Y$  be a random injective function. Let  $\mathsf{Game}_1, \mathsf{Game}_2$  refer to the games from Definition 23, and  $\widehat{\mathsf{Game}}_1, \widehat{\mathsf{Game}}_2$  refer to those games with  $\hat{H}$  instead of H. Since  $\hat{H}$  is injective, by Lemma 24,  $\hat{H}$  is collapsing with advantage 0, i.e.,  $\Pr[b=1:\widehat{\mathsf{Game}}_1]=\Pr[b=1:\widehat{\mathsf{Game}}_2].$ 

By Corollary 34, an adversary making q queries can distinguish H and  $\hat{H}$  only with probability  $O(q^3/|Y|)$ . Thus  $|\Pr[b=1:\mathsf{Game}_i] - \Pr[b=1:\widehat{\mathsf{Game}_i}]| \in O(q^3/|Y|)$  for i=1,2. Altogether  $|\Pr[b=1:\mathsf{Game}_1] - \Pr[b=1:\mathsf{Game}_2]| \in O(q^3/|Y|)$ .

For the next lemma, we fix some notation first:  $[N] := \{1, \dots, N\}$ . For functions  $f:[M] \to [N]$  and  $g:[M'] \to [N]$ , let  $f+g:[M+M'] \to [N]$  be defined via (f+g)(x) := f(x) for  $x=1, \dots, M$  and (f+g)(x) = g(x-M) for  $x=M+1, \dots, M+M'$ . For functions  $f:[M] \to [N]$  and  $g:[M'] \to [N']$ , let  $f|g:[M+M'] \to [N+N']$  be defined via (f|g)(x) := f(x) for  $x=1, \dots, M$  and (f|g)(x) := g(x-M) + N for  $x=M+1, \dots, M+M'$ .

**Lemma 36** Assume that  $M \geq N$ . Let  $\hat{f}, \hat{g} : [N] \rightarrow [N]$  and  $\hat{h} : [M] \rightarrow [M]$  and  $\hat{\varphi} : [N+M] \rightarrow [N+M]$  be uniformly distributed permutations (all independent), and let  $H : [2N+M] \rightarrow [N+M]$  be a uniformly distributed function.

Then for any q-query adversary A,

$$\left|\Pr[A^H = 1] - \Pr[A^{\hat{\varphi} \circ \left((\hat{f} + \hat{g})|\hat{h}\right)} = 1]\right| \in O(q^3/N).$$

*Proof.* Let the following functions be uniformly distributed:

- $f,g:[N] \rightarrow [N]$ .
- $h:[M] \rightarrow [M]$ .
- $\varphi: [N+M] \to [N+M]$ .
- $v : [N] \to [N + M] \text{ and } w : [M] \to [N + M].$
- $a:[N] \to [2N]$  and  $b:[2N] \to [2N]$  and  $c:[2N] \to [N+M]$ .
- $\bullet \ H: [2N+M] \to [N+M].$

Let  $f, \hat{g}, h, \hat{\varphi}, \hat{v}, \hat{w}, \hat{a}, b, \hat{c}$  be uniformly distributed *injective* functions (with the same domains and ranges as the functions above). All functions are chosen independently.

For two functions f, g, let  $f \approx g$  mean that that  $|\Pr[A^f = 1] - \Pr[A^g = 1]| \in O(q^3/N)$ for any q-query adversary. And let  $f \equiv g$  mean that f and g have the same distribution. We will show the following facts:

$$\varphi \approx \hat{\varphi} \qquad v \approx \hat{v} \qquad c \approx \hat{c}$$
 (19)

$$\varphi \approx \hat{\varphi}$$
  $v \approx \hat{v}$   $c \approx \hat{c}$  (19)  
 $w \circ \hat{h} \equiv w$   $\hat{c} \circ \hat{a} \equiv \hat{v}$   $\hat{c} \circ \hat{b} \equiv \hat{c}$  (20)

 $\forall \alpha \text{ with range } [N], \forall \beta \text{ with range } [M] : \varphi \circ (\alpha | \beta) \equiv (v \circ \alpha) + (w \circ \beta)$ (21)

$$\hat{a} \circ (\hat{f} + \hat{g}) \approx \hat{b} \tag{22}$$

$$c + w \equiv H \tag{23}$$

From Corollary 34 we get (19). (Corollary 34 gives the bound  $O(q^3/(N+M))$  for the distinguishing probability. Since  $M \geq N$  this also implies the desired bound  $O(q^3/N)$ . The equations in (20) are immediate by definition of  $w, \hat{h}, w, \hat{c}, \hat{a}, \hat{v}, \hat{b}$ .

In (21), first notice that  $\varphi \equiv v + w$  and thus  $\varphi \circ (\alpha | \beta) \equiv (v + w) \circ (\alpha | \beta)$ . Let the range of  $\alpha$  be [N'] and that of  $\beta$  be [M']. By case distinction over  $x \in \{1, \ldots, N'\}$  and  $x \in \{N'+1,\ldots,N'+M'\}$  we check  $(v+w)\circ(\alpha|\beta)(x)=(v\circ\alpha)+(w\circ\beta)(x)$ . Then (21)

To show (22), let  $f_1, g_1 : [N] \to [2N]$  be two uniformly random functions conditioned on having identical range. Let  $f_2, g_2 : [N] \to [2N]$  be two uniformly random functions conditioned on having disjoint range. [Zha15, Theorem 4.1] states that a q-query adversary distinguishes  $f_1, g_1$  from  $f_2, g_2$  with probability at most  $O(q^3/N)$ . (This is the "Set Equality Problem".) As a consequence, a q-query adversary distinguishes  $f_1 + g_1$  and  $f_2 + g_2$  with probability at most  $O(q^3/N)$ . One can verify that  $f_1 + g_1 \equiv \hat{a} \circ (\hat{f} + \hat{g})$  and  $f_2 + g_2 \equiv \hat{b}$ . Thus an adversary distinguishing  $\hat{a} \circ (\hat{f} + \hat{g})$  and  $\hat{b}$  also distinguishes  $f_1 + g_1$ and  $f_2 + g_2$  with the same probability. (22) follows.

And (23) is immediate.

We then have:

$$\hat{\varphi} \circ ((\hat{f} + \hat{g})|\hat{h}) \overset{\text{(19)}}{\approx} \varphi \circ ((\hat{f} + \hat{g})|\hat{h}) \overset{\text{(21)}}{\equiv} (v \circ (\hat{f} + \hat{g})) + (w \circ \hat{h}) \overset{\text{(20)}}{\equiv} (v \circ (\hat{f} + \hat{g})) + w \overset{\text{(19)}}{\approx} (\hat{c} \circ (\hat{f} + \hat{g})) + w \overset{\text{(20)}}{\approx} (\hat{c} \circ \hat{a} \circ (\hat{f} + \hat{g})) + w \overset{\text{(22)}}{\approx} (\hat{c} \circ \hat{b}) + w \overset{\text{(20)}}{\equiv} \hat{c} + w \overset{\text{(19)}}{\approx} c + w \overset{\text{(23)}}{\equiv} H.$$

(In some of these steps, we implicitly perform a reduction to (19) or (22). E.g., in  $\hat{c}+w\approx c+w$ , we use queries to  $\hat{c}$  to simulate queries to  $\hat{c}+w$ . In some of these reductions, it is not obvious that this simulation does not double the number of queries from q to 2q. However,  $O(q^3/N) = O((2q)^3/N)$ , so (19) or (22) apply with the same asymptotic bound to adversaries making 2q queries.)

Note that  $\approx$  is transitive (the distinguishing advantage of the adversary may double, but will still be in  $O(q^3/N)$ ). Thus  $\hat{\varphi} \circ ((\hat{f} + \hat{g})|\hat{h}) \approx H$  which proves the lemma.  $\square$ 

**Lemma 37** Assume that  $|Y| = \lceil \frac{2}{3}|X| \rceil$ . Then H is collapsing with advantage  $O(\sqrt{q^3/|X|})$ .

Proof sketch: For simplicity, we consider the case |Y|=2N, |X|=3N. Then, by Lemma 36 with M:=N, H is indistinguishable from  $H^*:=\hat{\varphi}\circ \left((\hat{f}+\hat{g})|\hat{h}\right)$ . Furthermore, for a random permutation  $\pi$ , H and  $H\circ\pi$  are identically distributed, and  $H\circ\pi$  is indistinguishable from  $H^*\circ\pi$ . Thus it is sufficient to show that  $H^*\circ\pi$  is collapsing. In turn, by Lemma 33, it is sufficient to show that  $H^*\circ\pi$  is half-collision resistant. To show that, observe that the half-collisions of  $H^*$  are the inputs  $1,\ldots,2N$ , but not  $2N+1,\ldots,3N$ . Thus the half-collisions of  $H^*\circ\pi$  are  $P:=\pi^{-1}(\{1,\ldots,2N\})$ . So, the half-collision resistance adversary has to find elements of P, without false positives, while given oracle access to  $H^*\circ\pi$ . But  $H^*\circ\pi$  is indistinguishable from  $H\circ\pi$ , so the adversary would also be able to find elements in P given  $H\circ\pi$ . Since  $H\circ\pi$  is a random function, independent of P, the adversary cannot do that without getting false positives. Hence  $H^*\circ\pi$  is half-collision resistant and thus collapsing. Hence H is collapsing.

*Proof.* Let N := |X| - |Y| and M := 2|Y| - |X|. Then  $M - N = 3|Y| - 2|X| \ge 3 \cdot \frac{2}{3}|X| + 2|X| = 0$ , hence  $M \ge N$ .

Since |X| = 2N + M and |Y| = N + M, we can assume that X = [2N + M] and Y = [N + M]. Thus, by Lemma 36, H is indistinguishable from  $H^* := \hat{\varphi} \circ ((\hat{f} + \hat{g})|\hat{h})$  where  $\hat{\varphi}, \hat{f}, \hat{g}, \hat{h}$  are random permutations as in Lemma 36. More precisely, a (4q + 4)-query adversary distinguishes H and  $H^*$  with probability at most  $\delta \in O((4q + 4)^3/N) = O(q^3/N)$ .

Let  $\pi: X \to X$  be a uniformly random permutation. Then also  $H \circ \pi$  and  $H^* \circ \pi$  are distinguished with probability at most  $\delta$ . And since  $H \circ \pi$  and H have the same distribution, H and  $H^* \circ \pi$  are distinguished with probability at most  $\delta$ .

Assume a q-query adversary (A, B) against the collapsing property of H with some advantage  $\varepsilon$ . We will prove that  $\varepsilon \in O(\sqrt{q^3/N}) = O(\sqrt{q^3/|X|})$ .

Since H and  $H^* \circ \pi$  cannot be distinguished with probability greater than  $\delta$ , it follows that (A, B) has advantage  $\geq \varepsilon - 2\delta$  against the collapsing property of  $H^* \circ \pi$ . (Because each of the probabilities in Definition 23 can change by at most  $\delta$ .)

Thus, by Lemma 33, there is an adversary D with advantage  $\geq (\varepsilon - 2\delta)^2/4$  against the half-collision resistance of  $H^* \circ \pi$ . D makes at most 4q + 4 queries. That is:

$$\Pr[D^{H^*\circ\pi} \text{ outputs half-collision}] \geq \tfrac{(\varepsilon-2\delta)^2}{4}, \quad \Pr[D^{H^*\circ\pi} \text{ outputs non-half-collision}] = 0$$

By definition of + and | from Lemma 36, and since  $\hat{\varphi}, \hat{f}, \hat{g}, \hat{h}$  are all permutations, the half-collisions of  $H^* = \hat{\varphi} \circ ((\hat{f} + \hat{g})|\hat{h})$  are  $1, \ldots, 2N$ , while  $2N + 1, \ldots, 2N + M$  are the

non-half-collisions. Thus the half-collisions of  $H^* \circ \pi$  are  $P := \pi^{-1}(\{1, \dots, 2N\})$ . Thus we have

$$\Pr[D^{H^* \circ \pi} \in P] \ge \frac{(\varepsilon - 2\delta)^2}{4}, \qquad \Pr[D^{H^* \circ \pi} \in X \setminus P] = 0.$$

Since  $H^*$  is  $\delta$ -indistinguishable from H by (4q + 4)-query adversaries (in particular by D), it follows that

$$p_{hit} := \Pr[D^{H \circ \pi} \in P] \ge \frac{(\varepsilon - 2\delta)^2}{4} - \delta, \qquad p_{miss} := \Pr[D^{H \circ \pi} \in X \setminus P] \le \delta.$$
 (24)

Since  $\pi$  is a permutation and H is a random function,  $(H \circ \pi, \pi)$  and  $(H, \pi)$  are identically distributed. Thus

$$p_{hit} = \Pr[D^H \in P], \qquad p_{miss} = \Pr[D^H \in X \setminus P].$$

(Recall that  $P = \pi^{-1}(\{1, \dots, 2N\})$ .) Since P is a uniformly random subset of X of size 2N, and independent of H, we have:

$$p_{hit} = \frac{|P|}{|X|} \Pr[D^H \in X], \qquad p_{miss} = \frac{|X \setminus P|}{|X|} \Pr[D^H \in X]. \tag{25}$$

Then

$$\frac{(\varepsilon-2\delta)^2}{4} - \delta \overset{(24)}{\leq} p_{hit} \overset{(25)}{=} \frac{|P|}{|X|} \frac{|X|}{|X \setminus P|} p_{miss} = \frac{2N}{M} p_{miss} \overset{(24)}{\leq} \frac{2N}{M} \delta \overset{M \geq N}{\leq} 2\delta.$$

Solving this inequality for  $\varepsilon$ , we get  $\varepsilon \leq \sqrt{12\delta} + 2\delta \in O(\sqrt{q^3/N}) = O(\sqrt{q^3/|X|})$ .

Since  $\varepsilon$  was the advantage of an arbitrary q-query adversary (A, B) against the collapsing property of H, the lemma follows.

**Theorem 38** Let Y be finite, and  $X \subseteq \{0,1\}^*$  (finite or infinite). Then  $H: X \to Y$  is collapsing with advantage  $O(\sqrt{q^3/|Y|})$ .

*Proof sketch:* H is indistinguishable from a composition  $f_n \circ \cdots \circ f_1$  of random functions  $f_n : X_n \to Y_n$  with  $|X_{n+1}| = |Y_n| = \frac{2}{3}|X_n|$ . By Lemma 37, each  $f_n$  is collapsing. Thus, by Corollary 28,  $f_n \circ \cdots \circ f_1$  is collapsing and hence H is collapsing.

*Proof.* We first consider the case that X = [M] for some M.

Since we are interested only in the asymptotic complexity, we can further assume  $|Y| \ge 11$ . And since the case  $|X| \le |Y|$  is covered by Lemma 35, we can assume |X| > |Y|.

Let  $t(x) := \lceil \frac{2}{3}x \rceil$ . Let  $n \ge 0$  be the smallest integer such that  $t^n(M) \le |Y|$ . (Such integer always exists: if  $t^i(M) > |Y| \ge 11$ , then  $t^{i+1}(M) < t^i(M)$ , hence  $t^i(M)$  decreases until it becomes smaller-equal |Y|.)

Further, since  $t^{i-1}(M) > |Y| \ge 11$  for i = 1, ..., n we have that

$$t^i(M) = \lceil \tfrac{2}{3} t^{i-1}(M) \rceil \leq \tfrac{2}{3} t^{i-1}(M) + 1 \leq \tfrac{2}{3} t^{i-1}(M) + \tfrac{1}{12} t^{i-1}(M) = \tfrac{3}{4} t^{i-1}(M)$$

for  $i = 1, \ldots, n$ . Thus

$$t^{n-i}(M) \ge (\frac{4}{3})^i t^n(M) \ge (\frac{4}{3})^i \frac{2}{3} t^{n-1}(M) \ge (\frac{4}{3})^i \frac{2}{3} |Y|$$
 for  $i = 0, \dots, n$ . (26)

For i = 1, ..., n, let  $f_i : [t^{i-1}(M)] \to [t^i(M)]$  be a uniformly random function.

Let  $h:[t^n(M)]\to Y$  be a uniformly random function. (h and all  $f_i$  are independent.) We define  $H^*:X\to Y$  as  $H^*:=h\circ f_n\circ\cdots\circ f_1$ .

We will first show that  $H^*$  is collapsing. By Lemma 37, there is a constant C > 0 such that each  $f_i$  is collapsing with advantage  $C\sqrt{q^3/t^{i-1}(M)}$ .

And by Lemma 35, h is collapsing with advantage  $C'q^3/|Y|$  for some constant C' > 0. (Note that the domain of h is smaller than its range by definition of n.)

Let  $\varepsilon_i$  denote a tight upper bound such that  $f_n \circ \cdots \circ f_{n-i+1}$  is collapsing with advantage  $\varepsilon_i$  for (q+2)-query adversaries. Then  $\varepsilon_0 = 0$  since the identity is collapsing with advantage 0 by Lemma 24.

By Lemma 27 (with  $f := f_{n-i+1}$  and  $g := f_n \circ \cdots \circ f_{n-i+2}$ ), we then get for  $i \ge 1$ :

$$\underbrace{\varepsilon_{i}}_{\text{advantage against}} \leq \underbrace{\varepsilon_{i-1}}_{\text{advantage against}} + \underbrace{C\sqrt{(q+4)^{3}/t^{n-i}(M)}}_{\text{advantage against}}.$$

$$\underbrace{g\circ f}_{f_{n}\circ\cdots\circ f_{n-i+1}} \circ \underbrace{g=f_{n}\circ\cdots\circ f_{n-i+2}}_{\text{in } q+2 \text{ queries}} \circ \underbrace{f=f_{n-i+1}}_{\text{in } q+4 \text{ queries}}.$$
(27)

Note that when applying Lemma 27, both the adversary for the left and the right summand in (27) makes two more queries to  $f = f_{n-i+1}$  than the (q+2)-query adversary having the advantage  $\varepsilon_i$  against  $g \circ f$ . However, since all  $f_i$  are chosen independently, the adversary in the left summand (who attacks  $g = f_n \circ \cdots \circ f_{n-i+2}$ ) can chose  $f = f_{n-i+1}$  himself. Thus the advantage in the left summand is with respect to adversaries that make only q+2 queries to g.

From (27) we get (using  $\varepsilon_0 = 0$ ):

$$\varepsilon_n \le \sum_{i=1}^n C\sqrt{(q+4)^3/t^{n-i}(M)} \stackrel{(26)}{\le} \sum_{i=1}^n C\sqrt{(q+4)^3/(\frac{4}{3})^i \frac{2}{3}|Y|}$$
$$\le C\sqrt{\frac{3}{2}(q+4)^3/|Y|} \cdot \sum_{i=1}^\infty (\frac{3}{4})^{i/2} \in O(\sqrt{q^3/|Y|}).$$

By definition,  $\varepsilon_n$  upper bounds the advantage of a (q+2)-query adversary against  $f_n \circ \cdots \circ f_1$ . And the advantage of a q-query adversary against h is  $\leq C'q^3/|Y|$  (see above). Thus by Lemma 27 (with g := h and  $f := f_n \circ \cdots \circ f_1$ ) the advantage of a q-query adversary against  $H^* = h \circ f_n \circ \cdots \circ f_1$  is at most

$$\delta := C'q^3/|Y| + \varepsilon_n \in O(\sqrt{q^3/|Y|}).$$

We have shown that  $H^*$  is collapsing with advantage  $O(\sqrt{q^3/|Y|})$ . To show that H is collapsing, we will first show that H and  $H^*$  are indistinguishable.

Let  $H_i:[t^i(M)] \to Y$  denote a uniformly random function. [Zha12, Corollary VII.5 (Small range distributions)] shows that for independent uniformly random functions  $a:A\to B, b:B\to C$ , and  $c:A\to C$ , a q-query adversary can distinguish  $b\circ a$  from c with probability at most  $27q^3/|B|$ . Hence for  $i=1,\ldots,n,\ H_i\circ f_i$  and  $H_{i-1}$  can be distinguished with probability at most  $27q^3/t^i(M)$ . Hence  $H_i^*:=H_i\circ f_i\circ\cdots\circ f_1$  and

 $H_{i-1}^* = H_{i-1} \circ f_{i-1} \circ \cdots \circ f_1$  can be distinguished with probability at most  $27q^3/t^i(M)$ . Thus  $H_0^*$  and  $H_n^*$  can be distinguished with probability at most

$$\gamma := \sum_{i=1}^{n} 27q^3/t^i(M) \overset{(26)}{\leq} \sum_{i=1}^{n} 27q^3 \tfrac{3}{2} (\tfrac{3}{4})^{n-i}/|Y| \le \tfrac{81}{2} q^3/|Y| \cdot \sum_{i=0}^{\infty} (\tfrac{3}{4})^i \in O(q^3/|Y|).$$

Note that  $H_n$  is identically distributed to h, hence  $H_n^*$  is identically distributed to  $H^*$ . And  $H_0^* = H_0 : [M] \to Y$  is identically distributed to H. Hence  $H^*$  and H can be distinguished with probability at most  $\gamma$ .

Now we can prove that H is collapsing. Since  $H^*$  is collapsing with advantage  $\leq \delta$ , we have that for any q-query adversary,

$$\left|\Pr[b=1:\mathsf{Game}_1 \text{ using } H^*] - \Pr[b=1:\mathsf{Game}_2 \text{ using } H^*]\right| \le \delta. \tag{28}$$

Here  $\mathsf{Game}_1$ ,  $\mathsf{Game}_2$  are the games from Definition 23. Since H and  $H^*$  are indistinguishable (with advantage  $\leq \gamma$ ), replacing  $H^*$  by H changes the two probabilities in (28) by at most  $\gamma$ . Hence we get

$$|\Pr[b=1:\mathsf{Game}_1 \text{ using } H] - \Pr[b=1:\mathsf{Game}_2 \text{ using } H]| \leq \delta + 2\gamma$$

Thus H is collapsing with advantage  $\leq \delta + 2\gamma \in O(\sqrt{q^3/|Y|})$ . The theorem follows for the case of |X| = [M].

The case for finite X follows immediately by setting M := |X|. (This is just a relabeling of the elements of X.)

Finally, we prove the theorem for infinite  $X \subseteq \{0,1\}^*$ : Fix a q-query adversary (A,B). Let  $\mu$  denote the advantage of (A,B) against the collapsing property of  $H:X\to Y$ . Let  $X_i:=\{x\in X:|x|\leq i\}$ . Let  $H_i:X_i\to Y$  be a uniformly random function. Let  $\mu_i$  denote the advantage of (A,B) against the collapsing property of  $H_i$ . Then  $\mu_i\to\mu$  for  $i\to\infty$ . Furthermore, we have already shown that against a finite  $H_i:X_i\to Y$ , the advantage is at most  $\delta+2\gamma$ . Hence  $\mu_i\leq \delta+2\gamma$ . Note that  $\delta+2\gamma$  does not depend on the size of  $X_i$ , only on the size of Y. Thus  $\mu_i\leq \delta+2\gamma$  implies  $\mu\leq \delta+2\gamma$ . Thus H is collapsing with advantage  $\leq \delta+2\gamma\in O(\sqrt{q^3/|Y|})$  for infinite X.

## 7 Zero-knowledge arguments of knowledge

In this section, we study the security of sigma-protocols. A sigma-protocol is a specific kind three-round proof system in which the verifier's message consists only of random bits. Sigma-protocols play an important role in classical constructions of zero-knowledge proof systems for two reasons: For a number of simple but important languages, sigma-protocols exist. And given sigma-protocols for simple languages, there are efficient constructions for more complex languages. (There are constructions for conjunctions and disjunctions of sigma-protocols, as well as more complex threshold constructions [CDS94].)

In the classical setting, it is relatively simple to give conditions under which sigmaprotocols are zero-knowledge proofs of knowledge. In the quantum setting, however, analyzing the security of sigma-protocols turns out to be much harder. Watrous [Wat09] presented a rewinding technique for proving the zero-knowledge property of sigma-protocols (see also Theorem 41 below). Unruh [Unr12] showed that sigma-protocols are quantum proofs of knowledge under a specific additional condition called "strict soundness". This condition requires that the third message ("response") in a valid interaction is uniquely determined by the first two. However, strict soundness is a strong additional assumption. [Unr12] showed how to achieve strict soundness by committing to the response already in the first message. However, the commitment scheme used for this needed to be perfectly-binding (actually, it needed to satisfy a somewhat stronger property, called "strict binding"). In particular, this implies that the commitment scheme cannot be information-theoretically hiding (hence the resulting protocol cannot be statistical zero-knowledge), and we cannot have short commitments (a perfectly-binding commitment will always be at least as long as the message inside).

Furthermore, Ambainis, Rosmanis, and Unruh [ARU14] showed that the condition of strict soundness is necessary, at least relative to an oracle. They also showed that even if we assume that strict soundness holds, but only against computationally limited adversaries, the resulting sigma-protocol will, in general, not be a quantum argument of knowledge. Even more, it might not even be a quantum argument. That is, a computationally limited adversary can successfully prove a wrong statement.

In this section we show how we can use collapse-binding commitments as a drop-in replacement for the perfectly-binding commitments in the construction from [Unr12]. One particular consequence is that given collapse-binding hash functions we can construct three-round statistical zero-knowledge quantum arguments of knowledge from sigma-protocols (without using a common-reference string). This assumes the sigma-protocol is statistical honest-verifier zero-knowledge and has special soundness. And that the challenge space (the set from which the verifier picks his random message) is polynomially-bounded. These properties, however, are also needed in the classical setting.

#### 7.1 Interactive proof systems

An interactive proof system (P, V) for some relation R consists of two interactive quantum machines P and V that get classical inputs  $(x, w) \in R$  and x, respectively. Afterwards, V outputs a bit. For formal definitions see [Unr12]. (In general, P and V can exchange quantum messages, but our concrete constructions below will be classical.)

We consider two important properties of interactive proof systems: First, we want them to be arguments of knowledge. Informally, they should convince the verifier that the prover knows a witness w for the statement x (i.e.,  $(x, w) \in R$ ). Second, we want them to be zero-knowledge. Informally, the proof should not leaks anything about the witness besides its existence.

<sup>&</sup>lt;sup>16</sup>I.e., it is hard to find two different valid interactions where the first two messages are equal but the response is different.

<sup>&</sup>lt;sup>17</sup>Argument and argument of knowledge are the variants of proof and proof of knowledge that consider a computationally limited malicious prover.

Quantum arguments of knowledge. The following definition of quantum arguments of knowledge follows the definition from [Unr15b], with one difference: we have formulated security against uniform malicious provers. That is, while in [Unr15b] the statement x and the auxiliary input  $|\Psi\rangle$  are all-quantified, in our setting they are chosen by an quantum-polynomial-time algorithm Z. The reason we consider only uniform malicious provers here is: A non-uniform adversary can break any non-interactive commitment (with classical messages) that is not already perfectly-binding. (Namely, the auxiliary input can simply contain one commitment and two different openings.) Thus, since we consider only non-interactive commitments in this paper, we need a uniform definition of quantum arguments of knowledge. For a motivation of the remaining definitional choices, see [Unr15b].

**Definition 39 (Quantum Arguments of Knowledge)** We call an interactive proof system (P,V) for a relation R (uniformly) quantum-computationally extractable with knowledge error  $\kappa$  if there exists a constant d>0, a polynomially-bounded function p>0, and a quantum-polynomial-time oracle algorithm K such that for any unitary quantum-polynomial-time algorithm  $P^*$ , for any polynomial  $\ell$ , and for any quantum-polynomial-time algorithm K (input generator), there exists a negligible  $\mu$  such that for any security parameter  $\eta \in \mathbb{N}$ , we have that

$$\begin{split} \Pr[\langle \mathsf{P}^*(1^\eta, x, Z), \mathsf{V}(1^\eta, x) \rangle &= 1: (x, Z) \leftarrow \mathsf{Z}(1^\eta)] \geq \kappa(\eta) \implies \\ \Pr[(x, w) \in R: (x, Z) \leftarrow \mathsf{Z}(1^\eta), w \leftarrow \mathsf{K}^{\mathsf{P}^*(1^\eta, x, Z)}(1^\eta, x)] \\ &\geq \frac{1}{p(\eta)} \Big( \Pr\big[\langle \mathsf{P}^*(1^\eta, x, Z), \mathsf{V}(1^\eta, x) \rangle = 1: (x, Z) \leftarrow \mathsf{Z}(1^\eta) \big] - \kappa(\eta) \Big)^d - \mu(\eta). \end{split}$$

Here  $\langle \mathsf{P}^*(1^\eta,x,Z),\mathsf{V}(1^\eta,x)\rangle$  is the output of  $\mathsf{V}$  after an interaction between  $\mathsf{P}^*$  and V on the respective inputs x and Z. Z is a quantum register, x is classical, both initialized using the algorithm Z. And  $\mathsf{K}^{\mathsf{P}^*(1^\eta,x,Z)}$  refers to an execution of  $\mathsf{K}$  with black-box access to  $\mathsf{P}^*(1^\eta,x,Z)$ . That is,  $\mathsf{K}$  can apply the unitary  $U_x$  describing the prover  $\mathsf{P}^*$  and its inverse  $U_x^\dagger$ . (See [Unr12] for a more detailed description of that black-box execution model.)

Quantum zero-knowledge. Roughly speaking, (P, V) is quantum-computationally zero-knowledge iff for any quantum-polynomial-time malicious verifier  $V^*$ , there exists a quantum-polynomial-time simulator S such that for any  $(x, w) \in R$ , the output state of S is quantum computationally indistinguishable from the from the output state of  $V^*$  in an interaction with  $P(1^{\eta}, x, w)$ .

Similarly, quantum statistical zero-knowledge is defined in the same way, except that  $V^*$  is not required to be quantum-polynomial-time.

We will not use the definition of quantum zero-knowledge directly, only the imported Theorem 41 from [Unr15b] will refer to it. We therefore omit the formal definition and refer to [Unr15b].

#### 7.2 Sigma-protocols

We now introduce sigma-protocols (following [Unr15a] with modifications as mentioned in the footnotes). The notions are like the standard classical definitions, all that was done to adopt them to the quantum setting was to make the adversary quantum-polynomial-time.

A sigma-protocol for a relation R is a three-message proof system. It is described by its challenge space  $N_z$  (where  $|N_z| \geq 2$ ), a classical-polynomial-time prover  $(P_1, P_2)$  and a deterministic classical-polynomial-time verifier V. The first message from the prover is  $a \leftarrow P_1(1^{\eta}, x, w)$  and is called the *commitment*, the uniformly random reply from the verifier is  $z \stackrel{\$}{\leftarrow} N_z$  (called *challenge*), and the prover answers with  $r \leftarrow P_2(1^{\eta}, x, w, z)$  (the response). We assume  $P_1, P_2$  to share state. Finally  $V(1^{\eta}, x, a, z, r)$  outputs whether the verifier accepts.

**Definition 40 (Properties of sigma-protocols)** Let  $\Sigma = (N_z, P_1, P_2, V)$  be a sigma-protocol. We define:

• Completeness: For any quantum-polynomial-time algorithm A,

$$\Pr[(x, w) \in R \land ok = 0 : (x, w) \leftarrow A(1^{\eta}),$$

$$a \leftarrow P_1(1^{\eta}, x, w), z \stackrel{\$}{\leftarrow} N_z, r \leftarrow P_2(1^{\eta}, x, w, z), ok \leftarrow V(1^{\eta}, x, a, z, r)]$$

is negligible.

• Computational special soundness: There is a quantum-polynomial-time algorithm  $E_{\Sigma}$  (the extractor)<sup>18</sup> such that for any quantum-polynomial-time A, we have that

$$\Pr[(x, w) \notin R \land z \neq z' \land ok = ok' = 1 : (x, a, z, r, z', r') \leftarrow A(1^{\eta}), \\ ok \leftarrow V(1^{\eta}, x, a, z, r), ok' \leftarrow V(1^{\eta}, x, a, z', r'), w \leftarrow E_{\Sigma}(1^{\eta}, x, a, z, r, z', r')]$$

is negligible.

• Honest-verifier zero-knowledge (HVZK): There is a quantum-polynomialtime algorithm  $S_{\Sigma}$  (the simulator)<sup>19</sup> such that for any quantum-polynomial-time algorithm A and any polynomial  $\ell$ , the following is negligible for all  $(x, w) \in R$  with  $|x|, |w| \leq \ell(\eta)$  and all states  $|\Psi\rangle$ :

$$|\operatorname{Pr}[b=1:a\leftarrow P_1(1^{\eta},x,w),\ z\stackrel{\$}{\leftarrow} N_z,\ r\leftarrow P_2(1^{\eta},x,w,z),\ b\leftarrow A(1^{\eta},|\Psi\rangle,a,z,r)] - \operatorname{Pr}[b=1:(a,z,r)\leftarrow S_{\Sigma}(1^{\eta},x),\ b\leftarrow A(1^{\eta},|\Psi\rangle,a,z,r)]|$$

• Statistical honest-verifier zero-knowledge (SHVZK): Like HVZK, except that we quantify over computationally unlimited A (not only quantum-polynomial-time A).

<sup>&</sup>lt;sup>18</sup>[Unr15a] requires a classical  $E_{\Sigma}$  here. By allowing  $E_{\Sigma}$  to be quantum here, we weaken the notion of computational special soundness slightly, and thus strengthen our results below.

<sup>&</sup>lt;sup>19</sup>[Unr15a] requires a classical  $S_{\Sigma}$  here. By allowing  $E_{\Sigma}$  to be quantum here, we weaken the notion of HVZK/SHVZK slightly, and thus strengthen our results below.

Note that the above are the standard conditions expected from sigma-protocols in the classical setting. In contrast, for a sigma-protocol to be a *quantum* proof of knowledge, a much more restrictive condition is required, strict soundness [Unr12, ARU14]. We show below how to circumvent this necessity by adding collapse-binding commitments to the sigma-protocol (at least when we only need a quantum *argument* of knowledge).

**Remark 1.** Any sigma-protocol  $(N_z, P_1, P_2, V)$  can be seen as an interactive proof (P, V) in a natural way: P sends the output a of  $P_1$  to V. V picks  $z \stackrel{\$}{\leftarrow} N_z$  and sends it to P. P sends the resulting output r of  $P_2$  to V. V checks the triple (a, z, r) using V.

The following theorem is shown in [Unr15b]:

Theorem 41 (HVZK implies zero-knowledge [Unr15b]) Let  $\Sigma = (N_z, P_1, P_2, V)$  be a sigma-protocol. We consider  $\Sigma$  as an interactive proof (P, V), see Remark 1.

If  $|N_z|$  is polynomially-bounded and is SHVZK, then  $\Sigma$  is quantum statistical zero-knowledge.

If  $|N_z|$  is polynomially-bounded and  $\Sigma$  is HVZK, then  $\Sigma$  is quantum computational zero-knowledge.

Due to this theorem, it will be sufficient to verify that the sigma-protocols we construct are HVZK/SHVZK. We will hence not need to use the definition of quantum zero-knowledge explicitly in the following.

### 7.3 Constructing zero-knowledge arguments of knowledge

In [Unr12], the following idea was used to construct quantum proofs of knowledge: We assume a sigma-protocol with special soundness and with polynomial-size  $|N_z|$ . We convert it into a sigma-protocol with strict soundness as follows: When the prover sends his commitment  $a \leftarrow P_1(x, w)$ , he additionally sends  $com(r_z)$  for all  $z \in N_z$  where  $r_z$  is the response to the challenge z. When the prover receives the challenge z, he opens  $com(r_z)$  instead of sending  $r_z$ . If the commitment has the "strict binding" property, the resulting sigma-protocol has strict soundness (without losing the special soundness or HVZK property). Strict binding is a strengthening of perfect binding, it means that not only the message in the commitment is information-theoretically determined, but also the opening information.

Given a sigma-protocol with strict and special soundness, we can show that it is a proof of knowledge. Basically, [Unr12] runs the protocol twice (using the inverse of the unitary malicious prover to rewind) to get two responses r, r' for different challenges  $z \neq z'$ . The difficulty here is that measuring r can disturb the state of the malicious prover, leading to a corrupt value r'. The trick here is that due to the strict soundness, the value r is essentially uniquely determined, and therefore the measurement does not introduce too much disturbance.<sup>21</sup>

<sup>&</sup>lt;sup>20</sup>This part was done only implicitly in [Unr12], in the analysis of the Hamiltonian cycle proof system. <sup>21</sup>There is some disturbance due to the fact that it is not determined whether r is a valid response or

an invalid one.

Unfortunately, that technique needs commitments with the strict binding property. First, it is easy to see that strict binding commitments must be longer than the messages they contain. Short strict binding commitments are not possible. Furthermore, the only known construction of strict binding commitments [Unr12] uses quantum 1-1 one-way functions. No candidates for those are known.

We show below that the same technique of committing to the responses works with collapse-binding commitments. The crucial point in the analysis from [Unr12] was that measuring the committed response does not change the state. The collapse-binding property guarantees something slightly weaker: when measuring the committed response, the state may change, but this cannot be noticed by a computationally limited adversary. So with collapse-binding commitments, an analog reasoning as in [Unr12] can be used, except that we get security only against quantum-polynomial-time adversaries. I.e., we get a quantum argument of knowledge.

We will now describe this in more detail.

First, we formalize the sigma-protocol in which we commit to the responses:

Definition 42 (Sigma-protocol with committed responses) Let  $(N_z, P_1, P_2, V)$ be a sigma-protocol with polynomially-bounded  $|N_z|$ . Let (com, verify) be a commitment scheme (with the responses of  $(N_z, P_1, P_2, V)$  as message space). We construct a sigma-protocol  $(N_z, P'_1, P'_2, V')$  as follows:

- $P'_1(1^{\eta}, x, w)$  runs:  $a \leftarrow P_1(1^{\eta}, x, w)$ . For each  $z \in N_z$ :  $r_z \leftarrow P_2(1^{\eta}, x, w, z)^{22}$  and  $(c_z, u_z) \leftarrow com(1^{\eta}, r_z)$ . Let  $a' := (a, (c_z)_{z \in N_z})$  and return a'.

    $P'_2(1^{\eta}, x, w, z)$  returns  $r' := (r_z, u_z)$ .

    $V'(1^{\eta}, x, a', z, r')$  with  $a' = (a, (c_z)_{z \in N_z})$  and r' = (r, u): Check whether
- $verify(1^{\eta}, c_z, r, u) = 1 \text{ and } V(1^{\eta}, a, z, r) = 1. \text{ Iff so, return } 1.$

We show that the above construction is a quantum argument of knowledge:

Theorem 43 (Quantum argument of knowledge) If  $(N_z, P_1, P_2, V)$  is a sigmaprotocol with computational special soundness for a relation R, and (com, verify) is collapse-binding, then  $(N_z, P'_1, P'_2, V')$  from Definition 42 is computationally quantum extractable for R with knowledge error  $1/\sqrt{|N_z|}$ .

The proof of this theorem will rely on the following lemma from [Unr12]. (That lemma is the core lemma of the rewinding technique from [Unr12].)

Lemma 44 (Extraction via quantum rewinding [Unr12]) Let C be a set with |C| = c. Let  $(P_i)_{i \in C}$  be projectors. Let  $|\Phi\rangle$  be a unit vector. Let  $V := \sum_{i \in C} \frac{1}{c} ||P_i|\Phi\rangle||^2$  and  $E := \sum_{i,j \in C, i \neq j} \frac{1}{c^2} ||P_iP_j|\Phi\rangle||^2$ . Then, if  $V \ge \frac{1}{\sqrt{c}}$ ,  $E \ge V(V^2 - \frac{1}{c})$ .

Proof of Theorem 43. Recall that any sigma-protocol can be seen as an interactive proof system by Remark 1. Let (P, V) denote the interactive proof system resulting from the sigma-protocol  $(N_z, P'_1, P'_2, V')$ . (In particular, the verifier V sends a random  $z \in N_z$ , and in the end checks whether  $verify(1^{\eta}, c_z, r, u) = 1$  and  $V(1^{\eta}, a, z, r) = 1$ .)

<sup>&</sup>lt;sup>22</sup>We can run  $P_2$  several times using the final state of  $P_1$  because  $P_1$  is classical.

Let  $P^*$  denote a malicious prover, i.e., a unitary quantum-polynomial-time algorithm. Since  $P^*$  attacks a sigma-protocol, it sends two messages. We can thus assume that  $P^*$  is of the following form:

- It operates on quantum registers Z, C, R, U. Here Z contains the internal state of  $P^*$  (initialized by algorithm Z). C is the register that will contain the first message  $a' = (a, (c_z)_z)$  sent by  $P^*$ . R, U contains the second message r' = (r, u) sent by  $P^*$ . And C, R, U are initialized with  $|0\rangle$ .
- The unitary  $U_x$  describes the unitary operation of  $\mathsf{P}^*$  on Z, C during the first invocation of  $\mathsf{P}^*$ .  $U_x$  is parametrized by the classical input x of  $\mathsf{P}^*$ . The message  $a' = (a, (c_z)_z)$  is obtained by measuring C in the computational basis.
- The unitary  $U_z$  describes the unitary operation of  $\mathsf{P}^*$  on Z, R, U during the second invocation of  $\mathsf{P}^*$ .  $U_z$  is parametrized by the challenge z that  $\mathsf{P}^*$  receives. The message r' = (r, u) is obtained by measuring R and U in the computational basis.

We fix some additional notation for this proof:

- $V_z$ : The projector on R, U onto the span of all  $|r, u\rangle$  with  $verify(1^{\eta}, c_z, r, u) = 1$ . (That is,  $V_z$  measures whether measuring R, U would yield a valid opening of  $c_z$ .)
- $W_z$ : The projector on R onto the span of all  $|r\rangle$  with  $V(1^{\eta}, a, z, r) = 1$ . (That is,  $W_z$  measures whether measuring R yields a valid response r for challenge z.)
- $P_z := U_z^{\dagger} W_z V_z U_z$ . Since  $V_z$  and  $W_z$  are projectors and diagonal in the computational basis, they commute and their product is a projector. And since  $U_z$  is a unitary,  $P_z$  is a projector (acting on registers Z, R, U).
- $x \leftarrow \mathbf{M}(X)$  denotes that x is assigned the result of measuring the register X in the computational basis.
- $ok \leftarrow P(X)$  means that ok is assigned 1 iff measuring the register X with projector P succeeds. (With P being, e.g., one of  $V_z, W_z, P_z$ .)
- We write U(X) or U(X) to mean that the unitary U is applied to the register X. (With U being, e.g., one of  $U_x, U_z$ ).

With that notation, we can rewrite the success probability of the malicious prover as follows:

$$\begin{aligned} \Pr_{V} &:= \Pr[\mathsf{P}^{*}(1^{\eta}, x, Z), \mathsf{V}(1^{\eta}, x)) = 1 : (x, Z) \leftarrow \mathsf{Z}(1^{\eta})] \\ &= \Pr[ok_{c} = ok_{v} = 1 : (x, Z) \leftarrow \mathsf{Z}(1^{\eta}), \ U_{x}(ZC), \ (a, (c_{z})_{z}) \leftarrow \mathbf{M}(C), \ z \xleftarrow{\$} N_{z}, \\ U_{z}(ZRU), \ r \leftarrow \mathbf{M}(R), \ u \leftarrow \mathbf{M}(U), \ ok_{c} = verify(1^{\eta}, c_{z}, r, u), \ ok_{v} = V(1^{\eta}, a, z, r)] \\ &= \Pr[ok = 1 : (x, Z) \leftarrow \mathsf{Z}(1^{\eta}), \ U_{x}(ZC), \ (a, (c_{z})_{z}) \leftarrow \mathbf{M}(C), \ z \xleftarrow{\$} N_{z}, \ ok \leftarrow P_{z}(ZRU)]. \end{aligned}$$

We now construct the extractor  $\mathsf{K}^{\mathsf{P}^*(1^\eta,x,Z)}(1^\eta,x)$  required by Definition 39. It operates on quantum registers S,C,R,U as follows:

$$(x, Z) \leftarrow \mathsf{Z}(1^{\eta}), \ U_x(ZC), \ (a, (c_z)_z) \leftarrow \mathbf{M}(C), \ z, z' \stackrel{\$}{\leftarrow} N_z, \ U_z(ZRU), \ ok_c \leftarrow V_z(RU),$$
  
 $r \leftarrow \mathbf{M}(R), \ U_z^{\dagger}(ZRU), \ U_{z'}(ZRU), \ r' \leftarrow \mathbf{M}(R), \ w \leftarrow E_{\Sigma}(1^{\eta}, x, a, z, r, z', r'), \ \text{return } w.$ 

Here  $E_{\Sigma}$  is the extractor of the sigma-protocol  $(N_z, P_1, P_2, V)$ . This extractor exists because the sigma-protocol has computational special soundness (see Definition 40). Note that K only uses black-box access to P (via the unitaries  $U_x, U_z, U_{z'}$  and their inverses).

We will now bound the success probability of the extractor

$$\begin{split} \Pr_E := & \Pr[(x,w) \in R : w \leftarrow \mathsf{K}^{\mathsf{P}^*(1^\eta,x,Z)}(1^\eta,x)] \\ = & \Pr[(x,w) \in R : (x,Z) \leftarrow \mathsf{Z}(1^\eta), \ U_x(ZC), \ (a,(c_z)_z) \leftarrow \mathbf{M}(C), \ z,z' \overset{\$}{\leftarrow} N_z, \\ & U_z(ZRU), \ ok_c \leftarrow V_z(RU), \ r \leftarrow \mathbf{M}(R), \ U_z^\dagger(ZRU), \ U_{z'}(ZRU), \\ & r' \leftarrow \mathbf{M}(R), \ w \leftarrow E_\Sigma(1^\eta,x,a,z,r,z',r')] \\ = & \Pr[(x,w) \in R : (x,Z) \leftarrow \mathsf{Z}(1^\eta), \ U_x(ZC), \ (a,(c_z)_z) \leftarrow \mathbf{M}(C), \ z,z' \overset{\$}{\leftarrow} N_z, \\ & U_z(ZRU), \ ok_c \leftarrow V_z(RU), \ r \leftarrow \mathbf{M}(R), \ ok_v \leftarrow V(1^\eta,x,a,z,r), \ U_z^\dagger(ZRU), \\ & U_{z'}(ZRU), \ r' \leftarrow \mathbf{M}(R), \ ok_v' \leftarrow V(1^\eta,x,a,z',r'), \ w \leftarrow E_\Sigma(1^\eta,x,a,z,r,z',r')]. \end{split}$$

Due to the computational special soundness of  $(N_z, P_1, P_2, V)$ , in the previous game, with overwhelming probability,  $z \neq z'$  and  $ok_v = 1$  and  $ok_{v'} = 1$  implies  $(x, w) \in R$ . Thus there exists a negligible  $\mu_1$  such that

$$\Pr_{E} \geq \Pr[z \neq z' \land ok_{v} = ok'_{v} = 1 : (x, Z) \leftarrow \mathsf{Z}(1^{\eta}), \ U_{x}(ZC), \ (a, (c_{z})_{z}) \leftarrow \mathbf{M}(C), \ z, z' \stackrel{\$}{\leftarrow} N_{z}, \\ U_{z}(ZRU), \ ok_{c} \leftarrow V_{z}(RU), \ r \leftarrow \mathbf{M}(R), \ ok_{v} \leftarrow V(1^{\eta}, x, a, z, r), \ U_{z}^{\dagger}(ZRU), \\ U_{z'}(ZRU), \ r' \leftarrow \mathbf{M}(R), \ ok'_{v} \leftarrow V(1^{\eta}, x, a, z', r')] - \mu_{1} =: \Pr_{E}' - \mu_{1}.$$

Instead of computing  $ok_v \leftarrow V(1^{\eta}, x, a, z, r)$  using the just measured r, we can instead measure whether the register R contains a value r that would make  $V(1^{\eta}, x, a, z, r) = 1$  true. I.e., we can replace  $ok_v \leftarrow V(1^{\eta}, x, a, z, r)$  by a measurement using the projector  $W_z$ . Since at that point, R was just measured in the computational basis, the measurement using  $W_z$  does not disturb the state of the system. Similarly, we can replace  $ok'_v \leftarrow V(1^{\eta}, x, a, z', r')$  by a measurement using  $W_{z'}$ . We get:

$$\begin{aligned} \Pr_E' &= \Pr[z \neq z' \land ok_v = ok_v' = 1 : (x, Z) \leftarrow \mathsf{Z}(1^{\eta}), \ U_x(ZC), \ (a, (c_z)_z) \leftarrow \mathbf{M}(C), \\ &z, z' \stackrel{\$}{\leftarrow} N_z, \ U_z(ZRU), \ ok_c \leftarrow V_z(RU), \ r \leftarrow \mathbf{M}(R), \ ok_v \leftarrow W_z(R), \ U_z^{\dagger}(ZRU), \\ &U_{z'}(ZRU), \ r' \leftarrow \mathbf{M}(R), \ ok_v' \leftarrow W_{z'}(R)] \\ &= \Pr[z \neq z' \land ok_v = ok_v' = 1 : (x, Z) \leftarrow \mathsf{Z}(1^{\eta}), \ U_x(ZC), \ (a, (c_z)_z) \leftarrow \mathbf{M}(C), \\ &z, z' \stackrel{\$}{\leftarrow} N_z, \ U_z(ZRU), \ ok_c \leftarrow V_z(RU), \ r \leftarrow \mathbf{M}_{ok_c}(R), \ ok_v \leftarrow W_z(R), \ U_z^{\dagger}(ZRU), \\ &U_{z'}(ZRU), \ r' \leftarrow \mathbf{M}(R), \ ok_v' \leftarrow W_{z'}(R)]. \end{aligned}$$

In the last probability,  $r \leftarrow \mathbf{M}_{ok_c}(R)$  refers to a measurement on R that is only executed if  $ok_c = 1$ . (And  $r := \bot$  otherwise.) The last two probabilities are equal because  $\mathbf{M}(R)$  and  $\mathbf{M}_{ok_c}(R)$  only differ if  $ok_c = 0$ , in which case " $z \neq z' \land ok_v = ok'_v = 1$ " is false anyway.

Since  $V_z$  measures whether R, U contains  $|r, u\rangle$  with  $verify(1^{\eta}, c_z, r, u) = 1$ , and since (com, verify) is collapse-binding, and since the outcome r is never used, we have that no quantum-polynomial-time adversary can distinguish between " $ok_c \leftarrow V_z(RU)$ ,  $r \leftarrow \mathbf{M}(R)$ " and " $ok_c \leftarrow V_z(RU)$ ", except with negligible probability. (Cf. Definition 12.) Thus there

is a negligible  $\mu_2$  such that

$$\Pr'_{E} \geq \Pr[z \neq z' \land ok_{v} = ok'_{v} = 1 : (x, Z) \leftarrow \mathsf{Z}(1^{\eta}), \ U_{x}(ZC), \ (a, (c_{z})_{z}) \leftarrow \mathbf{M}(C),$$

$$z, z' \stackrel{\$}{\leftarrow} N_{z}, \ U_{z}(ZRU), \ ok_{c} \leftarrow V_{z}(RU), \ ok_{v} \leftarrow W_{z}(R), \ U'_{z}(ZRU),$$

$$U_{z'}(ZRU), \ r' \leftarrow \mathbf{M}(R), \ ok'_{v} \leftarrow W_{z'}(R)] - \mu_{2} =: \Pr''_{E} - \mu_{2}.$$

Since  $\mathbf{M}(R)$  and  $W_{z'}(R)$  and  $V_{z'}(RU)$  commute, and since adding additional/removing operations after all values  $z, z', ok_v, ok'_v$  are fixed does not change the distribution of those values, we have that " $r' \leftarrow \mathbf{M}(R), ok'_v \leftarrow W_{z'}(R)$ " and " $ok'_c \leftarrow V_{z'}(RU), ok'_v \leftarrow W_z(R), U_{z'}^{\dagger}(ZRU)$ " lead to the same distribution of  $z, z', ok_v, ok'_v$ . This justifies (\*) in the following calculation:

$$\begin{aligned} \Pr_E'' &\stackrel{(*)}{=} \Pr[z \neq z' \land ok_v = ok_v' = 1 : (x, Z) \leftarrow \mathsf{Z}(1^\eta), \ U_x(ZC), \ (a, (c_z)_z) \leftarrow \mathbf{M}(C), \\ z, z' &\stackrel{\$}{\leftarrow} N_z, \ U_z(ZRU), \ ok_c \leftarrow V_z(RU), \ ok_v \leftarrow W_z(R), \ U_z^\dagger(ZRU), \\ U_{z'}(ZRU), \ ok_c' \leftarrow V_{z'}(RU), \ ok_v' \leftarrow W_{z'}(R), \ U_{z'}^\dagger(ZRU)] \\ & \geq \Pr[z \neq z' \land ok_c = ok_v = 1 \land ok_c' = ok_v' = 1 : (x, Z) \leftarrow \mathsf{Z}(1^\eta), \ U_x(ZC), \\ (a, (c_z)_z) \leftarrow \mathbf{M}(C), \ z, z' &\stackrel{\$}{\leftarrow} N_z, \ U_z(ZRU), \ ok_c \leftarrow V_z(RU), \ ok_v \leftarrow W_z(R), \\ U_z^\dagger(ZRU), \ U_{z'}(ZRU), \ ok_c' \leftarrow V_{z'}(RU), \ ok_v' \leftarrow W_{z'}(R), \ U_z^\dagger(ZRU)] \\ & = \Pr[z \neq z' \land ok = 1 \land ok = 1 : (x, Z) \leftarrow \mathsf{Z}(1^\eta), \ U_x(ZC), \ (a, (c_z)_z) \leftarrow \mathbf{M}(C), \\ z, z' &\stackrel{\$}{\leftarrow} N_z, \ ok \leftarrow P_z(ZRU), \ ok \leftarrow P_{z'}(ZRU)]. \end{aligned}$$

Let  $\alpha_{a'} := \Pr[a' = (a, (c_z)_z)]$  in the previous game, and let  $|\psi_{a'}\rangle$  denote the post-measurement-state of registers Z, R, U after the measurement  $(a, (c_z)_z) \leftarrow \mathbf{M}(C)$ . Then

$$\Pr_{E}'' = \sum_{a'} \alpha_{a'} \underbrace{\sum_{\substack{z,z'\\z \neq z'}} \frac{1}{|N_z|^2} \Big\| P_{z'} P_z |\psi_{a'}\rangle \Big\|^2}_{=:E_{a'}}.$$

Furthermore, note that

$$\Pr_{V} = \sum_{a'} \alpha_{a'} \underbrace{\sum_{z} \frac{1}{|N_z|} \left\| P_z |\psi_{a'}\rangle \right\|^2}_{=:V}.$$

Lemma 44 implies that if  $V_{a'} \geq 1/\sqrt{|N_z|}$ , then  $E_{a'} \geq V_{a'}(V_{a'}^2 - 1/|N_z|)$ . Or stated differently:  $E_{a'} \geq \varphi(V_{a'})$  where  $\varphi(x) := 0$  for  $x < 1/\sqrt{|N_z|}$  and  $\varphi(x) := x(x^2 - 1/|N_z|)$  for  $x \geq 1/\sqrt{|N_z|}$ . Since  $\varphi$  is convex on [0,1], by Jensen's inequality we get  $\Pr_E'' \geq \varphi(\Pr_V)$ . In other words  $\Pr_E'' \geq \Pr_V(\Pr_V^2 - 1/|N_z|)$  whenever  $\Pr_V \geq 1/\sqrt{|N_z|}$ . Furthermore, the inequalities derived above give  $\Pr_E \geq \Pr_E'' - \mu$  for  $\mu := \mu_1 + \mu_2$ . And  $\mu$  is negligible. It follows that:

$$\Pr_V \geq \frac{1}{\sqrt{N_z}} \qquad \Longrightarrow \qquad \Pr_E \geq \Pr_V \Big( \Pr_V^2 - \frac{1}{|N_z|} \Big) - \mu \geq \Big( \Pr_V - \frac{1}{\sqrt{|N_z|}} \Big)^3 - \mu.$$

Thus (P, V) is quantum-computationally extractable for R with knowledge error  $\kappa := 1/\sqrt{|N_z|}$ .

Finally, we show that our protocol is still HVZK/SHVZK. From this we conclude below (Corollary 46) that our protocol is quantum zero-knowledge.

**Lemma 45** If  $|N_z|$  is polynomially-bounded, and  $(N_z, P_1, P_2, V)$  is HVZK and (com, verify) is computationally hiding, and com is a polynomial-time algorithm, then  $(N_z, P'_1, P'_2, V')$  is HVZK.

If  $|N_z|$  is polynomially-bounded, and  $(N_z, P_1, P_2, V)$  is SHVZK and (com, verify) is statistically hiding, and com is a polynomial-time algorithm, then  $(N_z, P'_1, P'_2, V')$  is SHVZK.

*Proof.* We first prove the computational case of the lemma. Assume that  $|N_z|$  is polynomially-bounded, and  $(N_z, P_1, P_2, V)$  is HVZK and (com, verify) is computationally hiding.

We need to show that  $(N_z, P'_1, P'_2, V')$  is HVZK. By definition of HVZK, and by construction of  $(N_z, P'_1, P'_2, V')$ , that means that for any quantum-polynomial-time A,

$$\Pr_{1} := \Pr[b = 1 : a \leftarrow P_{1}(1^{\eta}, x, w), \text{ for each } z : r_{z} \leftarrow P_{2}(1^{\eta}, x, w, z),$$

$$\text{for each } z : (c_{z}, u_{z}) \leftarrow com(1^{\eta}, r_{z}), z \stackrel{\$}{\leftarrow} N_{z},$$

$$b' \leftarrow A(1^{\eta}, |\Psi\rangle, a, (c_{z})_{z}, z, r_{z}, u_{z})]$$

$$\approx \Pr[b = 1 : (a, (c_{z})_{z}, z, r_{z}, u_{z}) \leftarrow S'_{\Sigma}(1^{\eta}, x),$$

$$b' \leftarrow A(1^{\eta}, |\Psi\rangle, a, (c_{z})_{z}, z, r_{z}, u_{z})] =: \Pr_{sim}$$
(29)

Here  $S'_{\Sigma}$  is a quantum-polynomial-time simulator that we will construct below. And  $\approx$  means that the difference between the probabilities is negligible.

We then calculate:

Here (\*) uses that (com, verify) is computationally hiding and A is quantum-polynomialtime.  $com(1^{\eta}, 0)$  refers to a commitment to some fixed message 0 in the message space of com. And (\*\*) follows from the HVZK property of  $(N_z, P_1, P_2, V)$  for suitable quantum-polynomial-time  $S_{\Sigma}$ .

Let  $S'_{\Sigma}(1^{\eta}, x)$  perform the following steps:

$$(a, z, r_z) \leftarrow S_{\Sigma}(1^{\eta}, x), (c_z, u_z) \leftarrow com(1^{\eta}, r_z),$$
  
for each  $z' \neq z : (c_{z'}, u_{z'}) \leftarrow com(1^{\eta}, 0), \text{ return } (a, (c_z), z, r_z, u_z).$ 

Then  $S'_{\Sigma}$  is quantum-polynomial-time, and

$$\Pr_2 = \Pr[b = 1 : (a, (c_z)_z, z, r_z, u_z) \leftarrow S'_{\Sigma}(1^{\eta}, x), \ b' \leftarrow A(1^{\eta}, |\Psi\rangle, a, (c_z)_z, z, r_z, u_z)] = \Pr_{sim}.$$

Hence  $\Pr_1 \approx \Pr_{sim}$ , so (29) holds, and it follows that  $(N_z, P_1', P_2', V')$  is HVZK. This shows the lemma in the computational case.

The statistical case of the lemma is shown fully analogously, except that we do not assume A to be quantum-polynomial-time (and thus have to use the statistical hiding property of (com, verify) and the SHVZK property of  $(N_z, P_1, P_2, V)$ ).

Corollary 46 (Zero-knowledge) If  $|N_z|$  is polynomially-bounded, and  $(N_z, P_1, P_2, V)$  is HVZK and (com, verify) is computationally hiding, and com is a polynomial-time algorithm, then  $(N_z, P'_1, P'_2, V')$  is computational zero-knowledge.

If  $|N_z|$  is polynomially-bounded, and  $(N_z, P_1, P_2, V)$  is SHVZK and (com, verify) is statistically hiding, and com is a polynomial-time algorithm, then  $(N_z, P'_1, P'_2, V')$  is statistical zero-knowledge.

*Proof.* Immediate from Lemma 45 and Theorem 41.

## 8 Interactive quantum commitments

The definition of the collapse-binding property (Definition 12) was formulated specifically for non-interactive commitments where only classical messages are exchanged and where the verification in the opening phase is deterministic.

For completeness, we show here how the definition can be generalized to interactive commitments that may send quantum states and have a quantum verification algorithm. Note that we still consider the case where the message that we commit to is classical. Also, for technical reasons, we consider only commitments where the opening phase consists of a single quantum message.

We stress that, in contrast to Definition 12, we have not investigated this definition further. For example, we do not know whether commitments according to Definition 47 below are useful for constructing zero-knowledge arguments. We mainly state this definition for reference and leave it to future research to see how well the definition behaves.

We model an interactive commitment using two interactive algorithms SND (sender) and RCP (recipient) for the commit phase, and a quantum algorithm VER for the opening phase.  $(S, U, R) \leftarrow \langle \mathsf{SND}(1^{\eta}, m), \mathsf{RCP}(1^{\eta}) \rangle$  denotes an execution of the interaction

between SND and RCP where SND is committing to the message m (and with security parameter  $\eta$ ). Here the quantum registers S, U, R contain the state of SND, the opening information (which consists of a single message), and the state of RCP, respectively. The algorithm VER takes the security parameter and quantum registers M, U, R as input and outputs a single bit, indicating whether the opening phase succeeded.

**Definition 47 (Collapse-binding** – **generalized)** Let Z be an auxiliary quantum register. Let  $P_{\mathsf{VER}}^{\eta}$  be a projector on quantum registers M, U, R, Z (parametric in the security parameter  $\eta$ ), such that for any  $\eta$  and any quantum state  $|\Psi\rangle$  on M, U, R,  $\Pr[\mathsf{VER}(1^{\eta}, M, U, R) = 1 : MUR \leftarrow |\Psi\rangle] = \left|P_{\mathsf{VER}}^{\eta}(|\Psi\rangle \otimes |0\rangle)\right|^{2}.^{23}$ 

For an interactive algorithm A and a non-interactive algorithm B, consider the following games:

$$\begin{aligned} \mathsf{Game}_1: \quad & (S,M,U,R) \leftarrow \langle A(1^\eta), \mathsf{RCP}(1^\eta) \rangle, Z \leftarrow |0\rangle, ok \leftarrow P^\eta_{\mathsf{VER}}(M,U,R,Z), \\ & m \leftarrow M_{ok}(M), b \leftarrow B(1^\eta,S,M,U) \\ \mathsf{Game}_2: \quad & (S,M,U,R) \leftarrow \langle A(1^\eta), \mathsf{RCP}(1^\eta) \rangle, Z \leftarrow |0\rangle, ok \leftarrow P^\eta_{\mathsf{VER}}(M,U,R,Z), \\ & b \leftarrow B(1^\eta,S,M,U) \end{aligned}$$

Here  $(S, M, U, R) \leftarrow \langle A(1^{\eta}), \mathsf{RCP}(1^{\eta}) \rangle$  denotes an interaction between A and the honest recipient RCP. The quantum registers S, M, U are output by A, the register R contains the final state of RCP.  $Z \leftarrow |0\rangle$  means the quantum register Z is initialized with  $|0\rangle$ . ok  $\leftarrow P_{\mathsf{VER}}(M, U, R, Z)$  means that ok is the output of measuring the joint register M, U, R, Z with projector  $P_{\mathsf{VER}}$ .  $M_{ok}$  is as in Definition 12.

We say (SND, RCP, VER) is collapse-binding relative to  $P_{\text{VER}}$  iff for any quantum-polynomial-time interactive algorithm A and any quantum-polynomial-time algorithm B, the difference  $|\Pr[b=1:\mathsf{Game}_1] - \Pr[b=1:\mathsf{Game}_2]|$  is negligible in  $\eta$ .

We stress that the choice of the purification  $P_{\mathsf{VER}}^{\eta}$  of VER is not irrelevant. In general, different purifications  $P_{\mathsf{VER}}^{\eta}$  may have different post-measurement state even if they realize the same algorithm VER [Unr14]. Thus Definition 47 could be satisfied with one  $P_{\mathsf{VER}}^{\eta}$  and not satisfied with another. We conjecture that in most cases where the definition is used, one will simply need the existence of some quantum-polynomial-time  $P_{\mathsf{VER}}^{\eta}$ .

Notice that for a non-interactive commitment scheme with classical messages, Definition 47 coincides with Definition 12: In the non-interactive case, RCP simply stores the classical message c it receives, hence  $(S, M, U, R) \leftarrow \langle A, \mathsf{RCP} \rangle$  becomes  $(S, M, U, c) \leftarrow A(1^{\eta})$ . And the projector  $P_{\mathsf{VER}}$  from Definition 47 can be chosen as  $\sum_{c} V_c \otimes |c\rangle\langle c|$  where  $V_c$  is the projector from Definition 12.

 $<sup>^{23}</sup>$ In other words,  $P_{\mathsf{VER}}$  performs the same measurement as VER does using an ancilla system Z. Given a quantum-polynomial-time VER, we can always construct a polynomial-size quantum circuit implementing P: Let U be the purification of VER using ancillae Z. Let  $P_1$  be the projector that measures whether VER outputs 1. Then  $P_{\mathsf{VER}} := U^{\dagger} P_1 U$  is one possible choice for  $P_{\mathsf{VER}}$ .

## 9 Open problems

We list some questions for future research:

- We have constructed quantum arguments of knowledge from sigma-protocols by using collapse-binding commitments. However, our construction requires the challenge space  $N_z$  of the sigma-protocol to be of polynomially-bounded size. As a consequence, the resulting argument of knowledge will have a noticeable knowledge error; for a negligible knowledge error we need to use sequential repetition, resulting in a proof system with non-constant round complexity. Are there general constructions of arguments of knowledge from sigma-protocols that do not require the challenge space to be polynomially-bounded?
- Can we use collapse-binding commitments to construct a quantum OT protocol? For example, using the construction from [BBCS91] or a variation thereof?
- How are the various definitions of computationally binding commitments related? That is, which implications and separations exist between sum-binding, CDMS-binding, collapse-binding, and UC-secure commitments?
