#### Abstract

We propose practically efficient signature schemes which feature several attractive properties: (a) they only rely on the security of symmetric-key primitives (block ciphers, hash functions), and are therefore a viable candidate for post-quantum security, (b) they have extremely small signing keys, essentially the smallest possible, and, (c) they are highly parameterizable. For this result we take advantage of advances in two very distinct areas of cryptography. The first is the area of primitives in symmetric cryptography, where recent developments led to designs which exhibit an especially low number of multiplications. The second is the area of zero-knowledge proof systems, where significant progress for efficiently proving statements over general circuits was recently made. We follow two different directions, one of them yielding the first practical instantiation of a design paradigm due to Bellare and Goldwasser, which allows us to obtain tightly secure signatures. For both our schemes we explore the whole design spectrum to obtain optimal parameter choices for different settings, thereby also taking reduction tightness into account. Within limits, in all cases our schemes allow to trade-off computational effort with signature sizes. We also demonstrate that our schemes are parallelizable to the extent that they can practically take advantage of several cores on a CPU.

## 1 Introduction

More than two decades ago Shor published his polynomial-time quantum algorithm for factoring and computing discrete logarithms [Sho94]. Since then, we know that a sufficiently powerful quantum computer is able to break nearly all

[^0]public key cryptography used in practice today and essentially destroys confidentiality and integrity of all our digital communication. Clearly, this necessitates the invention of cryptographic schemes that remain secure in the advent of such an up to now hypothetical quantum computer-especially when considering the steady progress in constructing real-world quantum computers within the last two decades.

Today experts conjecture the advent of sufficiently powerful quantum computers within the next few decades. Although the statements seem rather speculative and far from certain, it is important to start the transition to post-quantum cryptography early enough to eventually not end up in a rush. Therefore, NIST recently announced a post-quantum crypto project ${ }^{4}$ seeking for public key encryption, key exchange and digital signatures basing their security on problems being assumed to be secure in a post-quantum era. A call for submissions to this competition is scheduled for late 2017.

In this paper we are concerned with constructing signature schemes. The building blocks of our schemes are interactive honest-verifier zero-knowledge proof systems ( $\Sigma$-protocols) and symmetric key primitives, which are conjectured to be secure also in a post-quantum world. We believe that a diversity in the used assumptions within the zoo of (post-quantum) signature schemes is important and increases the chance to obtain secure schemes despite cryptanalytic progress. As our focus is on provably secure schemes (i.e., ones that come with a reductionist security proof), we only compare our results to other provably secure candidates. Furthermore, we stress that although our approach is also of interest to the classical setting, we focus on a comparison with post-quantum signature candidates.
Post-Quantum Signatures. One-time signatures for a post-quantum world can be built when instantiating the approach due to Lamport [Lam79] using hash functions (aka hash-based signatures). As Grover's quantum algorithm to invert any black-box function [Gro96] gives a quadratic speed-up, this requires to double the bitsize of the hash function's domain, but requires no additional assumptions to provably achieve post-quantum security. Combined with Merkle-trees, this approach yields stateful signatures for any polynomial number of messages [Mer89] and combined with several other tricks and optimizations (cf. [Gol86]) this yields practical stateless hash-based signatures secure in the standard model $\left[\mathrm{BHH}^{+} 15\right]$. Code-based signature schemes can be obtained from identification schemes based on the syndrome decoding (SD) problem [Ste93, Vér96, MGS11] by applying a variant of the well known Fiat-Shamir ( $\mathrm{FS}_{\Sigma}$ ) transform [FS86]. Lattice-based signature schemes secure under the short integer solution (SIS) problem on lattices following the Full-Domain-Hash paradigm [BR93] have been introduced in [GPV08]. ${ }^{5}$ More efficient approaches [Lyu09, Lyu12, BG14, $\mathrm{ABB}^{+} 15$ ] rely on the $\mathrm{FS}_{\Sigma}$ transform instead of FDH. The entirely practical (and indeed highly efficient) scheme

[^1]BLISS [DDLL13] also relies on the $\mathrm{FS}_{\Sigma}$ transform, but buys efficiency at the cost of more pragmatic security assumptions, i.e., a ring version of the SIS problem. For signatures based on problems related to multivariate systems of quadratic equations only recently provably secure variants relying on the $\mathrm{FS}_{\Sigma}$ transform have been proposed in [HRSS16].

When it comes to trust, among all these existing approaches, arguably, hashbased signatures are preferable. All practical signatures supporting arbitrary message lengths need to rely on collision-resistant hash functions anyway, but in addition to that need to rely on some structured assumption. In the postquantum setting these assumption are related to lattices, codes or multivariate systems of quadratic equations (MQ). Our approach, like state-of-the-art hashbased signatures, also only requires symmetric primitives like hash functions and pseudorandom functions (PRFs) and we also require no additional structured assumptions.

On the Tightness of Security Proofs. When investigating (post-quantum secure) signature schemes, it is important and increasingly popular to assess the security of a scheme in a concrete [BR96] instead of an asymptotic setting. Thereby, the goal is to tightly relate the security of the signature scheme to that of the underlying problem. Tightness is important because it allows the implemented scheme to use small parameters (i.e., being as efficient as possible) while retaining provable security. The common way to assess the security of a cryptographic primitive is to perform a reductionist security proof. Thereby, one constructs a reduction algorithm $\mathcal{R}$ showing that any hypothetical algorithm $\mathcal{A}$ (the adversary) achieving a well defined adversarial goal (given by the security notion) yields a solver for a presumably hard problem, thus contradicting the hardness of this problem. Concrete security analysis now relates the runtime $t$ of the hypothetical adversary $\mathcal{A}$ as well as its success probability $\epsilon$ to the runtime $t^{\prime}$ and success probability $\epsilon^{\prime}$ of the reduction $\mathcal{R}$. A reductionist security proof is called tight, if $t^{\prime} \approx t$ and $\epsilon^{\prime} \approx \epsilon$ and non-tight if $t^{\prime} \gg t$ or $\epsilon^{\prime} \ll \epsilon$. Obviously, the desirable goal is to come up with a tight proof, as such a proof says that breaking the security of the primitive (within the respective model) is at least as hard as breaking the problem. A non-tight reduction, however, gives only much weaker guarantees and the primitive needs to be instantiated with larger security parameters to account for the non-tightness of the proof. This, in turn, often yields a noticeable performance penalty. Tightness has been studied for standard model signatures [HJ12, $\left.\mathrm{BHH}^{+} 15, \mathrm{BKKP} 15, \mathrm{BL} 16\right]$, various schemes in the ROM [BR96, GJ03, KW03] and generic compilers from identification to signature schemes (where FS is one of them) [AFLT12, ABP13, BPS16, KMP16].

When looking at existing post-quantum candidates, the state-of-the-art hashbased signature scheme SPHINCS $\left[\mathrm{BHH}^{+} 15\right]$ comes with a tight-reduction. All other practical code-based, lattice-based and MQ-based schemes discussed above use the $\mathrm{FS}_{\Sigma}$ transform and require a rewinding extractor (essentially the application of the forking lemma [PS96]) and thus come with a non-tight reduction loosing at least a factor $O\left(Q_{H}^{n}\right)(c f .[\mathrm{CK} 16])$, where $Q_{H}$ is the number of queries to the random oracle (RO) $H$ and $n$ the number of rewinds, in the overall secu-
rity. We illustrate the issue with non-tight security using the recent MQ-based post-quantum candidate from Asiacrypt'16 [HRSS16]. Their security reduction requires three rewinds of the adversary, yielding a multiplicative reduction loss of $\approx Q_{H}^{3}$. Considering an 128 -bit security level and assuming $Q_{H}=2^{60}$ (a very reasonable assumption already made 20 years ago in [BR96]), no provable security margin remains. In fact, one would have to increase the security level by 180 bits to 308 bit to obtain a scheme being provably secure at the 128-bit level.

Contribution. For post-quantum signature schemes it is most desirable to have security proofs in the quantum-accessible random oracle model (QROM; cf. $\left[\mathrm{BDF}^{+} 11\right]$ ), or even in the standard model. However, these strong models often impact the practicality of the schemes, which is why all existing practical candidates except for hash-based signatures come with a security proof in the random oracle model (ROM; cf. Section 7 for a more detailed discussion).

- We contribute a novel class of a post-quantum signature schemes to the existing zoo of post-quantum signatures. As with hash-based signatures, our approach only requires symmetric key primitives like hash functions and PRFs and does not require additional structured hardness assumptions as all the remaining candidates do. Our proofs of security are in the ROM.
- We present two concrete approaches to construct signature schemes from $\Sigma$-protocols for statements expressed as arithmetic circuits. In particular, we present a first construction via the $\mathrm{FS}_{\Sigma}$ transform and a second novel approach, which constitutes the first practically efficient instantiation of a design paradigm for signatures due to Bellare and Goldwasser [BG89] proposed more than 25 years ago. Together with our contribution, latter opens up a new direction for the design of practical signature schemes. While the approach relying on $\mathrm{FS}_{\Sigma}$ yields non-tight security reductions, we show how to obtain a tight security reduction for the second approach by carefully crafting the security proof of the scheme. This allows us to tightly relate the security of the signature scheme to the security parameter of the used symmetric primitive.
- We review existing symmetric primitives with respect to their suitability to be used in our application and conclude that the LowMC family of block ciphers $\left[\mathrm{ARS}^{+} 15, \mathrm{ARS}^{+} 16\right]$ is well suited. We explore the entire design space of the block cipher family LowMC and show that we can obtain various trade-offs between signature sizes and computation times. Thereby, our approach turns out to be very flexible as besides the aforementioned trade-offs we are also able to adjust the security parameter of our construction in a very fine-grained way.
- We provide an implementation of both schemes for 128 bit security in the pre- as well as post-quantum setting, demonstrating the practical relevance of our approach. Moreover, we rigorously compare our schemes with other practical provably secure post-quantum schemes.

### 1.1 Outline

Our goal in this paper is to design signature schemes that solely rely on the security of symmetric key primitives. In doing so we construct non-interactive zero-knowledge (NIZK) proof based signatures building upon the approachtermed ZKBoo - taken by Giacomelli et al. in [GMO16]. Their approach yields practically efficient $\Sigma$-protocols for statements expressible via arithmetic circuits, and their results show that proving pre-images of hash functions from the SHA-family results in reasonable performance. Subsequently, we briefly sketch the ideas behind the two directions we pursue to obtain secure signatures, i.e., signatures that are provably existentially unforgeable under adaptively chosen message attacks (EUF-CMA).
Fish. Our first scheme builds upon the well-known $\mathrm{FS}_{\Sigma}$ transform to turn $\Sigma$ protocols into EUF-CMA-secure signature schemes. Loosely speaking, the public key is the evaluation of a one-way function (OWF) on a random key. The signature is the transcript of the $\mathrm{FS}_{\Sigma}$-transformed non-interactive version of the ZKBoo protocol demonstrating knowledge of the respective key. Unfortunately, security proofs for such schemes require rewinding/application of the forking lemma and are thus non-tight (they loose at least a multiplicative factor $Q_{H}$, being the number of RO queries, in the success probability). Consequently, one cannot tightly relate the security of the scheme to the security parameter of the underlying OWF and when it comes to a concrete choice of parameters one has to compensate the loss by choosing larger parameters.
Begol. The second scheme builds upon a paradigm to construct signatures that has been proposed more than 25 years ago as a theoretical approach by Bellare and Goldwasser [BG89] and to the best of our knowledge has never been used in a practical setting so far. Loosely speaking, the public key is an encryption of a PRF key and the signature is an evaluation of a PRF on the message under the key together with a NIZK proof confirming that the key used for the PRF is the one in the ciphertext in the public key. Although the resulting signatures are larger than the ones from the first approach, we can tightly relate the security of the scheme to the security of the underlying PRF and encryption scheme, respectively. When adjusting the parameters to compensate the non-tightness of the first approach, we then obtain two comparable approaches regarding computational efficiency.
Big Picture. Figure 1 sketches the involved building blocks in our constructions. In a nutshell, in our first approach, we use the $\mathrm{FS}_{\Sigma}$ transform to directly turn the ZKBoo protocol for the languages of pre-images of a OWF into the EUF-CMA secure signature scheme Fish. In contrast, when following the Bellare-Goldwasser paradigm, we turn the ZKBoo protocol into a NIZK proof system (henceforth dubbed NIZKBoo) using an other variant of the Fiat-Shamir transform ( $\mathrm{FS}_{\text {NIZK }}$ ). Together with a symmetric encryption scheme $\Omega$ and a PRF we then obtain the EUF-CMA secure signature scheme Begol.
Technical Perspective. It is well known that (without assuming any specific properties of the underlying $\Sigma$-protocol), the $\mathrm{FS}_{\Sigma}$ yields a non-tight reduction.

Fig. 1. Overview of our constructions.

We revisit this approach in Section 3. Since we currently do not see how to bypass this loss (i.e., avoid rewinding), our main focus from a technical perspective lies on a tight security reduction for Begol. Our result in this context is summarized by the following theorem.
Theorem 1. Let NIZKBoo denote the ZKBoo protocol [GMO16] turned into a NIZK proof system via $F S_{\text {NIZK }}$ relative to $R O H: A \times X \rightarrow\{0,1,2\}^{\gamma}$, where the commitments are instantiated via a RO $H^{\prime}:\{0,1\}^{\alpha} \times\{0,1\}^{\beta} \times\{0,1\}^{\nu} \rightarrow$ $\{0,1\}^{\rho}$ so that $\{0,1\}^{\nu}$ is sampled uniformly at random for every commitment. Furthermore, let $Q_{S}$ be the number of signing queries, and let $Q_{H}$ and $Q_{H^{\prime}}$ be the number of queries to the ROs. If the Bellare-Goldwasser paradigm [BG89] is instantiated with a $\left(t_{\mathrm{e}}, \epsilon_{\mathrm{e}}\right)$-IND-EAV secure symmetric encryption scheme, $a$ $\left(t_{\mathrm{p}}, \epsilon_{\mathrm{p}}\right)$-secure PRF, and NIZKBoo, then Begol is $(t, \epsilon)$-EUF-CMA secure in the ROM, where

$$
\epsilon(\kappa) \leq \epsilon_{\mathrm{e}}(\kappa)+\epsilon_{\mathrm{p}}(\kappa)+\underbrace{\frac{Q_{H^{\prime}}^{2}}{2^{\rho}}+(2 / 3)^{\gamma}}_{\text {Lemma } 5}+\underbrace{\frac{\gamma}{2^{\nu}}+\frac{Q_{S} \cdot Q_{H}}{2^{3 \cdot \rho}}}_{\text {Lemma } 6} \text {, and } \underbrace{t \approx \max \left\{t_{\mathrm{e}}, t_{\mathrm{p}}\right\}}_{\text {Lemma } 4} \text {. }
$$

Throughout the next sections, we will prove the theorem above by proving Lemma 4-6. In Section 4 we first recall the Bellare-Goldwasser [BG89] approach and then prove Lemma 4, which resembles the results of Bellare and Goldwasser but details the required security guarantees of the underlying primitives and makes the bounds explicit. In Section 4.1 we present the instantiation of NIZKBoo and prove Lemma 5 and Lemma 6. In Lemma 5 we prove soundness of NIZKBoo without requiring to rewind the adversary. This yields a tighter bound than when using $s$-special soundness of the underlying ZKBoo protocol as a starting point. Finally, in Lemma 6, we prove zero-knowledge of NIZKBoo. Our proof for this lemma is similar to the general result for $\Sigma$-protocols in [FKMV12], but we require an additional technicality to account for the fact that the outputs of the simulator in ZKBoo are only statistically close to an original transcript (as opposed to the identical distribution in [FKMV12]). In addition we also provide explicit bounds.
Implementation Perspective. From an implementation point of view our findings are twofold. Firstly, we review existing symmetric primitives with respect to their suitability to be employed in our application. We conclude that the LowMC family of block ciphers $\left[\mathrm{ARS}^{+} 15, \mathrm{ARS}^{+} 16\right]$ provides favorable properties in this context (cf. Section 5). Secondly, we present a highly optimized imple-
mentation which uses SIMD instruction sets of modern CPU architectures and also exploits parallelization using standard APIs for parallel programming. Furthermore, we explore the whole design space of LowMC to find the most suitable parametrizations. Our results confirm that instantiations of both proposed signature schemes are entirely practical. A detailed overview of our implementation results is provided in Section 6.

### 1.2 Related Work

In this section we give a brief overview of other candidate schemes and defer a detailed comparison of parameters as well as performance figures to Section 6. We start with the only existing instantiation that only relies on standard assumptions, i.e., comes with a security proof in the standard model (SM) and does not require the ROM idealization. The remaining existing schemes rely on structured assumptions related to codes, lattices and multivariate systems of quadratic equations that are assumed to be quantum-immune and have a security proof in the ROM. By the end of the section, we review the state of the art in zero-knowledge proofs for non-algebraic statements.
Hash-Based Signatures (SM). Hash-based signatures are attractive in the sense that they can be proven secure in the standard model (i.e., without requiring ROs) under well-known properties of hash functions such as second preimage resistance. Unfortunately, efficient schemes like XMSS [BDH11] are stateful, a property which seems to be problematic for practical applications. Proper state management is not yet well understood $\left[\mathrm{MKF}^{+} 16\right]$ and seems to be a property that is desirable to omit. Stateless schemes like the most recent proposal SPHINCS $\left[\mathrm{BHH}^{+} 15\right]$ are thus more desirable, but are more inefficient in terms of lower speed and increased signature size. SPHINCS has a security reduction that tightly relates its EUF-CMA security to the security of the used building blocks, i.e., hash functions, PRGs and PRFs. On a 128 bit post-quantum security level (SPHINCS-256), one obtains a signature size of about 41 kB , and a public as well as a private key size of about 1 kB each.

Code-Based Signatures (ROM). In the code-based setting the most wellknown and provably secure approach is to convert identification schemes due to Stern [Ste93] and Véron [Vér96] to signatures using $\mathrm{FS}_{\Sigma}$. Consequently, the reductions require rewinding and are not tight. For the 128 bit security level (not accounting for the loss induced by the reduction) one obtains signature sizes of around $\approx 20 \mathrm{kB}$ (in the best case) and public key size of $\approx 80$ bytes. ${ }^{6}$ We note that there are also other code-based signatures [CFS01] based on the Niederreither [Nie86] dual of the McEliece cryptosystem [McE78], which do not come with a security reduction and also do not seem practical even for very low security levels [LS12].

[^2]Lattice-Based Signatures (ROM). In context of lattice based signatures there are two major directions. The first are schemes that rely on the hardness of worst-to-average-case problems in standard lattices [GPV08, Lyu12, BG14, $\left.\mathrm{DBG}^{+} 14, \mathrm{ABB}^{+} 15\right]$. Although they are desirable from a security point of view, they suffers from huge public keys, i.e., sizes in the orders of a few to some 10 MBs. The GPV scheme [GPV08] comes with a tight security reduction. Also TESLA ${ }^{7}\left[\mathrm{ABB}^{+} 15\right]$ (based upon [BG14, Lyu12]), using the proof strategy of Katz and Wang ${ }^{8}$ [KW03], has a tight reduction to the learning with error (LWE) problem on lattices. TESLA improves all aspects in the performance of GPV, but still has keys in the order of 1 MB . More efficient lattice-based schemes are based on ring analogues of classical lattice problems [DDLL13, BB13, GLP12] whose security is related to hardness assumptions in ideal lattices. These constructions allow to drop key sizes to the order of a few kBs. Most notable is BLISS [DDLL13, Duc14], which achieves very good performance nearly comparable to RSA. However, it has a non-tight security reduction as it uses the classical $\mathrm{FS}_{\Sigma}$ transform. It must also be noted, that ideal lattices have not been investigated nearly as deeply as standard lattices and thus there is less confidence in the related hardness conjectures (cf. [Pei16]).

MQ-Based Signatures (ROM). Recently, Hülsing et al. in [HRSS16] proposed a post-quantum signature scheme (MQDSS) whose security is based on the problem of solving a multivariate system of quadratic equations. Their scheme is obtained by building upon the 5-pass (or 3-pass) identification scheme in [SSH11] and applying the $\mathrm{FS}_{\Sigma}$ transform. Their security proof requires a rewinding extractor and thus yields a non-tight security reduction in the ROM. For 128 bit post-quantum security (which does not account for the reduction loss) signature sizes are about 40 kB , public key sizes are 72 bytes and secret key sizes are 64 bytes. We note that there are other MQ-based approaches like Unbalanced Oil-and-Vinegar (UOV) variants [PCG01] or $\mathrm{FHEv}^{-}$variants (cf. $\left[\mathrm{PCY}^{+} 15\right]$ ), having somewhat larger keys (order of kBs ) but much shorter signatures. However, they have no provable security guarantees, the parameter choice seems very aggressive, there are no parameters for conservative (post-quantum) security levels, and no implementations are available.
Zero-Knowledge for Arithmetic Circuits. Zero-knowledge proofs [GMR85] are a very powerful tool and exist for any language in NP [GMW86]. Nevertheless, practically efficient proofs, were until recently only known for restricted languages and in particular for proving algebraic statements in certain algebraic

[^3]structures, e.g., discrete logarithms [Sch91, CDS94] or equations over bilinear groups [GS08]. Expressing any NP language as a combination of algebraic circuits could be done for example by expressing the relation as a circuit, i.e., express each gate as an algebraic relation between input and output wires. However, for circuits interesting for practical applications (such as hash functions or block ciphers), this gets prohibitive. Even SNARKS, where proof size can be made small (and constant) and verification is highly efficient, have very costly proofs (cf. [GGPR13, $\mathrm{BCG}^{+} 13, \mathrm{CFH}^{+} 15$ ] and the references therein). Using SNARKS is reasonable in scenarios where provers are extremely powerful (such as verifiable computing [GGPR13]) or the runtime of the prover is not critical (such as Zerocash $\left[\mathrm{BCG}^{+} 14\right]$ ). Unfortunately, signatures require small proof computation times (efficient signing procedures), and this direction is not suitable.

Quite recently, dedicated zero-knowledge proof systems for statements expressed as Boolean circuits by Jawurek et al. [JKO13] and statements expressed as RAM programs by Hu et al. [HMR15] have been proposed. As we exclusively focus on circuits below lets take a look at Jawurek et al. [JKO13]. They proposed to use garbled circuits to obtain zero-knowledge proofs, which allow to efficiently prove statements like knowledge of a pre-image under a hash function like SHA-256. Unfortunately, this approach is inherently interactive and thus not suitable for the design of practical signature schemes. The very recent ZKBoo protocol due to Giacomelli et al. [GMO16], for the first time, allows to construct $\Sigma$-protocols with performance being of interest for many practical applications. We use their approach as a starting point for our work.

## 2 Building Blocks

Before we start, we recall the required building blocks. Henceforth, we denote algorithms by sans-serif letters, e.g., A, B. If not stated otherwise, all algorithms are required to run in polynomial time and return a special symbol $\perp$ on error. By $y \leftarrow \mathrm{~A}(x)$, we denote that $y$ is assigned the output of the potentially probabilistic algorithm A on input $x$ and fresh random coins. Similarly, $y \leftarrow^{R} S$ means that $y$ is sampled uniformly at random from a set $S$. We use $\langle\mathrm{A}, \mathrm{B}\rangle$ to denote a pair of interactive algorithms and use $\langle A, B\rangle=1$ to denote an interaction where both algorithms accept. We let $[n]:=\{1, \ldots, n\}$ and use $\|_{i \in[n]} x_{i}$ as a shorthand notation for $x_{1}\|\ldots\| x_{n}$. We write $\operatorname{Pr}[\Omega: \mathcal{E}]$ to denote the probability of an event $\mathcal{E}$ over the probability space $\Omega$. We use $\mathcal{C}$ to denote challengers of security experiments, and $\mathcal{C}_{\kappa}$ to make the security parameter explicit. A function $\varepsilon(\cdot)$ : $\mathbb{N} \rightarrow \mathbb{R}_{\geq 0}$ is called negligible, iff it vanishes faster than every inverse polynomial, i.e., $\forall k: \exists n_{k}: \forall n>n_{k}: \varepsilon(n)<n^{-k}$. Finally, we use poly(•) to denote a polynomial function.

We postpone the presentation of standard primitives such as OWFs $f: D \rightarrow$ R, PRFs $F: \mathcal{S} \times D \rightarrow \mathrm{R}$, symmetric encryption schemes $\Omega=$ (Gen, Enc, Dec), and signature schemes $\Sigma=$ (Gen, Sign, Verify) to Appendix A.
$\Sigma$-Protocols. Let $L \subseteq \mathrm{X}$ be an NP-language with associated witness relation $R$ so that $L=\{x \mid \exists w: R(x, w)=1\}$. A $\Sigma$-protocol for language $L$ is defined as follows.

Definition 1. A $\Sigma$-protocol for language $L$ is an interactive three-move protocol between a PPT prover $\mathrm{P}=($ Commit, Prove) and a PPT verifier $\mathrm{V}=$ (Challenge, Verify), where P makes the first move and transcripts are of the form $(\mathrm{a}, \mathrm{e}, \mathrm{z}) \in \mathrm{A} \times \mathrm{E} \times \mathrm{Z}$. Additionally they satisfy the following properties

Completeness. A $\Sigma$-protocol for language $L$ is complete, if for all security parameters $\kappa$, and for all $(x, w) \in R$, it holds that

$$
\operatorname{Pr}\left[\left\langle\mathrm{P}\left(1^{\kappa}, x, w\right), \mathrm{V}\left(1^{\kappa}, x\right)\right\rangle=1\right]=1
$$

$s$-Special Soundness. A $\Sigma$-protocol for language $L$ is s-special sound, if for all security parameters $\kappa$ there exists a PPT extractor E so that for all $x$, and for all sets of accepting transcripts $\left\{\left(\mathrm{a}, \mathrm{e}_{i}, \mathrm{z}_{i}\right)\right\}_{i \in[s]}$ with respect to $x$, generated by any algorithm with polynomial runtime in $\kappa$, it holds that

$$
\operatorname{Pr}\left[w \leftarrow \mathrm{E}\left(1^{\kappa}, x,\left\{\left(\mathrm{a}, \mathrm{e}_{i}, \mathrm{z}_{i}\right)\right\}_{i \in[s]}\right): \quad \forall i, j \in[s], i \neq j: \mathrm{e}_{i} \neq \mathrm{e}_{j}\right] \geq 1-\epsilon(\kappa)
$$

Special Honest-Verifier Zero-Knowledge. A $\Sigma$-protocol is special honestverifier zero-knowledge, if for all security parameters $\kappa$ there exists a PPT simulator $S$ so that for every $x \in L$ and every challenge e from the challenge space, it holds that a transcript $(\mathrm{a}, \mathrm{e}, \mathrm{z})$, where $(\mathrm{a}, \mathrm{z}) \leftarrow \mathrm{S}\left(1^{\kappa}, x, \mathrm{e}\right)$ is computationally indistinguishable from a transcript resulting from an honest execution of the protocol.

The $s$-special soundness property gives an immediate bound for the soundness of the protocol: if no witness exists then (ignoring a negligible error) the prover can successfully answer at most to $s-1 / t$ challenges, where $t=|\mathrm{E}|$ is the size of the challenge space. In case this value is too large, it is possible to reduce the soundness error using well known properties of $\Sigma$-protocols which we restate here for completeness.
Lemma 1. The properties of $\Sigma$-protocols are invariant under parallel repetition. In particular, the $\ell$ fold parallel repetition of a $\Sigma$-protocol for relation $R$ with challenge length $t$ yields a new $\Sigma$-protocol with challenge length $\ell t$.

Lemma 2. If there exists a $\Sigma$-protocol for $R$ with challenge length $t$, then there exists a $\Sigma$-protocol for $R$ with challenge length $t^{\prime}$ for any $t^{\prime}$.

Below, we recall another well known fact about the AND composition of $\Sigma$ protocols.
Lemma 3. Let $L_{1}$ and $L_{2}$ be two languages with associated witness relations $R_{1}$ and $R_{2}$, respectively. Further, let $\Sigma_{1}$ and $\Sigma_{2}$ be two $\Sigma$-protocols with identical challenge space so that $\Sigma_{1}$ is for $L_{1}$ and $\Sigma_{2}$ is for $L_{2}$. Then a $\Sigma$-protocol for the conjunction of $L_{1}$ and $L_{2}$, i.e., $L_{1} \wedge L_{2}:=\left\{\left(x_{1}, x_{2}\right) \mid \exists w_{1}, w_{2}:\left(x_{1}, w_{1}\right) \in\right.$ $\left.L_{1} \wedge\left(x_{2}, w_{2}\right) \in L_{2}\right\}$ is obtained by running $\Sigma_{1}$ and $\Sigma_{2}$ in parallel using a single common challenge e.

Finally, we note that an equality (EQ) composition of $\Sigma$-protocols resulting in a language $L=\left\{\left(x_{1}, x_{2}\right) \mid \exists w:\left(x_{1}, w\right) \in R_{1} \wedge\left(x_{2}, w\right) \in R_{2}\right\}$ can be achieved as a special case of an AND composition, where besides an identical challenge e also the same random tape is used for the prover in both instances.

The Fiat-Shamir Transform. The Fiat-Shamir (FS ${ }_{\text {NIZK }}$ ) transform [FS86] is a frequently used tool to convert $\Sigma$-protocols $\langle\mathrm{P}, \mathrm{V}\rangle$ to their non-interactive counterparts. Essentially, the transform removes the interaction between P and V by using a RO $H: \mathrm{A} \times \mathrm{X} \rightarrow \mathrm{E}$ to obtain the challenge e. ${ }^{9}$ That is, one uses a PPT algorithm Challenge ${ }^{\prime}\left(1^{\kappa}\right.$, a, $\left.x\right)$ which obtains $\mathrm{e} \leftarrow H(\mathrm{a}, x)$ and returns e. Then, the prover can locally obtain the challenge e after computing the initial message a. Starting a verifier $\mathrm{V}^{\prime}=\left(\right.$ Challenge ${ }^{\prime}$, Verify) on the same initial message a will then yield the same challenge e. More formally, we obtain the non-interactive PPT algorithms $\left(\mathrm{P}_{H}, \mathrm{~V}_{H}\right)$ indexed by the used RO:
$\mathrm{P}_{H}\left(1^{\kappa}, x, w\right)$ : Start P on $\left(1^{\kappa}, x, w\right)$, obtain the first message a, answer with $\mathrm{e} \leftarrow H(\mathrm{a}, x)$, and finally obtain z . Returns $\pi \leftarrow(\mathrm{a}, \mathrm{z})$.
$\mathrm{V}_{H}\left(1^{\kappa}, x, \pi\right)$ : Parse $\pi$ as $(\mathrm{a}, \mathrm{z})$. Start $\mathrm{V}^{\prime}$ on $\left(1^{\kappa}, x\right)$, send a as first message to the verifier. When $\mathrm{V}^{\prime}$ outputs e , reply with z and output 1 if V accepts and 0 otherwise.

Non-Interactive ZK Proof Systems. Now, we recall a standard definition of non-interactive zero-knowledge proof systems. Therefore, let $L$ be an NPlanguage with witness relation $R$, i.e., so that $L=\{x \mid \exists w: R(x, w)=1\}$.

Definition 2 (Non-Interactive Zero-Knowledge Proof System). A noninteractive proof system $\Pi$ is a tuple of algorithms (Setup, Proof, Verify), which are defined as follows:

Setup $\left(1^{\kappa}\right)$ : This algorithm takes a security parameter $\kappa$ as input, and outputs a common reference string crs.
Proof(crs, $x, w)$ : This algorithm takes a common reference string crs, a statement $x$, and a witness $w$ as input, and outputs a proof $\pi$.
Verify $(\mathrm{crs}, x, \pi):$ This algorithm takes a common reference string crs, a statement $x$, and a proof $\pi$ as input, and outputs a bit $b \in\{0,1\}$.

We require $\Pi$ to be complete, adaptively zero-knowledge and sound. In Appendix A. 1 we recall formal definition of those properties.
Converting $\Sigma$-protocols to Non-Interactive Proof Systems. One can obtain a non-interactive proof system satisfying the properties above by applying the $\mathrm{FS}_{\text {NIZK }}$ transform to any $\Sigma$-protocol where the min-entropy $\alpha$ of the commitment a sent in the first phase is so that $2^{-\alpha}$ is negligible in the security parameter $\kappa$ and the challenge space E is exponentially large in the security parameter. Formally, $\operatorname{Setup}\left(1^{\kappa}\right)$ fixes a RO $H: \mathrm{A} \times \mathrm{X} \rightarrow \mathrm{E}$, sets crs $\leftarrow\left(1^{\kappa}, H\right)$ and

[^4]returns crs. The algorithms Prove and Verify are defined as follows:
$$
\operatorname{Prove}(\operatorname{crs}, x, w):=\mathrm{P}_{H}\left(1^{\kappa}, x, w\right), \quad \text { Verify }(\operatorname{crs}, x, \pi):=\mathrm{V}_{H}\left(1^{\kappa}, x, \pi\right)
$$

Combining [FKMV12, Thm. 1, Thm. 2, Prop. 1] (among others) shows that a so-obtained proof system is complete, sound, and adaptively zero-knowledge if the underlying $\Sigma$-protocol is (2-)special sound and the commitments sent in the first move are unconditionally binding. Since ZKBoo only provides 3special soundness and the commitments in a are not perfectly binding, we later prove that those properties also hold for ZKBoo. Thereby, we also obtain tight, concrete bounds.

## 3 Fish: Signatures from Plain Fiat-Shamir

The $\mathrm{FS}_{\Sigma}$ transform can elegantly be used to convert (canonical) identification schemes into adaptively (EUF-CMA) secure signature schemes. The basic idea is similar to $\mathrm{FS}_{\text {NIZK }}$, but the challenge generation is defined via the RO $H: A \times \mathcal{M} \rightarrow \mathrm{E}$. More precisely, one uses the provers first message a and the message $m \in \mathcal{M}$ to be signed to obtain the challenge, i.e., compute the challenge as $\mathrm{e} \leftarrow H(\mathrm{a}, m)$. There are numerous works on the security of signatures schemes obtained from three move identification schemes [OO98, PS96, AABN02, KMP16, BPS16]. All these approaches to prove security of such constructions do yield non-tight reductions. Essentially, all these techniques rely on rewinding/forking and lose (depending on the number of rewinds) at least a multiplicative factor of $Q_{H}$ - the number of queries to the RO-in the overall success probability. We note that all above results are for three round schemes and there are also generalizations to schemes of $2 k+1$ rounds for $k>1\left[\mathrm{ADV}^{+} 12\right]$, which also yield non-tight reductions.

The only class of schemes for which the $\mathrm{FS}_{\Sigma}$ conversion yields tight security by means of a black-box transformation are so called lossy identification schemes [AFLT12]. These are identification schemes, which beside normal keys have lossy keys being computationally indistinguishable from real ones and given a lossy key, for an adversary it is statistically impossible to provide a valid response to a random challenge after making a commitment. Such identification schemes are known for various settings (cf. [KW03, AFLT12, ABP13]). While this approach applies when working with lattices [AFLT12] in the post-quantum setting, unfortunately, it does not help us with our approach to obtain tight security.

Now, consider a language $L_{R}$ with associated witness relation $R$ of pre-images of a OWF $f: D \rightarrow \mathrm{R}$ :

$$
(y, s) \in R \quad \Longleftrightarrow \quad y=f(s)
$$

When using ZKBoo to prove knowledge of such a pre-image, we know [GMO16] that this $\Sigma$-protocol provides 3 -special soundness. We apply the $\mathrm{FS}_{\Sigma}$ transform to this $\Sigma$-protocol to obtain an EUF-CMA secure signature scheme.

In the so obtained signature scheme the public verification key pk contains the image $y$ (and a description of $f$ ) and the secret signing key sk contains a
sufficiently large random element $s$ from R . The corresponding signature scheme, dubbed Fish, is illustrated in Scheme 1.

```
Gen(1/}): Choose s \stackrel{R}{\leftarrow}D\mathrm{ , compute }y\leftarrowf(\mathbf{s})\mathrm{ , set pk }\leftarrowy\mathrm{ and sk }\leftarrow(\textrm{pk},\mathbf{s})\mathrm{ and return
    (sk, pk).
Sign(sk,m): Parse sk as (pk, s), compute }\pi=(\textrm{a},\textrm{z})\leftarrow\mp@subsup{\textrm{P}}{H}{}(\mp@subsup{1}{}{\kappa},y,\textrm{s},m)\mathrm{ and return
    \sigma}\leftarrow\pi\mathrm{ , where internally the challenge is computed as e}\leftarrowH(\textrm{a},m)
Verify(pk,m,\sigma): Parse pk as y, and \sigma as \pi=(a,z). Return 1 if the following holds,
    and 0 otherwise:
                    V (1 (1 
    where internally the challenge is computed as e}\leftarrowH(\textrm{a},m)\mathrm{ .
```

Scheme 1: Fish: building upon Fiat-Shamir.

If we view ZKBoo as a canonical identification scheme that is secure against passive adversaries one just needs to keep in mind that most definitions are tailored to (2-)special soundness, and the 3-special soundness of ZKBoo requires an additional rewind. In particular, an adapted version of the proof of [Kat10, Theorem 8.2] which considers this additional rewind attests the security of Scheme 1. Secondly, using the results of [FKMV12] together with [CL06] (again considering the additional rewind), also immediately yields EUF-CMA secure signatures, but additionally requires to include the proven statement $x$ upon computing the challenge. Let us stick with the first approach, then we obtain the following:

Corollary 1. Scheme 1 instantiated with ZKBoo and a secure OWF yields an EUF-CMA secure signature scheme.

Note that the corollary above holds in the asymptotic sense, i.e., the reductions loses a multiplicative factor of $\approx Q_{H}^{2}$, with $Q_{H}$ being the number of queries to the RO. Thus one has to accordingly adjust the security parameter if concrete security is required.

## 4 Begol: Instantiating the Bellare-Goldwasser Paradigm

Bellare and Goldwasser in [BG89] introduced an approach to construct adaptively (EUF-CMA) secure signatures from a NIZK proof system $\Pi=$ (Setup, Proof, Verify) and any OWF $f$. In particular, the OWF-based primitives they require are a symmetric encryption scheme and a PRF.

Henceforth, let $\Omega$ be a symmetric encryption scheme $\Omega=$ (Gen, Enc, Dec) and $\mathcal{F}$ be a family of PRFs $F: \mathcal{S} \times \mathcal{M} \rightarrow\{0,1\}^{n}$. The private signing key of the scheme is the pair sk $:=(\mathrm{s}, \mathrm{k})$ where $\mathrm{s} \leftarrow^{R} \mathcal{S}$ is a PRF key and $\mathrm{k} \leftarrow \Omega$.Gen $\left(1^{\kappa}\right)$ is a random key for the encryption scheme $\Omega$. The public verification key pk $:=$ (crs, $c$ ) of the scheme consists of the CRS crs $\leftarrow \Pi$.Setup $\left(1^{\kappa}\right)$ of the NIZK proof system and a ciphertext $c \leftarrow \operatorname{Enc}(\mathrm{k}, \mathrm{s} ; \omega)$ being an encryption of the PRF key s
under randomness $\omega$. Let $L_{R}:=\{x \mid \exists w: R(x, w)=1\}$ with witness relation $R$ be defined as:

$$
((c, y, m),(\mathrm{s}, \mathrm{k}, \omega)) \in R \quad \Longleftrightarrow \quad c=\Omega . \operatorname{Enc}(\mathrm{k}, \mathrm{~s} ; \omega) \wedge y=F_{\mathbf{s}}(m)
$$

A signature for a message $m \in \mathcal{M}$ in the Bellare-Goldwasser approach is the pair $\sigma:=(y, \pi)$. Thereby, $y \leftarrow F_{\mathbf{s}}(m)$ is the evaluation of the PRF using key s , and $\pi \leftarrow \Pi \cdot \operatorname{Proof}(\mathrm{crs},(c, y, m),(\mathrm{s}, \mathrm{k} ; \omega))$ is a NIZK proof, proving the correct evaluation of the PRF on the message $m$ with respect to unknown PRF key s encrypted in $c$, where $c$ is part of the public key pk. In Scheme 2 we formally state the construction, which we term Begol.
$\operatorname{Gen}\left(1^{\kappa}\right): \operatorname{Run} \operatorname{crs} \leftarrow \Pi . \operatorname{Setup}\left(1^{\kappa}\right), \mathrm{k} \leftarrow \Omega . \operatorname{Gen}\left(1^{\kappa}\right)$, choose $\mathrm{s}{ }^{R} \mathcal{S}$, compute $c \leftarrow \Omega$.Enc $($ $\mathrm{k}, \mathrm{s})$, set $\mathrm{pk} \leftarrow(\mathrm{crs}, c)$ and $\mathrm{sk} \leftarrow(\mathrm{pk}, \mathrm{s}, \mathrm{k})$ and return ( $\mathrm{sk}, \mathrm{pk})$.
Sign $(\mathrm{sk}, m):$ Parse sk as $((\mathrm{crs}, c), \mathrm{s}, \mathrm{k})$, compute $y \leftarrow F_{\mathrm{s}}(m), \pi \leftarrow \Pi$. Proof(crs, $\tau,(c, y$, $m),(\mathrm{s}, \mathrm{k}))$, and return $\sigma \leftarrow(y, \pi)$.
Verify $(\mathrm{pk}, m, \sigma):$ Parse pk as (crs, $c$ ), and $\sigma$ as $(y, \pi)$. Return 1 if the following holds, and 0 otherwise:

$$
\text { П.Verify }(\text { crs },(c, y, m), \pi)=1
$$

Scheme 2: Begol: building upon Bellare-Goldwasser.

While BG do not the make the properties of the used primitives explicit, we are interested in obtaining particularly efficient instantiations and thus identify the minimum requirements for the underlying primitives. In doing so, we make the important observation that we only require IND-EAV security for the used symmetric encryption scheme. Now, in contrast to the well known IND-CPA security, which would require a randomized symmetric encryption scheme, the IND-EAV requirement can be satisfied by a deterministic symmetric encryption scheme. Thus, for our implementations we can use:

$$
\begin{equation*}
((c, y, m),(\mathrm{s}, \mathrm{k})) \in R \quad \Longleftrightarrow \quad c=\Omega . \operatorname{Enc}(\mathrm{k}, \mathrm{~s}) \wedge y=F_{\mathrm{s}}(m) \tag{1}
\end{equation*}
$$

Note that in contrast to randomized encryption, this reduces the size of the witness (no randomness $\omega$ is required) and the proof complexity. For our signature scheme this means that we can obtain shorter signatures and signing keys, as well as better computational efficiency.
Tight Security. As already mentioned, we are interested to tightly relate the security of our instantiation to the security of the underlying symmetric primitives. The subsequent lemma it tailored to our setting and makes the requirements for the underlying primitives explicit by making use of state-of-the-art security notions. Furthermore, we provide explicit bounds.

Lemma 4. If $\Omega$ is $\left(t_{\mathrm{e}}, \epsilon_{\mathrm{e}}\right)$-IND-EAV secure, $\mathcal{F}$ is a $\left(t_{\mathrm{p}}, \epsilon_{\mathrm{p}}\right)$-secure PRF family, $\Pi$ is $\epsilon_{\mathrm{s}}$-sound, and $\epsilon_{\mathrm{z}}$-adaptively zero-knowledge, then the $B G$ signature scheme is $(t, \epsilon)$-EUF-CMA secure, where

$$
\epsilon(\kappa) \leq 1 / 2^{\kappa}+\epsilon_{\mathrm{e}}(\kappa)+\epsilon_{\mathrm{p}}(\kappa)+\epsilon_{\mathrm{s}}(\kappa)+\epsilon_{\mathrm{z}}(\kappa), \text { and } t \approx \max \left\{t_{\mathrm{e}}, t_{\mathrm{p}}\right\}
$$

We prove the theorem above in Appendix B. Subsequently, we show how to instantiate the required non-interactive zero-knowledge proof-system NIZKBoo from ZKBoo and prove the required bounds for soundness and adaptive zeroknowledge which then completes the proof of Theorem 1.

### 4.1 Using ZKBoo as Non-Interactive ZK Proof System

In this section, we describe how to turn ZKBoo into a non-interactive zeroknowledge (NIZK) proof system so that it can be used to efficiently instantiate Begol. While ZKBoo is generally applicable to the class of functions which can be decomposed into three branches, so that the values computed in two branches reveal no information about the input to the respective function, we will henceforth focus on Boolean circuits being a subclass of these functions (cf. Section 5 for more details on this choice). Such a decomposition is called (2,3)-function decomposition and works as follows.
Linear (2,3)-Function Decomposition for Boolean Circuits [GMO16]. Let $\phi: W \rightarrow X$ be a function which can be expressed by a Boolean circuit with a total number $N$ of gates. The (2,3)-function decomposition is defined by the following building blocks. First, one requires three random tapes $\left(k_{1}, k_{2}, k_{3}\right)$. Second, the Share function computes a linear secret sharing $\left(s_{1}, s_{2}, s_{3}\right)$ of the input value $w \in W$ with respect to random tapes $\left(k_{1}, k_{2}, k_{3}\right)$. Third, the family $\mathcal{F}=\bigcup_{c=1}^{N}\left\{\phi_{1}^{(c)}, \phi_{2}^{(c)}, \phi_{3}^{(c)}\right\}$ is defined as follows. Let $w_{i}[c], i \in[3]$ denote the output of gate $c$, let $\left(w_{1}[0], w_{2}[0], w_{3}[0]\right)=\left(s_{1}, s_{2}, s_{3}\right)$, and let $\left(x_{1}, x_{2}, x_{3}\right)=$ $\left(w_{1}[N], w_{2}[N], w_{3}[N]\right)$. Then, depending on the type of the gate, the functions $\phi_{i}^{(c)}, i \in[3]$ are defined as follows, where the wires are coming from the gate numbers $a$ and $b$ with $a, b<c$ (only from $a$ for unary gates):

$$
\begin{aligned}
& \text { Unary XOR } \alpha \text { gate: } w_{i}[c]=\phi_{i}^{(c)}\left(w_{i}[a]\right)= \begin{cases}w_{i}[a] \oplus \alpha & \text { if } i=1, \text { and } \\
w_{i}[a] & \text { else. }\end{cases} \\
& \text { Unary AND } \alpha \text { gate: } w_{i}[c]=\phi_{i}^{(c)}\left(w_{i}[a]\right)=\alpha \wedge w_{i}[a] \text {. } \\
& \text { Binary XOR gate: } \quad w_{i}[c]=\phi_{i}^{(c)}\left(w_{i}[a], w_{i}[b]\right)=w_{i}[a] \oplus w_{i}[b] . \\
& \text { Binary AND gate: } \\
& w_{i}[c]=\phi_{i}^{(c)}\left(w_{i}[a, b], w_{i+1}[a, b], k_{i}, k_{i+1}\right) \\
& =w_{i}[a] \wedge w_{i}[b] \oplus w_{i+1}[a] \wedge w_{i}[b] \\
& \oplus w_{i}[a] \wedge w_{i+1}[b] \oplus F_{k_{i}}(c) \oplus F_{k_{i+1}}(c),
\end{aligned}
$$

where $F_{k_{i}}$ and $F_{k_{i+1}}$, respectively, denote PRFs, being sampled from an appropriate family using $k_{i}$ and $k_{i+1}$.

NIZK from ZKBoo $\Sigma$-Protocol (NIZKBoo). The NIZKBoo protocol is presented in Scheme 3, where we slightly abuse the notation introduced above and assume that the selection of the input wires is hard-coded into the functions $\phi_{i}^{(c)}$. Therefore, all functions $\phi_{i}^{(c)}$ take input $\left(w_{i}[0, \ldots, c-1], w_{i+1}[0, \ldots, c-1], k_{i}\right.$, $k_{i+1}$ ), i.e., the values of all wires up to gate number $c-1$, as well as the random tapes $k_{i}$ and $k_{i+1}$. Since ZKBoo builds up on commitments in the

ROM, we index the algorithms $\mathrm{P}_{H}, \mathrm{~V}_{H}$ with an additional RO $H^{\prime}:\{0,1\}^{\alpha} \times$ $\{0,1\}^{\beta} \times\{0,1\}^{\nu} \rightarrow\{0,1\}^{\rho}$. Furthermore, for our illustrations we assume that $H: \mathrm{A} \times \mathrm{X} \rightarrow\{0,1,2\}^{\gamma}$ with $\gamma=1$, and stress that we can adjust the soundness error arbitrarily by parallel composition, i.e., increasing $\gamma$ (cf. Lemma 1 and Lemma 2).
Modeling the BG Language. The witness relation in Equation (1) can be seen as the composition of witness relations using an AND and an EQ composition. Technically, we represent the entire statement as a single circuit which represents the combination of an encryption circuit $\Omega$.Enc and an PRF circuit where the inputs corresponding to the PRF seed s are re-used. In Section 5 we will discuss how we instantiate both building blocks from a block cipher (LowMC).

```
\(\mathrm{P}_{H, H^{\prime}}\left(1^{\kappa}, x, w\right)\) : Sample random tapes \(\left(k_{1}, k_{2}, k_{3}\right) \stackrel{R}{R}_{\leftarrow}^{\leftarrow}\left(\{0,1\}^{\alpha},\{0,1\}^{\alpha},\{0,1\}^{\alpha}\right)\), run
    \(\left(s_{1}, s_{2}, s_{3}\right)=\left(w_{1}[0], w_{2}[0], w_{3}[0]\right) \leftarrow \operatorname{Share}\left(w ; k_{1}, k_{2}, k_{3}\right)\). Obtain \(\left(w_{1}, w_{2}, w_{3}\right)=\)
    \(\left(\left(w_{1}[i], w_{2}[i], w_{3}[i]\right)\right)_{1<i \leq N}\), where
\[
\left(w_{j}[i] \leftarrow \phi_{j}^{(i)}\left(w_{j}[0, \ldots, i-1], w_{j+1}[0, \ldots, i-1], k_{j}, k_{j+1}\right)_{j \in[3], 1<i \leq N},\right.
\]
and let \(\left(x_{1}, x_{2}, x_{3}\right)=\left(w_{1}[N], w_{2}[N], w_{3}[N]\right)\). For \(i \in[3]\), compute \(c_{i} \leftarrow H^{\prime}\left(k_{i}\right.\), \(w_{i}, r_{i}\) ), where \(r_{i}{ }^{R}\{0,1\}^{\nu}\). Then, set a \(\leftarrow\left(x_{1}, x_{2}, x_{3}, c_{1}, c_{2}, c_{3}\right)\), compute \(\mathrm{e} \leftarrow\) \(H(\mathrm{a}, x)\), set \(\mathbf{z} \leftarrow\left(k_{\mathrm{e}}, k_{\mathrm{e}+1}, w_{\mathrm{e}}, w_{\mathrm{e}+1}, r_{\mathrm{e}}, r_{\mathrm{e}+1}\right)\) and return \(\pi \leftarrow(\mathrm{a}, \mathrm{z})\).
\(\mathrm{V}_{H, H^{\prime}}\left(1^{\kappa}, x, \pi\right)\) : Parse \(\pi\) as ( \(\mathrm{a}, \mathrm{z}\) ), compute \(\mathrm{e} \leftarrow H(\mathrm{a}, x)\), and check whether \(x=\) \(x_{1} \oplus x_{2} \oplus x_{3}\), if \(x_{i}=w_{i}[N]\) for \(i \in\{\mathrm{e}, \mathrm{e}+1\}\) and if the following holds for all \(1<i \leq N\) :
\[
\begin{aligned}
w_{\mathrm{e}}[i]= & \phi_{\mathrm{e}}^{(i)}\left(w_{\mathrm{e}}[0, \ldots, i-1], w_{\mathrm{e}+1}[0, \ldots, i-1], k_{\mathrm{e}}, k_{\mathrm{e}+1}\right) \wedge \\
& c_{\mathrm{e}}=H^{\prime}\left(k_{\mathrm{e}}, w_{\mathrm{e}}, r_{\mathrm{e}}\right) \wedge c_{\mathrm{e}+1}=H^{\prime}\left(k_{\mathrm{e}+1}, w_{\mathrm{e}+1}, r_{\mathrm{e}+1}\right) .
\end{aligned}
\]
```

If all checks hold, return 1 and 0 otherwise.
Scheme 3: NIZKBoo for $L_{\phi}$ with decomposition $\operatorname{Dec}_{\phi}=(\operatorname{Share}, \mathcal{F})$ and $\gamma=1$.

Given the completeness of the underlying ZKBoo protocol, the subsequent corollary follows from inspection.

Corollary 2. Scheme 3 is complete.
Now, we directly prove the remaining required security properties of NIZKBoo when used to instantiate the Bellare-Goldwasser paradigm. An important observation is that we are dealing with an NP-language where soundness actually gives sufficient guarantees for the security of the overall signature scheme and we do not need to be able to extract a witness. This allows us to bypass the requirement for rewinding the adversary, and to obtain a tight security bound.

Lemma 5. Let $\kappa$ be the security parameter and $Q_{H^{\prime}}$ be the number of queries to $H^{\prime}$. Then the probability $\epsilon(\kappa)$ for all PPT adversaries $\mathcal{A}$ to break soundness of $\gamma$ parallel executions of Scheme 3 is bounded by $\epsilon(\kappa) \leq Q_{H^{\prime}}^{2} / 2^{\rho}+(2 / 3)^{\gamma}$.

Proof. We prove the theorem above using a sequence of games.
Game 0: The original soundness game. The environment maintains the lists H and $\mathrm{H}^{\prime}$, which are initially empty. The ROs are honestly simulated:
$H(\mathrm{a}, x):$ If $\mathrm{H}[(\mathrm{a}, x)]=\perp$, set $\mathrm{H}[(\mathrm{a}, x)] \stackrel{R}{R}_{\leftarrow}\{0,1\}^{\gamma}$. Return $\mathrm{H}[(\mathrm{a}, x)]$. $H^{\prime}\left(\| \|_{j \in[\rho]}\left(k_{j}, w_{j}\right)\right)$ : If $H^{\prime}\left[\| \|_{j \in[\rho]}\left(k_{j}, w_{j}\right)\right]=\perp$, set $H^{\prime}\left[\left(k_{j}, w_{j}\right)_{j \in[\rho]}\right]{ }^{R}\{0,1\}^{\rho}$. Return $\mathrm{H}^{\prime}\left[| |_{j \in[\rho]}\left(k_{j}, w_{j}\right)\right]$.
Game 1: As Game 0, but we abort as soon as there $\exists x, y: \mathrm{H}^{\prime}[x]=\mathrm{H}^{\prime}[y] \neq$ $\perp \wedge x \neq y$. We term this abort event $E$.
Transition Game $0 \rightarrow$ Game 1: Game 0 and Game 1 proceed identically, unless event $E$ occurs. Thus, we have that for appropriately chosen $\rho$ both games are statistically close, i.e., $\left|\operatorname{Pr}\left[S_{0}\right]-\operatorname{Pr}\left[S_{1}\right]\right| \leq \operatorname{Pr}[E] \leq Q_{H^{\prime}}^{2} / 2^{\rho}$

In Game 1, it is impossible to find two different openings for a single RO commitment. Now, we observe that if $x \notin L$ and the adversary does not correctly guess the challenge, at least one challenge yields two inconsistent views. Since the challenge is uniformly random and independent of the adversary's view, this yields $\operatorname{Pr}\left[S_{1}\right] \leq(2 / 3)^{\gamma}$ and completes the proof.

Lemma 6. Let $\kappa$ be the security parameter, $Q_{H}$ be the number of queries to $H$, $Q_{S}$ be the overall queries to the simulator, and let the commitments in Scheme 3 be instantiated via a RO $H^{\prime}:\{0,1\}^{\alpha} \times\{0,1\}^{\beta} \times\{0,1\}^{\nu} \rightarrow\{0,1\}^{\rho}$ so that $\{0,1\}^{\nu}$ is sampled uniformly at random for every commitment. Then the probability $\epsilon(\kappa)$ for all PPT adversaries $\mathcal{A}$ to break adaptive zero-knowledge of $\gamma$ parallel executions of Scheme 3 is bounded by $\epsilon(\kappa) \leq \gamma / 2^{\nu}+\left(Q_{S} \cdot Q_{H}\right) / 2^{3 \cdot \rho}$.

The subsequent proof is similar to the general results for $\Sigma$-protocols from [FKMV12], yet we have to account for the additional challenge that the simulator only outputs transcripts which are statistically close to original transcripts (which is in contrast to the identically distributed transcripts in [FKMV12]). Furthermore, we also provide concrete bounds.

Proof. We bound the probability of any PPT adversary $\mathcal{A}$ to win the zeroknowledge game by showing that the simulation of the proof oracle is statistically close to the real proof oracle.

Game 0: The zero-knowledge game where the proofs are honestly computed, and the ROs are simulated exactly as in the proof of Lemma 5.
Game 1: As Game 0, but whenever the adversary requests a proof for some tuple $(x, w)$ we choose $\mathrm{e} \leftarrow^{R}\{0,1,2\}^{\gamma}$ before computing a and z. If $\mathrm{H}[(\mathrm{a}, x)] \neq$ $\perp$ we abort. Otherwise, we set $\mathrm{H}[(\mathrm{a}, x)] \leftarrow \mathrm{e}$.
Transition - Game $0 \rightarrow$ Game 1: Game 0 and Game 1 proceed identically unless $E$ happens. The message a includes 3 RO commitments with respect to $H^{\prime}$, i.e., a lower bound for the min-entropy is $3 \cdot \rho$. We have that $\mid \operatorname{Pr}\left[S_{0}\right]-$ $\operatorname{Pr}\left[S_{1}\right] \mid \leq\left(Q_{S} \cdot Q_{H}\right) / 2^{3 \cdot \rho}$.
Game 2: As Game 1, but we compute $\left(\left(c_{i 1}, c_{i 2}, c_{i 3}\right)\right)_{i \in[\gamma]}$ in a so that the commitments which will never be opened according to e contain random values.

Transition - Game $1 \rightarrow$ Game 2: The statistical difference between Game 1 and Game 2 can be upper bounded by $\left|\operatorname{Pr}\left[S_{1}\right]-\operatorname{Pr}\left[S_{2}\right]\right| \leq \gamma \cdot 1 / 2^{\nu}$ (for compactness we collapsed the $\gamma$ game changes into a single game).
Game 3: As Game 2, but we use the HVZK simulator to obtain (a, e, z).
Transition - Game $2 \rightarrow$ Game 3: This change is conceptual, i.e., $\operatorname{Pr}\left[S_{2}\right]=\operatorname{Pr}\left[S_{3}\right]$.
In Game 0, we sample from the first distribution of the zero-knowledge game, whereas we sample from the second one in Game 3; the distinguishing bounds shown above conclude the proof.

## 5 Selecting an Underlying Symmetric Primitive

Our schemes require one or more symmetric primitives suitable to instantiate an OWF, a PRF, as well as a symmetric cipher. In this section we first investigate how choosing a primitive with certain properties impacts an overall instantiation of our schemes. From this, we derive concrete requirements, and, finally, present our chosen primitive.
Signature Size. The size of the signature is mostly influenced by two factors. Firstly by the number $\gamma$ of parallel repetitions and, secondly, by the size $\beta$ of the views generated during the ZKBoo protocol. The latter is fully determined by the choice of the OWF $f$ for Fish, and the PRF $F$ and symmetric encryption scheme $\Omega$ for Begol. We denote by $a_{f}, a_{F}$ and $a_{\Omega}$ the number of binary multiplication gates contained in the circuit representation of $f, F$ and $\Omega$, and by $\lambda_{f}, \lambda_{F}$ and $\lambda_{\Omega}$ the respective sizes of rings in which the multiplications take place. Furthermore we denote by $\left(D_{f}, D_{F}, D_{\Omega}\right)$ and $\left(I_{f}, I_{F}, I_{\Omega}\right)$ the size of the domain and the images of the functions. More explicitly, the signature sizes are as follows. For instantiations of the Fish scheme we obtain signatures taking up

$$
\underset{\text { image of } f}{I_{f}}+\underset{\text { challenge }}{2 \cdot \gamma}+\gamma \cdot(\underbrace{3 \cdot \rho}_{\text {commitments }}+\underbrace{2 \cdot(\overbrace{D_{f}+\lambda_{f} \cdot a_{f}+I_{f}}^{3 \cdot \rho} \stackrel{\text { randomness }}{\nu+\alpha})}_{\text {openings }})
$$

bits of storage. When using Begol, twice as many views and commitments need to be stored as well as another $3 \cdot \gamma$ images. Hence we get signatures of bitlength

$$
\begin{aligned}
& \underset{\text { image of } F}{I_{F}}+\underset{\text { challenge }}{2 \cdot \gamma}+\gamma \cdot(\underset{\text { commitments }}{6 \cdot \rho}+ \\
& \frac{\text { views for } F}{2 \cdot(\overbrace{D_{F}+\lambda_{F} \cdot a_{F}+I_{F}}^{2}+\stackrel{\text { views for } \Omega}{D_{\Omega}+\lambda_{\Omega} \cdot a_{\Omega}+I_{\Omega}}+\stackrel{\text { randomness }}{\stackrel{\text { rand }}{2 \cdot(\nu+\alpha)}})}) .
\end{aligned}
$$

Runtime for Signing and Verification. In the context of multi-party computation (MPC) it is often argued that the runtime is mainly determined by the number of AND gates. Intuitively, the runtime should thus be directly proportional to the signature size. While this is definitely true in an asymptotic sense, the runtime of a concrete instantiation is also influenced by the number of XOR gates (especially for larger numbers of XOR gates). This is also confirmed by our implementation results in Section 6.

### 5.1 Survey of Suitable Primitives

The size of the signature depends on constants that are close to the security expectation (say, 128 or 256 ; cf. Section 6 for our concrete choices). The only exceptions are the number of binary multiplication gates, and the size of the rings, which all depend on the choice of the primitive. Hence we survey existing designs that can serve as a OWF, PRF, or IND-EAV secure symmetric cipher, respectively. We focus on the following categories.

- Standardized and widely used primitives such as AES, or SHA-256 or SHA512 or SHA-3.
- Low complexity, "lightweight" ciphers for use in constrained environments.
- Custom block and stream ciphers designed for evaluation by a fully/somewhat homomorphic encryption scheme, a SNARK, or in an MPC protocol.

Standardized General-Purpose Primitives. The smallest known Boolean circuit of AES-128 needs 5440 AND gates, AES-192 needs 6528 AND gates, and AES-256 needs 7616 AND gates [BMP13]. An AES circuit in $\mathbb{F}_{2^{4}}$ might be more efficient in our setting, as in this case the number of multiplications is lower than $1000\left[\mathrm{CGP}^{+} 12\right]$. This results in an impact on the signature size that is equivalent to 4000 AND gates. Even though collision resistance is often not required, hash functions like SHA-256 are a popular choice for proof-ofconcept implementations. The number of AND gates of a single call to the SHA256 compression function is about 25000 and a single call to the permutation underlying SHA-3 is 38400 .
Lightweight Ciphers. Most early designs in this domain focused on small area when implemented as a circuit in hardware where the size of an XOR gate is by a small factor larger than the size of an AND or NAND gate. Notable designs with a low number of AND gates at the 128-bit security level are the block ciphers Noekeon [DPVAR00] (2048) and Fantomas [GLSV14] (2112). Furthermore, one should mention Prince $\left[\mathrm{BCG}^{+} 12\right]$ (1920), or the stream cipher Trivium [DP08] (1536 AND gates to compute 128 output bits) with 80-bit security.
Custom Ciphers with a Low Number of Multiplications. Motivated by various applications in SHE/FHE schemes, MPC protocols and SNARKs, recently a trend to design symmetric encryption primitives with a low number of multiplications or a low multiplicative depth started to evolve. As we shall see, this is a trend we can take advantage of.

We start with the block cipher family called LowMC [ARS $\left.{ }^{+} 15\right]$. In the most recent version of the proposal $\left[\mathrm{ARS}^{+} 16\right]$, the number of AND gates can be below 500 for 80 -bit security, below 800 for 128 -bit security, and below 1400 for 256 -bit security. The stream cipher Kreyvium [CCF ${ }^{+}$16] needs similarly to Trivium 1536 AND gates to compute 128 output bits, but offers a higher security level of 128 bit. Even though FLIP [MJSC16] was designed to have especially low depth, it needs hundreds of AND gates per bit and is hence not competitive in our setting.

Last but not least there are the block ciphers and hash functions around MiMC $\left[\mathrm{AGR}^{+} 16\right]$ which need less than $2 \cdot s$ multiplications for $s$-bit security in a
field of size close to $2^{s}$. Note that MiMC is the only design in this category which aims at minimizing multiplications in a field larger than $\mathbb{F}_{2}$. However, since the size of the signature depends on both the number of multiplications and the size of the field, this leads to a factor $2 s^{2}$ which, for all arguably secure instantiations of MiMC, is already larger than the number of AND gates in the AES circuit.

LowMC has two important advantages over other designs: It has the lowest number of AND gates for every security level: The closest competitor Kreyvium needs about twice as many AND gates and only exists for the 128 -bit security level. The fact that it allows for an easy parameterization of the security level is another advantage. We hence use LowMC for our concrete proposal and discuss it in more detail in the following.

### 5.2 LowMC

LowMC is a flexible block cipher family based on a substitution-permutation network where the block size $n$, the key size $k$, the number of 3 -bit Sboxes $m$ in the substitution layer and the allowed data complexity $d$ of attacks can independently be chosen. To reduce the multiplicative complexity, the number of Sboxes applied in parallel can be reduced, leaving part of the substitution layer as the identity mapping. The number of rounds $r$ needed to achieve the goals is then determined as a function of all these parameters. For the sake of completeness we include a brief description of LowMC in Appendix C.

To minimize the number of AND gates for a given $k$ and $d$, we want to minimize $r \cdot m$. A natural strategy would be to set $m$ to 1 , and then look for an $n$ that minimizes $r$. Examples of such an approach are already given in the document describing version 2 of the design $\left[\mathrm{ARS}^{+} 16\right]$. In our setting, this approach may not lead to the best results in practice, as it ignores the impact of the large amount of XOR operations it requires. What we hence do to find the most suitable parameterization is to explore a larger range of values from $m$ also.

Whenever we want to use LowMC to instantiate one of the required symmetric primitives with $s$-bit security, we set $k=d=s$. For post-quantum security we double those parameters to take generic quantum-speedups into account. This takes into account current knowledge of quantum-cryptanalysis for models that are very generous to the attacker [KLLN16, KLLN15].

An exception to this conservative choice can be found in our optimization discussion in Section 6.5 where we describe why a less conservative choice for the parameter $d$ is possible.

## 6 Implementation and Design Space Exploration

We provide a library implementing both the Fish and the Begol signature scheme. The library provides an API exposing an interface to generate LowMC instances for a given parameter set, as well as an easy to use interface for key generation, signature generation/verification in both schemes. To be able to explore various directions in the LowMC parameter space, we also implemented a benchmarking
framework. The library is implemented in C using the OpenSSL ${ }^{10}$ and m4ri ${ }^{11}$ libraries and is available online at https://github.com/IAIK/fish-begol.

### 6.1 Implementation of Building Blocks

The building blocks in the protocol are instantiated similar as in the implementation of ZKBoo [GMO16]:
PRNG. Random tapes are generated pseudorandomly using AES in counter mode, where the AES keys are generated using OpenSSL's secure random number generator. In the linear decomposition of the AND gates we use a random function that picks the bits from the bit stream generated using AES. Since the number of AND gates is known a-priori, we can pre-compute all random bits at the beginning of the protocol.
Commitments. The RO $H^{\prime}$ used to commit to the views is implemented using SHA-256, i.e. $\operatorname{Com}(k, w):=\operatorname{SHA}-256(k, w, r)$ where $r \leftarrow^{R}\{0,1\}^{\nu}$.
Challenge Generation. For both approaches we instantiate RO $H:\{0,1\}^{*} \rightarrow$ $\{0,1,2\}^{\gamma}$ using SHA-256 and rejection sampling: we split the output bits of SHA-256 in pairs of two bits and reject all pairs with both bits set.
LowMC-Based Primitives. It is straight forward to use LowMC as PRF and IND-EAV secure encryption scheme. The OWF is instantiated by fixing a plaintext and using the input to the OWF as key for LowMC.

### 6.2 Circuit for LowMC

For the linear (2,3)-decomposition we view LowMC as circuit over $\mathbb{F}_{2}$. From the description of LowMC it is clear, that the circuit consists only of AND and XOR gates. Hence we have $\lambda_{f}=\lambda_{F}=\lambda_{\Omega}=1$. When optimizing the circuit so that modified AND gates as described in [GMO16] are used, the number of bits we have to store for each view is further reduced to $a_{f}=a_{F}=a_{\Omega}=3 \cdot r \cdot m$, where $r$ is the number of rounds and $m$ is the number of Sboxes in LowMC.

Our implementation builds upon the m4ri library [ABH10] and to better fit the memory layout used by m4ri, all operations are performed using transposed matrices and column vectors. For improved performance of the Sbox layer, we use a bit-sliced version of the Sbox, i.e., instead of looping over $m$ bit triples and applying the Sbox separately, we evaluate the full Sbox layer using a sequence of AND, XOR and shift instructions independent of $m$.

Since the affine layer of LowMC only consists of AND and XOR operations, it benefits from using block sizes such that all computations of this layer can be performed using SIMD instruction sets that provide bitwise AND and XOR instruction for 128 bit respectively 256 bit operands like AVX2 and SSE2 or NEON. Similarly the bit-sliced version of the Sbox layer can be improved by using SIMD AND and XOR instructions. Only inter-lane bit-shifts, which are

[^5]necessary for the bit-sliced Sbox, do not fit the model of SIMD instruction sets. Thus shifts require up to five instructions and only benefit slightly. Since our implementation uses (arrays of) native words to store the bit vectors, the implementation benefits from a choice of parameters such that $3 \cdot m$ is close to the word size. This choice allows us to maximize the number of parallel Sbox evaluations in the bitsliced implementation. Note that also the storage overhead of individual views benefits from $3 \cdot m$ close to byte boundaries as we always use bytes instead of individual bits.

While we optimized the AND and XOR gates in the LowMC circuit to use SIMD instructions where possible, we have kept the implementation very generic for arbitrary choices of the LowMC parameters. Hence we are able to explore the parameter space in multiple directions while still profiting from the speed up of vectorized operations.

### 6.3 Experimental Setup and Results

Our experiments were performed on an Intel Core i7-4790 CPU at 3.60 GHz with 4 cores $^{12}$ and 16 GB RAM running Ubuntu 16.04. We omit any benchmarks of Gen, since the key generation only needs to request $k$ respectively $2 \cdot k$ bits from the random number generator and to compute one LowMC encryption and has a runtime of some microseconds. Henceforth, we target the 128 bit pre- as well as post-quantum setting and we globally set our repetition count to $\gamma:=219$. Based on this, we globally fix the output size of the RO to $\rho:=256$, and the size of the randomness in the RO commitment to $\nu:=136$ (then all terms in the bound involving these factors are negligible in the security parameter).
Selection of the Most Suitable LowMC Instances. We now explore the design space of LowMC to select the most suitable instances among the 128 bit pre- as well as post-quantum instances. Our results are presented in Figure 2 (note that the plot axes are in logarithmic scale). Choosing a concrete LowMC instance results in a trade-off between computational efficiency and signature size, parametrized by the number of rounds and by the number of Sboxes.

We select the instances yielding the best balance between signature size and computational efficiency. In particular, using the notation [blocksize]-[keysize]-[\#sboxes]-[\#rounds], we choose the 128-128-12-26 instance from the 128 bit prequantum instances and the 256-256-20-31 instance from the 128 post-quantum instances. To underpin our argumentation regarding the choice of LowMC, we also include the runtime and proof size of the SHA-256 implementation (with one call to the compression function) from the authors of ZKBoo in [GMO16]. Informally speaking, this can be seen as a rough estimation of a lower bound for an instantiation of our scheme Fish with SHA-256 instead of LowMC.

An immediate conclusion we can draw from these results is that both signature schemes can be instantiated such that they are entirely practical.
Taking the Reduction Tightness into Account. We now investigate how in a concrete rather than asymptotic setting the number of queries the adversary

[^6]
(a) Asymptotic 128 bit pre-quantum security.

(b) Asymptotic 128 bit post-quantum security.

Fig. 2. Measurements for instance selection (average over 100 runs).
is assumed to make to the RO impacts the signature size and the computational efficiency. Figure 3 illustrates this impact on the performance of our schemes for concrete 128 bit pre- and post-quantum security. We thereby, successively increase the number of RO queries from $2^{60}$ to $2^{100}$. To make the plots easier to read, we omit to increase $\rho$ with increasing number of RO queries. With this omission, the difference in the signature size of Begol is less than one kB and even lower for Fish. The runtime for both schemes is not noticeably affected.

The interesting conclusion we draw from our results is that increasing the number of queries to the RO eventually leads to a point where our scheme Begol
becomes more efficient than our scheme Fish (both in terms of signature size as well as in terms of computational efficiency). In other words, depending on how conservative/progressive the power of an adversary is estimated, either one of our schemes can be the right choice.

(a) Concrete 128 -bit pre-quantum security level.

(b) Concrete 128 -bit post-quantum security level.

Fig. 3. Efficiency of Sign relative to number of RO queries (average over 100 runs).

Parallelization. One positive aspect regarding the $\gamma$ parallel repetitions is that they are independent of each other. ${ }^{13}$ In particular, this holds for all steps in the signing and verification algorithm up to the initial requests to OpenSSL's random number generator and the computation of the challenge. This allows us to take advantage of the multi-core architecture of modern processors using OpenMP. ${ }^{14}$ As exemplified for Begol in Figure 4, we can observe a significant performance increase until the number of threads matches the actual number of CPU cores. We note that exactly the same effects also occur for instantiations of Fish. Furthermore, they also occur regardless of the LowMC parameters.

Signing Arbitrary Length Messages. We have not discussed signing of messages of arbitrary length with our approaches so far. For Fish, this is already covered by the $\mathrm{FS}_{\Sigma}$ transform as we are not limited in the message length in the challenge computation. For Begol, we observe that it needs a bit more care as we need use a collision-resistant (CR) hash function prior to computing the signature and thus have to adjust the output size of the CR hash with the input size of the PRF. If we follow the argumentation of Bernstein [Ber09], then like with Fish our instantiations in the benchmarks already support arbitrary length messages when using SHA-256 as a CR hash. If we follow the more conservative approach of assuming cost $2^{b / 3}$ for $b$ bit collisions, then for the 128 -bit post-quantum setting we would have to slightly increase the input size of the PRF (i.e., change the blocksize of the second LowMC instance to 384 bit). This would slightly increase computation times as well as signature sizes.

Fig. 4. Runtime of the parallelized version of Sign and Verify of Begol at 128-bit prequantum security level using an increasing number of threads.

[^7]
### 6.4 Comparison with Related Work

To compare our signature scheme to other recent proposals, we selected schemes which have reference implementations freely available. We benchmarked these implementations on the machine we used to perform our benchmarks. Table 1 gives an overview of the results, including MQDSS [HRSS16], TESLA [ABB ${ }^{+}$15], ring-TESLA $\left[\mathrm{ABB}^{+} 16\right]$, BLISS [DDLL13], and SPHINCS-256 [BHH $\left.{ }^{+} 15\right] .{ }^{15}$

Our implementation can be considered as a general-purpose implementation, which is flexible enough to cover the entire design spectrum of both our approaches. In contrast, the implementations of other candidate schemes used for comparison come with a highly optimized implementation targeting a specific security level (and often also specific instances). Thus, our timings can be considered to be more conservative than the ones of the other schemes used for comparison. Yet, both signing and verification times are comparable to the ones of the MQ 5pass scheme, and the signing times are comparable to SPHINCS-256.

| Scheme | Gen <br> [ms] | [ms] | Verify [ms] | $\begin{array}{r} \|\mathrm{sk}\| \\ \text { [bytes] } \end{array}$ | \|pk| <br> [bytes] | $\begin{array}{r} \|\sigma\|, \\ \text { [bytes] } \end{array}$ | Tight | M | PQ |

| TESLA-768 | 48570.01 | 0.65 | 0.36 | 3293216 | 4227072 | 2336 | $\checkmark$ | (Q)ROM | $\checkmark$ |

Table 1. Timings and sizes of private keys (sk), public keys ( pk ) and signatures $(\sigma)$.

It seems that avoiding additional structured hardness assumptions comes at the cost of larger signatures. An interesting observation when compared to SPHINCS-256 (which is the only other scheme without additional structured hardness assumptions) is that our approach can be interpreted as using the RO heuristic to trade smaller keys for larger signatures. Furthermore, it should also be noted that our work establishes a new direction to design signature schemes and we believe that there is much room for improvement, e.g., by the design of new symmetric primitives especially focusing on optimizing the metrics required by our approach.

[^8]
### 6.5 Optimizing Signature Sizes

It is a natural question to ask whether it is possible to further decrease the signatures sizes. We observe that for our implementation of Begol there seems to be some room for a more aggressive choice of parameters: while we tackle the minimally required data complexity for the encryption scheme from a theoretical point of view (via the IND-EAV notion), our used LowMC instances are tailored to a higher data complexity. Likewise, the way we use the OWF in Fish would allow to use less conservative values for the data complexity. In particular, the most progressive choice would be to use a data complexity $d=1$ (where the adversary gets to see at most 2 plaintext-ciphertext pairs under the target key).

To give a lower bound on the signature sizes obtained via more progressive parameters, we use instances with a minimal number of AND gates. That is, we use instances with only one S -box $(m=1)$ as our results above show that these instances yield the smallest possible signature sizes. For $m=1$ and $d=1$ we derive a suitable number of rounds $r$. This yields the instance 128-128-1-156 for the 128 -bit pre-quantum setting and the instance 256-256-1-243 for the 128 -bit post-quantum setting. ${ }^{16}$ The resulting signature sizes are 61124 bytes for Fish in the 128-bit pre-quantum setting, 89446 bytes for Fish and 214167 bytes for Begol in the 128-bit post-quantum setting.

We note here however that currently our main proposal is with the more conservative $d=n$ rather than $d=1$ possibility discussed above. This may be seen as a way to introduce a security margin, taking into account the fact that LowMC is a rather novel design and progress in cryptanalysis is ongoing [DEM15, DLMW15].

## 7 Conclusion and Open Questions

In this paper we contribute two new practically efficient post-quantum signature candidates called Fish and Begol, which open up a new direction for the design of EUF-CMA secure signature schemes. Likewise to all other practical post-quantum signature candidates besides hash-based signatures, our scheme comes with a security proof in the ROM.

A major open question in all those works is whether it is possible to lift the corresponding security proofs to the QROM while preserving practicality. One major obstacle in the QROM is to handle the rewinding of adversaries within security reductions [DFG13]. Possibilities to circumvent this issue are via history-free reductions $\left[\mathrm{BDF}^{+} 11\right]$ or the use of oblivious commitments within $\mathrm{FS}_{\Sigma}$ (as, e.g., used by the TESLA authors). Unfortunately, these directions do not apply to both our approaches. Nevertheless, a very interesting and indeed promising approach is the adoption of straight-line extractable NIZK secure in the QROM as proposed by Unruh in [Unr15]. Unfortunately, his results cannot be directly applied, among others, due to the 3 -special soundness of ZKBoo.

[^9]Another very important observation is that the security proof for Begol does not require to rewind the adversary which yields a viable direction for future work. In particular, such an approach might allow to bypass the overhead imposed by the requirement for straight-line extractability.

Our work in this paper also informs future developments in the design of symmetric primitives with few multiplications. In order to be competitive with other post-quantum signature candidates we could not rely on already standardized approaches like AES or SHA-3, but need to use new ones. Even though LowMC turned out to be the most suitable option, none of the available designs directly considers the metric we would be most interested in for minimizing our signature size: the product of the number of binary multiplication gates contained in the circuit representation and the ring sizes in which the multiplications take place.

Another interesting open issue is a rigorous analysis of resistance of our approaches to power- or timing-based side-channel attacks or fault attacks. A first observation in this direction is that the structure of ZKBoo seems to inherently bring some resistance against side-channel attacks due to the use of secret sharing techniques.

## A Required Primitives

One-Way Functions. Below, we recall the notion of one-way functions.
Definition 3. A function $f: D \rightarrow \mathrm{R}$ is called a one-way function, if (1) there exists a PPT algorithm $\mathcal{A}_{1}$ so that $\forall x \in D: \mathcal{A}_{1}(x)=f(x)$, and if (2) for every PPT algorithm $\mathcal{A}_{2}$ there is a negligible function $\varepsilon(\cdot)$ such that it holds that

$$
\operatorname{Pr}\left[x \leftarrow^{R} D, x^{\star} \leftarrow \mathcal{A}_{2}\left(1^{\kappa}, f(x)\right): f(x)=f\left(x^{\star}\right)\right] \leq \varepsilon(\kappa) .
$$

Unless stated otherwise, we assume $D$ to be efficiently sampleable.
Pseudorandom Functions. Let $F: \mathcal{S} \times D \rightarrow \mathrm{R}$ be a family of functions and let $\Gamma$ be the set of all functions $D \rightarrow \mathrm{R} . F$ is a pseudorandom function (family) if it is efficiently computable and for all PPT distinguishers $\mathcal{D}$ there is a negligible function $\varepsilon(\cdot)$ such that

$$
\left|\operatorname{Pr}\left[\mathrm{s} \leftarrow^{R} \mathcal{S}, \mathcal{D}^{F_{\mathrm{s}}(\cdot)}\left(1^{\kappa}\right)\right]-\operatorname{Pr}\left[f \leftarrow_{\leftarrow}^{R} \Gamma, \mathcal{D}^{f(\cdot)}\left(1^{\kappa}\right)\right]\right| \leq \varepsilon(\kappa)
$$

Symmetric Encryption. In the following, we recall the definition of symmetric encryption schemes $\Omega$.

Definition 4 (Symmetric Encryption Scheme). A symmetric encryption scheme $\Omega$ is a tuple of PPT algorithms which are defined as follows:

Gen $\left(1^{\kappa}\right)$ : This algorithm takes a security parameter $\kappa$ as input and outputs a key k .
Enc( $\mathrm{k}, m$ ): This algorithm takes a key k and a message $m$ as input and outputs a ciphertext c.
$\operatorname{Dec}(\mathrm{k}, \mathrm{c})$ : This algorithm takes a key k and a ciphertext c as input and outputs a message $m$ or $\perp$.

We require $\Omega$ to be correct and to provide the very mild requirement of ciphertext indistinguishability in the presence of an eavesdropper (IND-EAV security) as defined below:

Definition 5 (IND-EAV Security). $\Omega$ is IND-EAV secure, if for all PPT adversaries $\mathcal{A}$ there exists a negligible function $\epsilon(\cdot)$ such that

$$
\operatorname{Pr}\left[\begin{array}{lrr}
\mathrm{k} \stackrel{R}{R}_{\leftarrow}^{\operatorname{Gen}\left(1^{\kappa}\right),\left(m_{0}, m_{1}, \mathrm{st}\right) \leftarrow \mathcal{A}\left(1^{\kappa}\right),} & b=b^{*} \wedge \\
b \leftarrow_{\leftarrow}^{R}\{0,1\}, c \leftarrow \operatorname{Enc}\left(\mathrm{k}, m_{b}\right), b^{*} \leftarrow \mathcal{A}(c, \mathrm{st}) & : & \left|m_{0}\right|=\left|m_{1}\right|
\end{array}\right] \leq 1 / 2+\varepsilon(\kappa),
$$

where $|m|$ denotes the length of message $m$.

Signature Schemes. Below we recall a standard definition of signature schemes.

Definition 6. A signature scheme $\Sigma$ is a triple (Gen, Sign, Verify) of PPT algorithms, which are defined as follows:

Gen $\left(1^{\kappa}\right)$ : This algorithm takes a security parameter $\kappa$ as input and outputs a secret (signing) key sk and a public (verification) key pk with associated message space $\mathcal{M}$ (we may omit to make the message space $\mathcal{M}$ explicit).
Sign(sk, $m$ ): This algorithm takes a secret key sk and a message $m \in \mathcal{M}$ as input and outputs a signature $\sigma$.
Verify $(\mathrm{pk}, m, \sigma)$ : This algorithm takes a public key pk , a message $m \in \mathcal{M}$ and a signature $\sigma$ as input and outputs a bit $b \in\{0,1\}$.

Besides the usual correctness property, $\Sigma$ needs to provide some unforgeability notion. In this paper we are only interested in schemes that provide existential unforgeability under adaptively chosen message attacks (EUF-CMA security), which we define below.

Definition 7 (EUF-CMA). A signature scheme $\Sigma$ is EUF-CMA secure, if for all PPT adversaries $\mathcal{A}$ there is a negligible function $\varepsilon(\cdot)$ such that

$$
\operatorname{Pr}\left[\begin{array}{lr}
(\mathrm{sk}, \mathrm{pk}) \leftarrow \operatorname{Gen}\left(1^{\kappa}\right), & \operatorname{Verify}\left(\mathrm{pk}, m^{\star}, \sigma^{\star}\right)=1 \wedge \\
\left(m^{\star}, \sigma^{\star}\right) \leftarrow \mathcal{A}^{\text {Sign(sk,.) }}(\mathrm{pk}) & : \\
m^{\star} \notin \mathcal{Q}^{\text {Sign }}
\end{array}\right] \leq \varepsilon(\kappa),
$$

where the environment keeps track of the queries to the signing oracle via $\mathcal{Q}^{\text {Sign }}$.

## A. 1 Security Properties of Non-Interactive Proof Systems

Definition 8 (Completeness). A non-interactive proof system $\Pi$ is complete, if for every adversary $\mathcal{A}$ it holds that

$$
\operatorname{Pr}\left[\begin{array}{lr}
\operatorname{crs} \leftarrow \operatorname{Setup}\left(1^{\kappa}\right),(x, w) \leftarrow \mathcal{A}(\operatorname{crs}), & : \quad \text { Verify }(\operatorname{crs}, x, \pi)=1 \\
\pi \leftarrow \operatorname{Proof}(\operatorname{crs}, x, w) & \wedge(x, w) \in R
\end{array}\right] \approx 1
$$

Definition 9 (Soundness). A non-interactive proof system $\Pi$ is sound, if for every PPT adversary $\mathcal{A}$ there is a negligible function $\epsilon(\cdot)$ such that
$\operatorname{Pr}\left[\operatorname{crs} \leftarrow \operatorname{Setup}\left(1^{\kappa}\right),(x, \pi) \leftarrow \mathcal{A}(\operatorname{crs}): \operatorname{Verify}(\operatorname{crs}, x, \pi)=1 \wedge x \notin L_{R}\right] \leq \epsilon(\kappa)$.
If we quantify over all adversaries $\mathcal{A}$ and require $\epsilon=0$, we have perfect soundness, but we present the definition for computationally sound proofs (arguments).

Definition 10 (Adaptive Zero-Knowledge). A non-interactive proof system $\Pi$ is adaptively zero-knowledge, if there exists a PPT simulator $S=\left(\mathcal{S}_{1}, \mathcal{S}_{2}\right)$ such that for every PPT adversary $\mathcal{A}$ there is a negligible function $\epsilon(\cdot)$ such that

$$
\left|\begin{array}{l}
\operatorname{Pr}\left[\operatorname{crs} \leftarrow \operatorname{Setup}\left(1^{\kappa}\right): \mathcal{A}^{\mathcal{P}(\mathrm{crs}, \cdot, \cdot)}(\mathrm{crs})=1\right]- \\
\operatorname{Pr}\left[(\mathrm{crs}, \tau) \leftarrow \mathcal{S}_{1}\left(1^{\kappa}\right): \mathcal{A}^{\mathcal{S}(\mathrm{crs}, \tau, \cdot, \cdot)}(\mathrm{crs})=1\right]
\end{array}\right| \leq \epsilon(\kappa),
$$

where, $\tau$ denotes a simulation trapdoor. Thereby, $\mathcal{P}$ and $\mathcal{S}$ return $\perp$ if $(x, w) \notin R$ or $\pi \leftarrow \operatorname{Proof}(\mathrm{crs}, x, w)$ and $\pi \leftarrow \mathcal{S}_{2}(\mathrm{crs}, \tau, x)$, respectively, otherwise.

## B Proof of Lemma 4

Proof. We prove Lemma 4 using a sequence of games, where $S_{i}$ denotes the success probability in Game $i$.

Game 0: The original EUF-CMA game.
Game 1: As in the original game, but we use the following modified Verify algorithm Verify' to check whether the forgery is valid:
Verify ${ }^{\prime}(\mathrm{pk}, m, \sigma)$ : Parse pk as (crs, $c$ ), and $\sigma$ as $(y, \pi)$. Return 1 if the following holds, and 0 otherwise:

$$
\text { П.Verify }(\mathrm{crs},(c, y, m), \pi)=1 \wedge F_{\mathbf{s}}(m)=y .
$$

Transition - Game $0 \rightarrow$ Game 1: Game 0 and Game 1 proceed identically, unless $F_{\mathrm{s}}(M) \neq y$. If this happens, we have a valid proof $\pi$ falsely attesting that $(c, y, M) \in L_{R}$. Assume a hybrid game, where we engage with a soundness challenger to obtain crs upon Gen. Whenever, it happens that $F_{\mathrm{s}}(M) \neq y$ we output $((c, y, M), \pi)$ and break soundness. This gives us the bound $\left|\operatorname{Pr}\left[S_{0}\right]-\operatorname{Pr}\left[S_{1}\right]\right| \leq \epsilon_{\mathrm{s}}(\kappa)$.

Game 2: As Game 1, but we use the following modified key generation algorithm Gen':
$\operatorname{Gen}^{\prime}\left(1^{\kappa}\right):$ Run $($ crs,$\tau) \leftarrow \mathcal{S}_{1}\left(1^{\kappa}\right)$ and store $\tau$, run $\mathrm{k} \leftarrow \Omega . \operatorname{Gen}\left(1^{\kappa}\right)$, choose $\mathrm{s} \leftarrow^{R} \mathcal{S}$, compute $c \leftarrow \Omega$.Enc $(\mathrm{k}, \mathrm{s})$, set $\mathrm{pk} \leftarrow(\mathrm{crs}, c)$ and $\mathrm{sk} \leftarrow(\mathrm{pk}, \mathrm{s}, \mathrm{k})$ and return (sk, pk).
Furthermore, we use the following modified signing algorithm Sign' inside the signing oracle:
$\operatorname{Sign}^{\prime}(\mathrm{sk}, m):$ Parse sk as $((\mathrm{crs}, c), \mathrm{s}, \mathrm{k})$, compute $y \leftarrow F_{\mathrm{s}}(m), \pi \leftarrow \mathcal{S}_{2}(\mathrm{crs}, \tau$, $(c, y, m))$, and return $\sigma \leftarrow(y, \pi)$.
Transition - Game $1 \rightarrow$ Game 2: To show that Game 1 and Game 2 are indistinguishable, we present a hybrid game, which uses the adaptive zeroknowledge challenger $\mathcal{C}_{\mathrm{zk}}^{\kappa}$ as an oracle to either simulate Game 1 or Game 2. We use the following key generation algorithm Gen':
$\operatorname{Gen}^{\prime}\left(1^{\kappa}\right)$ : Run crs $\leftarrow \mathcal{C}_{\mathrm{zk}}^{\kappa}$, run $\mathrm{k} \leftarrow \Omega$.Gen $\left(1^{\kappa}\right)$, choose $\mathrm{s} \leftarrow^{R} \mathcal{S}$, compute $c \leftarrow$ $\Omega \cdot \operatorname{Enc}(\mathrm{k}, \mathrm{s})$, set $\mathrm{pk} \leftarrow(\mathrm{crs}, c)$ and $\mathrm{sk} \leftarrow(\mathrm{pk}, \mathrm{s}, \mathrm{k})$ and return ( $\mathrm{sk}, \mathrm{pk})$.
Furthermore, we use the following modified signing algorithm Sign' inside the signing oracle:
$\operatorname{Sign}^{\prime}(\mathrm{sk}, m):$ Parse sk as $((\mathrm{crs}, c), \mathrm{s}, \mathrm{k})$, compute $y \leftarrow F_{\mathrm{s}}(m), \pi \leftarrow \mathcal{C}_{\mathrm{zk}}^{\kappa} \cdot \mathcal{P} / \mathcal{S}($ $(c, y, m),(\mathrm{s}, \mathrm{k}))$, and return $\sigma \leftarrow(y, \pi)$.
Then, if the challenger samples from the first distribution we are in Game 1, whereas we are in Game 2 if the challenger samples from the second distribution (with $\mathcal{P} / \mathcal{S}$ we denote the oracle provided by the challenger that the challenger, which either honestly computes the proof or simulates it). Thus, we have that $\mid \operatorname{Pr}\left[S_{2}\right]-\operatorname{Pr}\left[S_{1}\right] \leq \epsilon_{\mathbf{z}}(\kappa)$.
Game 3: As Game 2, but we further modify the key generation algorithm Gen': $\operatorname{Gen}^{\prime}\left(1^{\kappa}\right): \operatorname{Run}(\operatorname{crs}, \tau) \leftarrow \mathcal{S}_{1}\left(1^{\kappa}\right)$ and store $\tau$, run $\mathrm{k} \leftarrow \Omega$.Gen $\left(1^{\kappa}\right)$, choose $\left(\mathrm{s}, \mathrm{s}^{\prime}\right) \stackrel{R}{R}^{R} \mathcal{S}^{2}$, compute $c \leftarrow \Omega . \operatorname{Enc}\left(\mathrm{k}, \mathrm{s}^{\prime}\right)$, set $\mathrm{pk} \leftarrow(\mathrm{crs}, F, c)$ and $\mathrm{sk} \leftarrow$ ( $\mathrm{pk}, \mathrm{s}, \mathrm{k}$ ) and return ( $\mathrm{sk}, \mathrm{pk}$ ).
Transition - Game $2 \rightarrow$ Game 3: A distinguisher $\mathcal{D}^{2 \rightarrow 3}$ is an adversary against IND-EAV of $\Omega$. Consider the following hybrid Game, where we engage with an IND-EAV challenger $\mathcal{C}_{\mathrm{e}}^{\kappa}$.
$\operatorname{Gen}^{\prime}\left(1^{\kappa}\right): \operatorname{Run}(\operatorname{crs}, \tau) \leftarrow \mathcal{S}_{1}\left(1^{\kappa}\right)$ and store $\tau$, run $\mathrm{k} \leftarrow \perp$, choose $\left(\mathrm{s}, \mathrm{s}^{\prime}\right) \leftarrow_{\leftarrow}^{R} \mathcal{S}^{2}$, compute $c \leftarrow \mathcal{C}_{\mathrm{e}}^{\kappa}\left(\mathrm{s}, \mathrm{s}^{\prime}\right)$, set $\mathrm{pk} \leftarrow(\mathrm{crs}, c)$ and $\mathrm{sk} \leftarrow(\mathrm{pk}, \mathrm{s}, \mathrm{k})$ and return (sk, pk).
If the challenger's bit is 0 , we are in Game 2, whereas we are in Game 3 if the challengers bit is 1 . Thus, $\left|\operatorname{Pr}\left[S_{2}\right]-\operatorname{Pr}\left[S_{3}\right]\right| \leq \epsilon_{\mathrm{e}}(\kappa)$.
Game 4: As Game 3, but we further modify Verify' as follows:
Verify ${ }^{\prime}(\mathrm{pk}, m, \sigma)$ : Parse pk as (crs, $c$ ), and $\sigma$ as $(y, \pi)$, sample $y^{\prime} \leftarrow^{R}\{0,1\}^{\kappa}$.
Return 1 if the following holds, and 0 otherwise:

$$
\text { П.Verify }(\mathrm{crs},(c, y, m), \pi)=1 \wedge y^{\prime}=y \text {. }
$$

Additionally, we further modify the signing algorithm Sign' used in the signing oracle:
$\operatorname{Sign}^{\prime}(\mathrm{sk}, m):$ Parse sk as $((\mathrm{crs}, c), \mathrm{s}, \mathrm{k})$, compute $y \leftarrow^{R}\{0,1\}^{\kappa}, \pi \leftarrow \mathcal{S}_{2}(\mathrm{crs}, \tau$, $(c, y, m))$, and return $\sigma \leftarrow(y, \pi)$.
Transition - Game $3 \rightarrow$ Game 4: We bound the success probability of a distinguisher $\mathcal{D}^{3 \rightarrow 4}$ using the following hybrid game. Let $\mathcal{C}_{\mathrm{p}}^{\kappa}$ be a PRF challenger providing the oracle $F_{\mathrm{s}} / f(\cdot)$, and let Gen', Sign', and Verify' be as follows. $\operatorname{Gen}^{\prime}\left(1^{\kappa}\right): \operatorname{Run}(\operatorname{crs}, \tau) \leftarrow \mathcal{S}_{1}\left(1^{\kappa}\right)$ and store $\tau$, run $\mathrm{k} \leftarrow \Omega$.Gen $\left(1^{\kappa}\right)$, choose $\mathrm{s} \leftarrow \perp$, compute $c \leftarrow \Omega . \operatorname{Enc}(\mathrm{k}, \mathrm{s})$, set $\mathrm{pk} \leftarrow(\mathrm{crs}, c)$ and $\mathrm{sk} \leftarrow(\mathrm{pk}, \mathrm{s}, \mathrm{k})$ and return (sk, pk).
$\operatorname{Sign}^{\prime}(\mathrm{sk}, m):$ Parse sk as $((\mathrm{crs}, c), \mathrm{s}, \mathrm{k})$, compute $y \leftarrow \mathcal{C}_{\mathrm{p}}^{\kappa} \cdot F_{\mathrm{s}} / f(m), \pi \leftarrow \mathcal{S}_{2}($ crs, $\tau,(c, y, m))$, and return $\sigma \leftarrow(y, \pi)$.
Verify ${ }^{\prime}(\mathrm{pk}, m, \sigma):$ Parse pk as (crs, $\left.c\right)$, and $\sigma$ as $(y, \pi)$, sample $y^{\prime} \leftarrow^{R}\{0,1\}^{\kappa}$. Return 1 if the following holds, and 0 otherwise:

$$
\text { П.Verify }(\mathrm{crs},(c, y, m), \pi)=1 \wedge y=\mathcal{C}_{\mathrm{p}}^{\kappa} \cdot F_{\mathrm{s}} / f(m)
$$

Then, depending on the distribution the PRF challenger samples from, we are either in Game 3 or in Game 4, i.e., $\left|\operatorname{Pr}\left[S_{3}\right]-\operatorname{Pr}\left[S_{4}\right]\right| \leq \epsilon_{\mathrm{p}}(\kappa)$.

In the last game, the adversary can only guess, which concludes the proof.

## C Description of LowMC

LowMC by Albrecht et al. $\left[\mathrm{ARS}^{+} 15, \mathrm{ARS}^{+} 16\right]$ is very parameterizable symmetric encryption scheme design enabling instantiation with low AND depth and low multiplicative complexity. Given any blocksize, a choice for the number of Sboxes per round, and security expectations in terms of time and data complexity, instantiations can be created minimizing the AND depth, the number of ANDs, or the number of ANDs per encrypted bit. Table 2 lists the choices for the parameters which are also highlighted in the figures. The files with all parameters used for our experiments are provided online at https://github.com/IAIK/fishbegol.

The description of LowMC is possible independently of the choice of parameters using a partial specification of the Sbox and arithmetic in vector spaces over $\mathbb{F}_{2}$. In particular, let $n$ be the blocksize, $m$ be the number of Sboxes, $k$ the key size, and $r$ the number of rounds, we choose round constants $C_{i} \stackrel{R}{\leftarrow} \mathbb{F}_{n}$ for $i \in[1, r]$, full rank matrices $K_{i} \leftarrow^{R} \mathbb{F}_{2}^{n \times k}$ and regular matrices $L_{i} \leftarrow_{\leftarrow}^{R} \mathbb{F}_{2}^{n \times n}$ independently during the instance generation and keep them fixed. Keys for LowMC are generated by sampling from $\mathbb{F}_{2}^{k}$ uniformly at random.

LowMC encryption starts with key whitening which is followed by several rounds of encryption. A single round of LowMC is composed of an Sbox layer, a linear layer, addition with constants and addition of the round key, i.e.

$$
\begin{aligned}
\operatorname{LowMCRound}(i) & =\operatorname{KeyAddition}(i) \circ \operatorname{ConstantAddition}(i) \\
& \circ \operatorname{LinEARLAYER}(i) \circ \operatorname{SboxLayER} .
\end{aligned}
$$

| Blocksize | Sboxes | Keysize | Data |  |  |  |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| n | k | Rounds <br> d | \# of ANDs | ANDS per bit |  |  |
| 128 | 2 | 128 | 128 | 128 | 768 |  |
| 128 | 12 | 128 | 128 | 26 | 936 | 6.00 |
| 128 | 32 | 128 | 128 | 19 | 1824 | 7.31 |
| 256 | 2 | 256 | 256 | 174 | 1044 | 14.25 |
| 256 | 2 | 256 | 256 | 232 | 1392 | 4.08 |
| 256 | 20 | 256 | 256 | 31 | 1860 | 5.44 |
| 256 | 26 | 256 | 256 | 18 | 1404 | 7.27 |
| 256 | 64 | 256 | 256 | 14 | 2688 | 7.31 |
| 256 | 80 | 256 | 256 | 22 | 5280 | 10.5 |
| 384 | 4 | 384 | 384 | 172 | 2064 | 20.62 |
| 384 | 30 | 384 | 384 | 33 | 2970 | 5.38 |
| 384 | 126 | 384 | 384 | 25 | 9450 | 7.73 |
| 512 | 6 | 512 | 512 | 152 | 2736 | 24.61 |
| 512 | 34 | 512 | 512 | 37 | 3774 | 5.34 |
| 512 | 170 | 512 | 512 | 25 | 12750 | 7.37 |

Table 2. A range of different parameter sets for LowMC. The number of rounds corresponds to the AND depth.

SboxLayer is an $m$-fold parallel application of the same 3-bit Sbox on the first $3 \cdot m$ bits of the state. The Sbox is defined as $S(a, b, c)=(a \oplus b c, a \oplus b \oplus$ $a c, a \oplus b \oplus c \oplus a b)$.

The other layers only consist of $\mathbb{F}_{2}$-vector space arithmetic. LinearLayer $(i)$ multiplies the state with the linear layer matrix $L_{i}$, ConstantAdditon $(i)$ adds the round constant $C_{i}$ to the state, and KeyAddition $(i)$ adds the round key to the state, where the round key is generated by multiplying the master key with the key matrix $K_{i}$.

Algorithm 1 gives a full description of the encryption.

```
Input: plaintext \(p \in \mathbb{F}_{2}^{n}\) and key \(y \in \mathbb{F}_{2}^{k}\)
    \(s \leftarrow K_{0} \cdot y+p\)
    for \(i \in[1, r]\) do
        \(s \leftarrow S b o x(s)\)
        \(s \leftarrow L_{i} \cdot s\)

        \(s \leftarrow K_{i} \cdot y+s\)
    end for
    return \(s\)
```

Algorithm 1 LowMC encryption for key matrices $K_{i} \in \mathbb{F}_{2}^{n \times k}$ for $i \in[0, r]$,
linear layer matrices $L_{i} \in \mathbb{F}_{2}^{n \times n}$ and round constants $C_{i} \in \mathbb{F}_{2}^{n}$ for $i \in[1, r]$.

## D List of Symbols

$-t$ : running time of adversary;
$-\epsilon$ : success probability of adversary;
$-\kappa$ : security parameter;

- $Q_{H}$ : adversarial queries to oracle $H$;
- $H$ : random oracle used to generate Fiat-Shamir challenge;
- $\gamma$ : number of repetition of the $\Sigma$-protocol and output size of $H$;
- $H^{\prime}$ : random oracle used to implement commitments in ZKBoo;
$-\alpha$ : size of random tapes for each thread in ZKBoo;
$-\beta$ : size of "view" in each thread in ZKBoo;
$-\nu$ : size of salt used when committing with $H^{\prime}$;
- $\rho$ : size of commitments and output size of $H^{\prime}$;
- $\Omega$ : IND-EAV symmetric encryption scheme;
$-n$ : size of PRF output;
$-a_{f}$ : number of multiplication gates in circuit implementing $f$;
$-\lambda_{f}$ : size of ring in which the multiplications take place;
$-D_{f}$ : bit-length of elements from domain of $f$;
$-I_{f}$ : bit-length of elements from image of $f$;
$-r$ : number of rounds in LowMC instance;
- $m$ : number of SBoxes in LowMC instance;

    ${ }^{5}$ Lattice-based signatures have actually been proposed far earlier [GGH97], but this approach turned out to be insecure.

[^2]:    ${ }^{6}$ The given estimations are taken from a recent talk of Nicolas Sendrier (available at https://pqcrypto.eu.org/mini.html), as, unfortunately, there are no free implementations available.

[^3]:    ${ }^{7}$ The authors of TESLA also show how to adapt their security reduction to the QROM, but do not implement their benchmarks accordingly and say: "We believe that the need for a chameleon hash function is merely an artifact of the proof and we would be surprised if our decision to use SHA-256 could be exploited in an attack."
    ${ }^{8}$ This strategy allows to obtain tight reductions when relying on decisional assumptions on the public key: if the instance is valid then we have a real key and in case of a fake key an adversary can only guess a valid signature with negligible probability. This idea has later been generalized by Abdalla et al. [AFLT12] via the notion of lossy identification schemes.

[^4]:    ${ }^{9}$ This is a stronger variant of FS (cf. [FKMV12, BPW12]). The original weaker variant of the FS transform does not include the statement $x$ in the challenge computation.

[^5]:    ${ }^{10}$ https://openssl.org
    11 https://bitbucket.org/malb/m4ri

[^6]:    ${ }^{12}$ HyperThreading was disabled for the experiments to reduce noise in the benchmarks.

[^7]:    ${ }^{13}$ This observation was also made for ZKBoo in [GMO16].
    ${ }^{14}$ http://openmp.org

[^8]:    ${ }^{15}$ Key sizes and signature sizes from BLISS were taken from [DDLL13], as they were not readily available in the implementation.

[^9]:    ${ }^{16}$ Note that our signature size estimation uses the instance 256-256-1-458 for the PRF in Begol (which requires a data complexity of $d=256$ ).
