**Abstract.** Code-based Cryptography is one of the main areas of interest for the Post-Quantum Cryptography Standardization call. In this paper, we introduce DAGS<sup>4</sup>, a Key Encapsulation Mechanism (KEM) based on Quasi-Dyadic Generalized Srivastava codes. The scheme is proved to be IND-CCA secure in both Random Oracle Model and Quantum Random Oracle Model. We believe that DAGS will offer competitive performance, especially when compared with other existing code-based schemes, and represent a valid candidate for post-quantum standardization.

**Keywords**: post-quantum cryptography, code-based cryptography, key exchange.

## 1 Introduction

The availability of large-scale quantum computers is getting ever closer to reality, and with it, all of the public-key cryptosystems currently in use, which rely on number theory problems (e.g., factorization), and discrete logarithm problems will become obsolete [37]. Therefore, it is of extreme importance to be able to offer a credible alternative that can resist attackers equipped with quantum technology. NIST's call for papers

<sup>&</sup>lt;sup>4</sup> DAGS is not only an acronym but also one of the names for the Elder Futhark rune pictured above. The shape of the rune recalls the dyadic property of the matrices at the core of our scheme.

for post-quantum standardization is a further reassurance about the need for solid post-quantum proposals.

Code-based cryptography is one of the main candidates for this task. The area is based on the Syndrome Decoding Problem [8], which shows no vulnerabilities to quantum attacks. Over the years, since McEliece's seminal work [28], many cryptosystems have been proposed, trying to balance security and efficiency and in particular dealing with inherent flaws such as the large size of the public keys. In fact, while McEliece's cryptosystem, which is based binary Goppa codes, is still unbroken, it features a key of several megabytes, which has effectively prevented its use in many applications.

There are currently two main trends to deal with this issue, and they both involve structured matrices: the first, is based on "traditional" algebraic codes such as Goppa or Srivastava codes; the second suggests to use sparse matrices as in LDPC/MDPC codes. This work builds on the former approach, initiated in 2009 by Berger et al. [7], who proposed Quasi-Cyclic (QC) codes, and Misoczki and Barreto [29], suggesting Quasi-Dyadic (QD) codes instead (later generalized to Quasi-Monoidic (QM) codes [6]). Both proposals feature very compact public keys due to the introduction of the extra algebraic structure, but unfortunately this also leads to a vulnerability. Indeed, Faugère, Otmani, Perret and Tillich [18] devised a clever attack (known simply as FOPT) which exploits the algebraic structure to build a system of equations, which can successively be solved using Gröbner bases techniques. As a result, the QC proposal is definitely compromised, while the QD/QM approach needs to be treated with caution. In fact, for a proper choice of parameters, it is still possible to design secure schemes, using for instance binary Goppa codes, or Generalized Srivastava (GS) codes as suggested by Persichetti in [33].

**Our Contribution.** In this paper, we present DAGS, a Key Encapsulation Mechanism (KEM) that follows the QD approach using GS codes. KEMs are the primitive favored by NIST for Key Exchange schemes, and can be used to build encryption schemes with the Hybrid Encryption paradigm introduced by Cramer and Shoup [16]. To the best of our knowledge, this is the first code-based KEM that uses structured algebraic codes. The KEM achieves IND-CCA security following the recent framework by Kiltz et al. [24], and features compact public keys and efficient encapsulation and decapsulation algorithms. We modulate our parameters to achieve an efficient scheme, while at the same time keeping out of range of the FOPT attack. We provide an initial performance analysis of our scheme; a full implementation using C++ code is underway and will be included in the full version of this paper.

**Related Work.** We show that our proposal compares well with other post-quantum KEMs. These include the well-known McBits [10], as well as more recent proposals such as CAKE [5]. The former, built using binary Goppa codes, benefits from a well-understood security assessment (following the work of Persichetti [34]), but suffers from the same public key size issue as "classic" McEliece-like cryptosystems. On the other hand, CAKE, a protocol based on QC-MDPC codes, possesses some very nice features like compact keys and an easy implementation approach, but the QC-MDPC encryption scheme on which it is based suffers from a security-related drawback. This means that, in order to circumvent the Guo-Johansson-Stankovski (GJS) attack [22], the protocol is forced to employ ephemeral keys. Moreover, due to its non-trivial Decoding Failure Rate (DFR), achieving IND-CCA security becomes very hard, so that the CAKE protocol only claims to be IND-CPA secure.

More distantly-related are lattice-based schemes like NewHope [2] and Frodo [12], based respectively on LWE and its Ring variant. While these schemes are not necessarily a direct comparison term, it is nice to observe that DAGS offers comparable performance.

**Organization of the Paper.** This paper is organized as follows. We start by giving some preliminary notions in Section 2. We describe the DAGS protocol in Section 3, and we discuss its provable security in Section 4, showing that DAGS is IND-CCA secure in the Random Oracle Model. Section 5 features a discussion about practical security, including general decoding attacks (ISD) and the FOPT attack, and presents parameters for the scheme. Performance details are given in Section 6. Finally, we conclude in Section 7.

# 2 Preliminaries

## 2.1 Linear Codes

The Hamming weight of a vector  $x \in \mathbb{F}_q^n$  is given by the number wt(x) of its nonzero components. We define a linear code using the metric induced by the Hamming weight.

**Definition 1.** An (n, k)-linear code C of length n and dimension k over  $\mathbb{F}_q$  is a k-dimensional vector subspace of  $\mathbb{F}_q^n$ .

A linear code can be represented by means of a matrix  $G \in \mathbb{F}_q^{k \times n}$ , called *generator matrix*, whose rows form a basis for the vector space defining the code. Alternatively, a linear code can also be represented as kernel of a matrix  $H \in \mathbb{F}_q^{(n-k) \times n}$ , known as *parity-check matrix*, i.e.  $\mathcal{C} = \{c : Hc^T = 0\}$ . Thanks to the generator matrix, we can easily define the codeword *u* corresponding to a vector  $\mu \in \mathbb{F}_q^k$  as  $u = \mu G$ . Finally, we call *syndrome* of a vector  $c \in \mathbb{F}_q^n$  the vector  $y = Hc^T$ .

## 2.2 Structured Matrices and GS Codes

**Definition 2.** Given a ring  $\mathcal{R}$  (in our case the finite field  $\mathbb{F}_{q^m}$ ) and a vector  $\bar{h} = (h_0, \ldots, h_{n-1}) \in \mathcal{R}^n$ , the dyadic matrix  $\Delta(\bar{h}) \in \mathcal{R}^{n \times n}$  is the symmetric matrix with components  $\Delta_{ij} = h_{i\oplus j}$ , where  $\oplus$  stands for bitwise exclusive-or on the binary representations of the indices. The sequence  $\bar{h}$  is called its signature. Moreover,  $\Delta(t, \bar{h})$  denotes the matrix  $\Delta(\bar{h})$  truncated to its first t rows. Finally, we call a matrix quasi-dyadic if it is a block matrix whose component blocks are  $t \times t$  dyadic submatrices.

If n is a power of 2, then every  $2^k \times 2^k$  dyadic matrix can be described recursively as

$$M = \begin{pmatrix} A & B \\ B & A \end{pmatrix}$$

where each block is a  $2^{k-1} \times 2^{k-1}$  dyadic matrix (and where any  $1 \times 1$  matrix is dyadic).

**Definition 3.** For  $m, n, s, t \in \mathbb{N}$  and a prime power q, let  $\bar{\alpha} = (\alpha_1, \ldots, \alpha_n)$ ,  $\bar{w} = (w_1, \ldots, w_s)$  be n + s distinct elements of  $\mathbb{F}_{q^m}$ , and  $(z_1, \ldots, z_n)$  be nonzero elements of  $\mathbb{F}_{q^m}$ . The Generalized Srivastava (GS) code of order st and length n is defined by a parity-check matrix of the form:

$$H = \begin{pmatrix} H_1 \\ H_2 \\ \vdots \\ H_s \end{pmatrix}$$

where each block is

$$H_i = \begin{pmatrix} \frac{z_1}{\alpha_1 - w_i} & \cdots & \frac{z_n}{\alpha_n - w_i} \\ \frac{z_1}{(\alpha_1 - w_i)^2} & \cdots & \frac{z_n}{(\alpha_n - w_i)^2} \\ \vdots & \vdots & \vdots \\ \frac{z_1}{(\alpha_1 - w_i)^t} & \cdots & \frac{z_n}{(\alpha_n - w_i)^t} \end{pmatrix}$$

The parameters for such a code are the length  $n \leq q^m - s$ , dimension  $k \geq n - mst$  and minimum distance  $d \geq st + 1$ . GS codes are part of the family of Alternant codes, and therefore benefit of an efficient decoding algorithm. Moreover, it can be easily proved that every GS code with t = 1 is a Goppa code. More information about this class of codes can be found in [27, Ch. 12, §6].

# 3 DAGS

In this section we introduce the three algorithms that form DAGS – a key-encapsulation mechanism based on Quasi-Dyadic GS codes. System parameters are the code length n and dimension k, the values s and t which define a GS code, the cardinality of the base field q and the degree of the field extension m. In addition, we have k = k' + k'', where k' is another parameter that is set to be "small". In practice, k' is such that a vector of length k' can be efficiently stored in 256 bits, depending on the base field. This makes the hash functions (see below) easy to compute, and ensures that the overhead due to the IND-CCA2 security in the QROM is minimal.

The key generation process uses the following fundamental equation

$$\frac{1}{h_{i\oplus j}} = \frac{1}{h_i} + \frac{1}{h_j} + \frac{1}{h_0}.$$
(1)

to build the vector  $\bar{h} = (h_0, \ldots, h_{n-1})$  of elements of  $\mathbb{F}_{q^m}$  known as *signature* of a dyadic matrix. This is then used to form a Cauchy matrix, i.e. a matrix  $C(\bar{u}, \bar{v})$  with components  $C_{ij} = \frac{1}{u_i - v_j}$ . The matrix is then successively powered (element by element) forming several blocks which are superimposed and then multiplied by a random diagonal matrix. Finally, the resulting matrix is projected onto the base field and row-reduced to systematic form. The process is described in detail below.

#### Algorithm 1. Key Generation

- 1. Generate dyadic signature  $\bar{h}$ . To do this:
  - (a) Choose random non-zero distinct  $h_0$  and  $h_j$  for  $j = 2^l, l = 0, \ldots, \lfloor \log q^m \rfloor$ .
  - (b) Form the remaining elements using (1).
  - (c) Return a selection<sup>5</sup> of blocks of dimension s up to length n.
- 2. Build the Cauchy support. To do this:
  - (a) Choose a random<sup>6</sup> offset  $\omega \stackrel{\$}{\leftarrow} \mathbb{F}_{q^m}$ .
  - (b) Set  $u_i = 1/h_i + \omega$  and  $v_j = 1/h_j + 1/h_0 + \omega$  for i = 0, ..., s 1and j = 0, ..., n - 1.
  - (c) Set  $\bar{u} = (u_0, \dots, u_{s-1})$  and  $\bar{v} = (v_0, \dots, v_{n-1})$ .
- 3. Form Cauchy matrix  $\hat{H}_1 = C(\bar{u}, \bar{v})$ .
- 4. Build blocks  $\hat{H}_i$ , i = 1, ..., t, by raising each element of  $\hat{H}_1$  to the power of i.
- 5. Superimpose blocks to form matrix  $\hat{H}$ .
- 6. Choose random elements  $z_i \stackrel{s}{\leftarrow} \mathbb{F}_{q^m}$  with the restriction  $z_{is+j} = z_{is}$  for  $i = 0, \ldots, n_0 1, j = 0, \ldots, s 1$ .
- 7. Form  $H = \hat{H} \cdot \text{Diag}(\bar{z})$ .
- 8. Project H onto the base field  $\mathbb{F}_q$  using the co-trace function.
- 9. Compute systematic form  $(M \mid I_{n-k})$ .
- 10. The public key is the generator matrix  $G = (I_k \mid M^T)$ .
- 11. The private key is the pair  $(H, \bar{u})$ .

The encapsulation and decapsulation algorithms make use of two hash functions  $\mathbf{G} : \mathbb{F}_q^{k'} \to \mathbb{F}_q^k$  and  $\mathbf{H} : \mathbb{F}_q^{k'} \to \mathbb{F}_q^{k'}$ , the former with the task of generating randomness for the scheme, the latter to provide "plaintext confirmation" as in [24]. The shared symmetric key is obtained via another hash function  $\mathbf{K} : \{0, 1\}^* \to \{0, 1\}^{\ell}$ , where  $\ell$  is the desired key length.

 $<sup>^{5}</sup>$  Making sure to exclude any block containing an undefined entry.

<sup>&</sup>lt;sup>6</sup> See Appendix A for restrictions about the choice of the offset.

# Algorithm 2. Encapsulation

- 1. Choose  $\mu \stackrel{\hspace{0.1em}\mathsf{\scriptscriptstyle\$}}{\leftarrow} \mathbb{F}_q^{k'}$ .
- 2. Compute  $r = \mathbf{G}(\mu)$  and  $d = \mathbf{H}(\mu)$ .
- 3. Parse r as  $(\rho \parallel \sigma)$  then set  $u = (\rho \parallel \mu)$ .
- 4. Generate error vector e of length n and weight w from  $\sigma$ .
- 5. Compute c = uG + e.
- 6. Compute  $K = \mathbf{K}(\mu)$ .
- 7. Output C = (c, d); the encapsulated key is K.

#### Algorithm 3. Decapsulation

- 1. Decode c to obtain codeword u'G and error e'.
- 2. Output  $\perp$  if decoding fails or  $\mathsf{wt}(e') \neq w$
- 3. Recover u' and parse it as  $(\rho' \parallel \mu')$ .
- 4. Compute  $r' = \mathbf{G}(\mu')$  and  $d' = \mathbf{H}(\mu')$ .
- 5. Parse r' as  $(\rho'' \parallel \sigma')$ .
- 6. Generate error vector e'' of length n and weight w from  $\sigma'$ .
- 7. If  $e' \neq e'' \lor \rho' \neq \rho'' \lor d \neq d'$  output  $\bot$ .
- 8. Else compute  $K = \mathbf{K}(\mu')$ .
- 9. The decapsulated key is K.

DAGS is built upon the McEliece encryption framework, with a notable exception. In fact, we incorporate the "randomized" version of McEliece by Nojima et al. [32] into our scheme. This is extremely beneficial for two distinct aspects: first of all, it allows us to use a much shorter vector m to generate the remaining components of the scheme, greatly improving efficiency. Secondly, as we will see in Section 4, it allows us to get tighter security bounds. Note that our protocol differs slightly from the paradigm presented in [24], in the fact that we don't perform a full re-encryption in the decapsulation algorithm. Instead, we simply re-generate the randomness and compare it with the one obtained after decoding. This is possible since, unlike a generic PKE, McEliece decryption reveals the randomness used, in our case e (and  $\rho$ ). It is clear that if the re-generated randomness is equal to the retrieved one, the resulting encryption will also be equal. This trick allows us to further decrease computation time.

The selection of the parameters for the scheme will be discussed in Section 5.4.

# 4 KEM Security

In this section, we discuss some aspects of provable security, and in particular we show that DAGS satisfies the notion of IND-CCA security for KEMs, as defined below.

**Definition 4.** The adaptive chosen-ciphertext attack game for a KEM proceeds as follows:

- 1. Query a key generation oracle to obtain a public key pk.
- 2. Make a sequence of calls to a decryption oracle, submitting any string C of the proper length. The oracle will respond with Decaps(sk, C).
- 3. Query an encryption oracle. The oracle runs  $\mathsf{Encaps}(pk)$  to generate a pair  $(\tilde{K}, \tilde{C})$ , then chooses a random  $b \in \{0, 1\}$  and replies with the "challenge" ciphertext  $(K^*, \tilde{C})$  where  $K^* = \tilde{K}$  if b = 1 or  $K^*$  is a random string of length  $\ell$  otherwise.
- 4. Keep performing decryption queries. If the submitted ciphertext is  $C^*$ , the oracle will return  $\perp$ .
- 5. Output  $b^* \in \{0, 1\}$ .

The adversary succeeds if  $b^* = b$ . More precisely, we define the advantage of  $\mathcal{A}$  against KEM as

$$\mathsf{Adv}_{KEM}^{IND-CCA}(\mathcal{A},\lambda) = \left|\mathsf{Pr}[b^*=b] - \frac{1}{2}\right|.$$
 (2)

We say that a KEM is secure if the advantage  $\operatorname{Adv}_{KEM}^{IND-CCA}$  of any polynomial-time adversary  $\mathcal{A}$  in the above CCA attack model is negligible.

Before discussing the IND-CCA security of DAGS, we show that the underlying PKE (i.e. Randomized McEliece) satisfies a simple property. This will allow us to get better security bounds in our reduction.

**Definition 5.** Consider a probabilistic PKE with randomness set R. We say that PKE is  $\gamma$ -spread if for a given key pair (sk, pk), a plaintext  $\mu$  and a string y in the ciphertext domain, we have

$$\Pr[r \stackrel{s}{\leftarrow} \mathsf{R} \mid y = \textit{Enc}_{pk}(\mu, r)] \le 2^{-\gamma},$$

for a certain  $\gamma \in \mathbb{R}$ .

The definition above is presented as in [24], but note that in fact this corresponds to the notion of  $\gamma$ -uniformity given by Fujisaki and Okamoto in [21], except for a change of constants. In other words, a scheme is  $\gamma$ -spread if it is  $2^{-\gamma}$ -uniform.

It was proved in [14] that a simple variant of the (classic) McEliece PKE is  $\gamma$ -uniform for  $\gamma = 2^{-k}$ , where k is the code dimension as usual (more in general,  $\gamma = q^{-k}$  for a cryptosystem defined over  $\mathbb{F}_q$ ). We can extend this result to our scheme as follows.

**Lemma 1.** Randomized McEliece is 
$$\gamma$$
-uniform for  $\gamma = \frac{q^{-k''}}{\binom{n}{w}}$ .

*Proof.* Let y be a generic vector of  $\mathbb{F}_q^n$ . Then either y is a word at distance t from the code, or it isn't. If it isn't, the probability of y being a valid ciphertext is clearly exactly 0. On the other hand, suppose y is at distance t from the code; then there is only one choice of  $\rho$  and one choice of e that satisfy the equation (since w is below the GV bound), i.e. the probability of y being a valid ciphertext is exactly  $1/q^{k''} \cdot 1/\binom{n}{w}$ , which concludes the proof.

We are now ready to present the security results.

**Theorem 1.** Let  $\mathcal{A}$  be an IND-CCA adversary against DAGS that makes at most  $q_{RO} = q_{\mathbf{G}} + q_{\mathbf{K}}$  total random oracle queries<sup>7</sup> and  $q_D$  decryption queries. Then there exists an IND-CPA adversary  $\mathcal{B}$  against PKE, running in approximately the same time as  $\mathcal{A}$ , such that

$$\mathsf{Adv}_{KEM}^{IND-CCA}(\mathcal{A}) \leq q_{RO} \cdot 2^{-\gamma} + 3 \cdot \mathsf{Adv}_{PKE}^{IND-CPA}(\mathcal{B}).$$

*Proof.* The thesis is a consequence of the results presented in Section 3.3 of [24]. In fact, our scheme follows the  $\mathsf{KEM}_m^{\perp}$  framework that consists of applying two generic transformations to a public-key encryption scheme. The first step consists of transforming the IND-CPA encryption scheme into a OW-PCVA (i.e. Plaintext and Validity Checking) scheme. Then, the resulting scheme is transformed into a KEM in a "standard" way.

<sup>&</sup>lt;sup>7</sup> Respectively  $q_{\mathbf{G}}$  many queries to the random oracle  $\mathbf{G}$  and  $q_{\mathbf{K}}$  many queries to the random oracle  $\mathbf{K}$ .

Both proofs are obtained via a sequence of games, and the combination of them shows that breaking IND-CCA security of the KEM would lead to break the IND-CPA security of the underlying encryption scheme. Note that Randomized McEliece, instantiated with Quasi-Dyadic GS codes, presents no correctness error (the value  $\delta$  in [24]), which greatly simplifies the resulting bound.

The value d included in the KEM ciphertext does not contribute to the security result above, but it is a crucial factor to provide security in the Quantum Random Oracle Model (QROM). We present this in the next theorem.

**Theorem 2.** Let  $\mathcal{A}$  be a quantum IND-CCA adversary against DAGS that makes at most  $q_{RO} = q_{\mathbf{G}} + q_{\mathbf{K}}$  total quantum random oracle queries<sup>8</sup> and  $q_D$  (classical) decryption queries. Then there exists a OW-CPA adversary  $\mathcal{B}$  against PKE, running in approximately the same time as  $\mathcal{A}$ , such that

$$\mathsf{Adv}_{KEM}^{IND-CCA}(\mathcal{A}) \leq 8q_{RO} \cdot \sqrt{q_{RO} \cdot \sqrt{\mathsf{Adv}_{PKE}^{OW-CPA}(\mathcal{B})}}.$$

*Proof.* The thesis is a consequence of the results presented in Section 4.4 of [24]. In fact, our scheme follows the  $\mathsf{QKEM}_m^{\perp}$  framework that consists of applying two generic transformations to a public-key encryption scheme. The first step transforming the IND-CPA encryption scheme into a OW-PCVA (i.e. Plaintext and Validity Checking) scheme, is the same as in the previous case. Now, the resulting scheme is transformed into a KEM with techniques suitable for the QROM. The combination of the two proofs shows that breaking IND-CCA security of the KEM would lead to break the OW-CPA security of the underlying encryption scheme. Note, therefore, that the IND-CPA security of the underlying PKE has in this case no further effect on the final result, and can be considered instead just a guarantee that the scheme is indeed OW-CPA secure. The bound obtained is a "simplified" and "concrete" version (as presented by the authors) and, in particular, it is easy to notice that it does not depend on the number of queries  $q_{\mathbf{G}}$  presented to the random oracle **H**. The bound is further simplified since, as above, the underlying PKE presents no correctness error. 

<sup>&</sup>lt;sup>8</sup> Same as above.

# 5 Practical Security and Parameters

Having proved that DAGS satisfies the notion of IND-CCA security for KEMs, we now move onto a treatment of practical security issues. In particular, we will briefly present the hard problem on which DAGS is based, and then discuss the main attacks on the scheme and related security concerns.

#### 5.1 Hard Problems from Coding Theory

Most of the code-based cryptographic constructions are based on the hardness of the following problem, known as the (q-ary) Syndrome Decoding Problem (SDP).

Problem 1. Given an  $(n-k) \times n$  full-rank matrix H and a vector y, both defined over  $\mathbb{F}_q$ , and a non-negative integer w, find a vector  $e \in \mathbb{F}_q^n$  of weight w such that  $He^T = y$ .

The corresponding decision problem was proved to be NP-complete in 1978 [8], but only for binary codes. In 1994, A. Barg proved that this result holds for codes over all finite fields ([3], in Russian, and [4, Theorem 4.1]).

In addition, many schemes (including the original McEliece proposal) require the following computational assumption.

**Assumption 1** The public matrix output by the key generation algorithm is computationally indistinguishable from a uniformly chosen matrix of the same size.

The assumption above is historically believed to be true, except for very particular cases. For instance, there exists a distinguisher (Faugère et al. [17]) for cryptographic protocols that make use of high-rate Goppa codes (like the CFS signature scheme [15]). Moreover, it is worth mentioning that the "classical" methods for obtaining an indistinguishable public matrix, such as the use of scrambling matrices S and P, are rather outdated and unpractical and can introduce vulnerabilities to the scheme as per the work of Strenzke et al. ([38,39]). Thus, traditionally, the safest method (Biswas and Sendrier, [11]) to obtain the public matrix is simply to compute the systematic form of the private matrix.

#### 5.2 Decoding Attacks

The main approach for solving SDP is the technique known as Information Set Decoding (ISD), first introduced by Prange [36]. Among several variants and generalizations, Peters showed [35] that it is possible to apply Prange's approach to generic q-ary codes. Other approaches such as Statistical Decoding [25,30] are usually considered less efficient. Thus, when choosing parameters, we will focus mainly on defeating attacks of the ISD family.

Hamdaoui and Sendrier in [23] provide non-asymptotic complexity estimates for ISD in the binary case. For codes over  $\mathbb{F}_q$ , instead, a bound is given in [31], which extends the work of Peters. For a practical evaluation of the ISD running times and corresponding security level, we used Peters's ISDFQ script[1].

Quantum Speedup. Bernstein in [9] shows that Grover's algorithm applies to ISD-like algorithms, effectively halving the asymptotic exponent in the complexity estimates. Later, it was proven in [26] that more several variants of ISD have the potential to achieve a better exponent, however the improvement was disappointingly away from the factor of 2 that could be expected. For this reason, we decided to estimate the security against quantum attackers by dividing by two the complexity exponent obtained with classical attacks. We believe that, while this might seem like a conservative choice, a more precise evaluation would probably not be significantly different.

# 5.3 FOPT

While, as we discussed above, recovering a private matrix from a public one can be in general a very difficult problem, the presence of extra structure in the code properties can have a considerable effect in lowering this difficulty.

A very effective structural attack was introduced by Faugère, Otmani, Perret and Tillich in [18]. The attack (for convenience referred to as FOPT) relies on the simple property (valid for every linear code)  $H \cdot G^T = 0$  to build an algebraic system, using then Gröbner bases techniques to solve it. The special properties of alternant codes are fundamental, as they contribute to considerably reduce the number of unknowns of the system. The attack was originally aimed at two variants of McEliece, introduced respectively in [7] and [29]. The first variant, using quasi-cyclic codes, was completely broken, and falls out of the scope of this paper. The second variant, instead, only considered quasi-dyadic Goppa codes. In this case, most of the parameters proposed have also been broken very easily, except for the binary case (i.e. base field  $\mathbb{F}_2$ ). This was, in truth, not connected to the base field per se, but rather depended on the fact that, with a smaller base field, the authors provided a much higher extension degree m, as they were keeping constant the value  $q^m = 2^{16}$ . As it turns out, the extension degree m plays a key role in the attack, as it defines the dimension of the solution space, which is equal, in fact, exactly to m - 1. In a successive paper [19], the authors provide a theoretical complexity bound for the attack, and point out that any scheme for which this dimension is less or equal to 20 should be within the scope of the attack.

Since GS codes are also alternant codes, the attack can be applied to our proposal as well. In the case of GS codes, though, there is one important difference to keep in mind. In fact, as shown in [33], the dimension of the solution space is defined by mt-1, rather than m-1 as for Goppa codes. This provides greater flexibility when designing parameters for the code, and it allows, for example, to keep the extension degree m small.

Recently, an extension of the FOPT attack appeared in [20]. The authors introduce a new technique called "folding", and show that it is possible to reduce the complexity of the FOPT attack to the complexity of attacking a much smaller code (the "folded" code), thanks to the strong properties of the automorphism group of the alternant codes in use. The attack turns out to be very efficient against Goppa codes, as it is possible to recover a folded code which is also a Goppa code. The paper features two tables with several sets of parameters, respectively for signature schemes, and encryption schemes. The parameters are either taken from the original papers, or generated ad hoc. While codes designed to work for signature schemes turn out to be very easy to attack (due to their particular nature), the situation for encryption is more complex. Despite a refinement in the techniques used to solve the algebraic system, some of the parameters could not be solved in practice, and even the binary Goppa codes of [29], with their relatively low dimension of 15, require a considerably high computational effort (at least  $2^{150}$  operations).

It is not clear how the attack performs against GS codes, since the authors didn't present any explicit result against this particular family of codes, nor attempted to decode GS codes specifically. Thus, an attack against GS codes would use generic techniques for Alternant codes, and wouldn't benefit from the speedups which are specific to (binary) Goppa codes. Furthermore, the authors do not propose a concrete bound, but only provide experimental results. For these reasons, and until an accurate complexity analysis for an attack on GS codes is available, we choose to attain to the latest measurable guidelines (those suggested in [19]) and choose our parameters such that the dimension of the solution space for the algebraic system is strictly greater than 20.

## 5.4 Parameter Selection

To choose our parameters, we have to first keep in mind all of the remarks from the previous sections about decoding and structural attacks. For FOPT, we have the condition  $mt \ge 21$ . This guarantees at least 128 bits of security according to the bound presented in [19]. On the other hand, for ISD to be computationally intensive we require a sufficiently large number w of errors to decode: this is given by st/2 according to the minimum distance of GS codes.

In addition, we tune our parameters to optimize performance. In this regard, the best results are obtained when the extension degree m is as small as possible. This, however, requires the base field to be large enough to accommodate sufficiently big codes (against ISD attacks), since the maximum size for the code length n is capped by  $q^m - s$ . Realistically, this means we want  $q^m$  to be at least  $2^{12}$ , and an optimal choice in this sense seems to be  $q = 2^6, m = 2$ . Finally, note that s is constrained to be a power of 2, and that odd values of t seem to offer best performance.

Putting all the pieces together, we are able to present three set of parameters, in the following table. The first two columns represent the quantum security bits (column ISD) and estimated complexity of the structural attack (column FOPT).

| ISD | FOPT       | q       | m | n    | k   | k' | s       | t  | w   |
|-----|------------|---------|---|------|-----|----|---------|----|-----|
| 128 | $\geq 128$ | $2^{6}$ | 2 | 2112 | 704 | 32 | $2^{6}$ | 11 | 352 |
| 96  | $\geq 128$ | $2^{6}$ | 2 | 1216 | 512 | 32 | $2^{5}$ | 11 | 176 |
| 64  | $\geq 128$ | $2^{5}$ | 2 | 832  | 416 | 32 | $2^{4}$ | 13 | 104 |

Table 1: Suggested DAGS Parameters.

For practical reasons, during the rest of the paper we will refer to these parameters respectively as DAGS\_128, DAGS\_96 and DAGS\_64.

## 6 Performance Analysis

## 6.1 Components

For DAGS\_128 and DAGS\_96, the finite field  $\mathbb{F}_{2^6}$  is built using the polynomial  $x^6 + x + 1$  and then extended to  $\mathbb{F}_{2^{12}}$  using  $x^2 + x + \alpha^{34}$ , where  $\alpha$  is the primitive element of  $\mathbb{F}_{2^6}$ . For DAGS\_64, we build  $\mathbb{F}_{2^5}$  using  $x^5 + x^2 + 1$  and then extend it to  $\mathbb{F}_{2^{10}}$  via  $x^2 + \alpha^4 x + \alpha$ .

Below we list all of the computations involved in the DAGS algorithms, which are detailed as follows:

# Key generation:

- 1. Two polynomial multiplications, respectively in  $\mathbb{F}_{q^m}$  and  $\mathbb{F}_q$ .
- 2. Two polynomial inversions, respectively in  $\mathbb{F}_{q^m}$  and  $\mathbb{F}_q$ .
- 3. Two polynomial squarings, respectively in  $\mathbb{F}_{q^m}$  and  $\mathbb{F}_q$ .
- 4. One polynomial addition in  $\mathbb{F}_{q^m}$  and  $\mathbb{F}_q$ .
- 5. One random generation of a polynomial in  $\mathbb{F}_{q^m}$ .

#### **Encapsulation**:

- 1. One polynomial multiplication in  $\mathbb{F}_q$ .
- 2. One polynomial addition in  $\mathbb{F}_q$ .
- 3. One random generation of a polynomial in  $\mathbb{F}_q$ .
- 4. One hash function computation.

#### Decapsulation:

- 1. One polynomial multiplication in  $\mathbb{F}_{q^m}$ .
- 2. One polynomial power in  $\mathbb{F}_{q^m}$ .
- 3. One polynomial addition in  $\mathbb{F}_{q^m}$ .
- 4. One random generation of a polynomial in  $\mathbb{F}_q$ .
- 5. One hash function computation.

## 6.2 Measurements

In Table 2 we recall the flow between two parties  $P_1$  and  $P_2$  in a standard Key Exchange protocol derived from a KEM.

Table 2: KEM-based Key Exchange flow

| P <sub>1</sub>                       |                    | $P_2$                              |
|--------------------------------------|--------------------|------------------------------------|
| $(pk, sk) \gets KEM.KeyGen$          |                    |                                    |
|                                      | $\xrightarrow{pk}$ |                                    |
|                                      |                    | $(K, C) \leftarrow KEM.Encaps(pk)$ |
|                                      | <i>←C</i>          |                                    |
| $K/\bot \leftarrow KEM.Decaps(C,sk)$ |                    |                                    |
|                                      | Shared Key $:= K$  |                                    |

When instantiated with DAGS, the public key is given by the generator matrix G. The non-identity block  $M^T$  is  $k \times (n-k) = k \times mst$  and is dyadic of order s, thus requires only kmst/s = kmt elements of the base field for storage. The private key is given by the two vectors forming the Cauchy support, plus the elements  $z_i$ , respectively s, n and  $n_0$  (again, thanks to dyadicity) elements of  $\mathbb{F}_{q^m}$ . Finally, the ciphertext C is the pair (c, d), that is, a q-ary vector of length n plus 256 bits. This leads to the following measurements (in bytes).

 Table 3: Memory Requirements.

| Parameter Set | Public Key | Private Key | Ciphertext |
|---------------|------------|-------------|------------|
| DAGS_128      | 11616      | 3313.5      | 1616       |
| DAGS_96       | 8448       | 1929        | 944        |
| DAGS_64       | 6760       | 1125        | 552        |

| Table 4. Communication Dangwidth        |
|---|
| <b>Labic 4.</b> Communication Danawidth |

|  | Message<br>Flow | Transmitted<br>Message | Size     |         |         |  |  |
|--|-----------------|------------------------|----------|---------|---------|--|--|
|  |                 |                        | DAGS_128 | DAGS_96 | DAGS_64 |  |  |
|  | $P_1 \to P_2$   | G                      | 11616    | 8448    | 6760    |  |  |
|  | $P_2 \to P_1$   | (c,d)                  | 1616     | 944     | 552     |  |  |

## 7 Conclusion

In this paper, we presented DAGS, a Key Encapsulation Mechanism based on Quasi-Dyadic Generalized Srivastava codes. We proved that DAGS is IND-CCA secure in the Random Oracle Model, and in the Quantum Random Oracle Model. Thanks to this feature, it is possible to employ DAGS not only as a key-exchange protocol (for which IND-CPA would be a sufficient requirement), but also in other contexts such as Hybrid Encryption, where IND-CCA is of paramount importance.

In terms of performance, DAGS compares well with other code-based protocols. The public key is dramatically smaller than systems based on classical code families (e.g. binary Goppa codes) like McBits, and of the same order of magnitude of CAKE. With respect to CAKE, it is possible to notice that, for the same security level, DAGS requires lower overall communication bandwidth. This is because, while the size of a CAKE public key is slightly less than a DAGS key, DAGS uses much shorter codes, and as a consequence the ciphertext is quite small compared to a CAKE ciphertext. Moreover, we remark that CAKE uses ephemeral keys, has a non-negligible decoding failure rate, and only claims IND-CPA security, all factors that can restrict its use in various applications.

As is the case in most code-based protocols, all the objects involved in the computations are vectors of finite fields elements, which in turn are represented as binary strings; thus computations are fast. The cost of computing the hash functions is minimized thanks to the parameter choice that makes sure the input  $\mu$  is only 256 bits. As a result, we expect our scheme to be implemented efficiently on multiple platforms.

Another advantage of our proposal is that it doesn't involve any decoding error. This is particularly favorable in a comparison with some lattice-based schemes like [13], [2] and [12], as well as CAKE. No decoding error allows for a simpler formulation and better security bounds in the IND-CCA security proof.

Finally, we would like to highlight that a DAGS-based Key Exchange features an "asymmetric" structure, where the bandwidth cost and computational effort of the two parties are considerably different. In particular, in the flow described in Table 2, the party  $P_2$  benefits from a much smaller message and faster computation (the encapsulation operation), whereas  $P_1$  has to perform a key generation and a decapsulation (which includes a run of the decoding algorithm), and transmit a larger message (the public matrix). This is suitable for traditional client-server applications where the server side is usually expected to respond to a large number of requests and thus benefits from a lighter computational load. On the other hand, it is easy to imagine an instantiation, with reversed roles, which could be suitable for example in Internet-of-Things (IoT) applications, where it would be beneficial to lesser the burden on the client side, due to its typical processing, memory and energy constraints. All in all, our scheme offers great flexibility in key exchange applications, which is not the case for traditional key exchange protocols like Diffie-Hellman.

In light of all these aspects, we believe that DAGS is a valid candidate for post-quantum cryptography standardization as a key-encapsulation mechanism.

# A Note on the choice of $\omega$

In this section we point out some considerations about the choice of the offset  $\omega$  during the key generation process.

The usual decoding algorithm for alternant codes, for example as in [27], relies on the special form of the parity-check matrix  $(H_{ij} = y_j x_j^{i-1})$ . The first step is to recover the error locator polynomial  $\sigma(x)$ , by means of the euclidean algorithm for polynomial division; then it proceeds by finding the roots of  $\sigma$ . There is a 1-1 correspondence between these roots and the error positions: in fact, there is an error in position *i* if and only if  $\sigma(1/x_i) = 0$ .

Of course, if one of the  $x_i$ 's is equal to 0, it is not possible to find the root, and to detect the error.

Now, the generation of the error vector is random, hence we can assume the probability of having an error in position i to be around st/2n; since the codes give the best performance when mst is close to n/2, we can estimate this probability as 1/4m, which is reasonably low for any nontrivial choice of m; however, we still argue that the code is not fully decodable and we now explain how to adapt the key generation algorithm to ensure that all the  $x_i$ 's are nonzero.

As part of the key generation algorithm we assign to each  $x_i$  the value  $L_i$ , hence it is enough to restrict the possible choices for  $\omega$  to the set  $\{\alpha \in \mathbb{F}_{q^m} | \alpha \neq 1/h_i + 1/h_0, i = 0, \ldots, n-1\}$ . In doing so, we considerably restrict the possible choices for  $\omega$  but we ensure that the decoding algorithm works properly.
