# Strain: A Secure Auction for Blockchains

Erik-Oliver Blass<sup>1</sup> and Florian Kerschbaum<sup>2</sup>

<sup>1</sup> Airbus, Munich, Germany erik-oliver.blass@airbus.com <sup>2</sup> University of Waterloo, Waterloo, Canada florian.kerschbaum@uwaterloo.ca

Abstract. We present Strain, a new auction protocol running on top of blockchains and guaranteeing bid confidentiality against fully-malicious parties. As our goal is efficiency and low blockchain latency, we abstain from using traditional, highly interactive MPC primitives such as secret shares. We focus on a slightly weaker adversary model than MPC which allows Strain to achieve constant latency in both the number of parties and the bid length. The main idea behind Strain is a new maliciously-secure two-party comparison mechanism executed between any pair of bids in parallel. Using zero-knowledge proofs, Strain broadcasts the outcome of comparisons on the blockchain in a way that all parties can verify each outcome. Strain's latency is not only asymptotically optimal, but also efficient in practice, requiring a total of just 4 blocks of the underlying blockchain. Strain provides typical auction security requirements such as nonretractable bids against fully-malicious adversaries.

# 1 Introduction

Today's blockchains offer transparency and integrity features which could make them ideal for hosting auctions. Once a bid has been submitted to a smart contract managing the auction on the blockchain, the bid cannot be retracted anymore. After a deadline has passed, everybody can verify the winning bid. Due to its attractive features, block-chain auctions are already considered in the real-world. As a prominent example to fight nepotism and corruption, Ukraine will host blockchain auctions to sell previously seized goods [31].

However, today's blockchain transparency features disqualify them in scenarios where input data must remain confidential. For example, in a procurement auction, another prime application example for blockchains [1], an *auctioneer* requests offers for some good ("Need 1M grade V2X steel screws") as part of a smart contract. A set of *suppliers* submits bids for the good, and the lowest bid wins the procurement auction. Realizing a decentralized auction as a smart contract has the above transparency features, mitigates corruption, and avoids a possibly corrupt, centralized auctioneer. Yet, bids are confidential. Suppliers have mutual distrust, and leaking the value of a bid to a competitor must be avoided. In some situations, one supplier should not even learn whether or not another supplier is participating in an auction. To make matters worse, multiple suppliers might collude, be fully-malicious, behave randomly (not rationally), and abort participation in the auction to disturb its outcome. Still, the auction should run as expected.

Kosba et al. [24] already mention that one could revert to implementing the auction with Secure Multi-Party Computation (MPC) on the blockchain. While there has been a flurry of research on MPC, and generic frameworks are readily available [36], a main MPC drawback is its high interactivity. Yet, interactivity is extremely expensive on a blockchain in terms of latency. Broadcasting a message, changing the state of a smart contract (code execution), and any kind of party interactivity requires a valid transaction. As transactions are attached to blocks, any interactivity requires (at least) one block interval for completion. Block interval times are large, e.g., roughly 15 s for Ethereum [18]. Thus, high interactivity, a large number of MPC rounds, automatically rules out short-term, short living auctions.

**This paper** We present Strain ("Secure aucTions foR blockchAINs"), a new protocol for secure auctions on blockchains. At the heart, we improve Fischlin [20]'s comparison protocol in several key aspects tailored for adoption in blockchains. First, Strain features a distributed key generation for Goldwasser-Micali encryption based on a new mechanism to verifiably share each supplier's private key. Suppliers initially commit to their bids by encrypting them with their public key. A honest majority of suppliers can then open a commitment in case a supplier aborts the protocol.

Strain's second main feature is an efficient zero-knowledge (ZK) proof that two Goldwasser-Micali ciphertexts, encrypted under different keys, contain the same plaintext. For this proof, we require existence of a semi-honest *judge* party which must not collude with either of the comparing parties. In the context of auctions, the judge can be implemented by, e.g., the auctioneer. Using ZK proofs, the judge verifies (and publishes on the blockchain) whether both parties use previously committed values as input to the comparison. Again using a ZK proof, the comparing party then publishes the outcome of the comparison on the blockchain. Together, the two ZK proofs allow everybody to verify correctness of the comparison's result in only 3 blocks (totaling 4 blocks for the entire Strain protocol). We achieve such low latency by providing slightly weaker security guarantees than MPC would have. Specifically, the semi-honest judge would not be required in MPC. Strain also leaks the order of bids, but not their value.

Strain optionally supports anonymous auctions by using a combination of Dining Cryptographer networks and blind signatures. Suppliers can be anonymized, such that no supplier knows which other suppliers are participating in an auction. Note that we specifically avoid payment channels [35], and all communication will run through the blockchain. The advantage is no or only little data stored at parties, crucial information stored at the central ledger, and no direct network connectivity required between parties.

We benchmarked main cryptographic operations, and our analysis shows that Strain supports auctions of up to dozens of concurrent suppliers within 3 Ethereum blocks.

In summary, the technical highlights of this paper are:

- A new blockchain auction protocol, Strain, protecting confidentiality of bids. Strain provides provable security against fully-malicious suppliers and semi-honest auctioneers. It is efficient and completes an auction in a constant (four) number of interactions, i.e., blockchain blocks. Its round complexity is independent from the bit length of the bids (multiplicative depth of a comparison circuit) and the number of suppliers.
- After bidding, no supplier can retract or modify a bid. However, in case of dispute, commitments can be opened by an honest majority. Strain will complete, even if ma-

licious parties fail to respond and abort the auction without any supplier being able to change their bid. Computation of the winning bid is performed solely by the suppliers and entirely on the blockchain. The contribution of the auctioneer to the auction is only to verify correctness of computations in zero-knowledge.

We stress that the lack of smart contract data confidentiality is independent from privacy-preserving coin transactions, see, e.g., ZeroCash [3] for an overview. To reach consensus, blockchain miners generally require access to all contract input data. Also, permissioned blockchains such as Hyperledger (Fabric) lack confidentiality, even if contract execution can be restricted to only those parties participating in a contract.

#### Background 2

Let  $\mathcal{S} = \{S_1, \dots, S_s\}$  be the set of s suppliers in the system with public-private key pairs  $(pk_i, sk_i)$ . The procurement auction is run by auctioneer A having public-private key pair  $(pk_A, sk_A)$ . Assume that all suppliers and A know each other's public keys, so A can run an auction accepting bids from valid suppliers only.

#### **Preliminaries** 2.1

Let  $\lambda$  be the security parameter. For an integer n, let  $QR_n$  be the set of quadratic residues of group  $\mathbb{Z}_n$ , and  $QNR_n$  is the set of quadratic non-residues of  $\mathbb{Z}_n$ . Function  $J_n(x)$  computes the Jacobi symbol  $\left(\frac{x}{n}\right)$ , and we define set  $\mathbb{J}_n = \{x \in \mathbb{Z}_n | J_n(x) = 1\}$ . Finally,  $QNR_n^1 = \{x \in QNR_n | J_n(x) = 1\}$  (set of "pseudo-squares").

*Ouadratic Residues modulo Blum Integers.* An integer n is a Blum integer, if  $n = p \cdot q$ for two distinct primes p,q and  $p=q=3 \mod 4$ . If n is a Blum integer, testing whether some  $x \in \mathbb{Z}_n$  with  $J_n(x) = 1$  is in  $QR_n$  can be implemented by checking whether  $x^{\frac{(p-1)\cdot(q-1)}{4}} = 1 \mod n$  [23]. Moreover, observe that the DDH assumption holds in group  $(\mathbb{J}_n, \cdot)$ . For  $r \stackrel{\$}{\leftarrow} \mathbb{Z}_n^*$ ,  $g = -r^2 \mod n$  is a generator of group  $(\mathbb{J}_n, \cdot)$ , see Section A.1 of Couteau et al. [12]. In particular  $z = -1 = -(1^2) \mod n$  is a generator of  $\mathbb{J}_n$ .

GM Encryption. A Goldwasser-Micali (GM) [21] key pair comprises private key sk<sup>GM</sup> and public key  $pk^{\text{GM}}$ . For p and q being distinct, strong random primes of length  $\lambda$ , the private key is  $sk^{\text{GM}} = \frac{(p-1)\cdot(q-1)}{4}$ . We require  $p = q = 3 \mod 4$ , and therefore  $n = p \cdot q$ is a Blum integer. We set  $z=n-1=-1 \mod n$ . The public key is  $pk^{\mathsf{GM}}=(n,z)$ . With *n* being a Blum integer,  $z \in QNR_n^1$ .

With randomly chosen  $r_i \stackrel{\$}{\leftarrow} \mathbb{Z}_n^*$ , GM encryption of bit string  $M \in \{0,1\}^\eta$  is  $C = \mathsf{Enc}_{pk^{\mathsf{GM}}}^{\mathsf{GM}}(M_1 \dots M_\eta) = (r_1^2 \cdot z^{M_1} \mod n, \dots, r_\eta^2 \cdot z^{M_\eta} \mod n)$ . All parties automatically dismiss a ciphertext C if  $C \notin \mathbb{J}_n$ .

Decryption of ciphertext C simply checks whether each component of  $C = (c_1, ..., c_n)$  $c_{\eta}$ ) is in  $QR_n$ . As n is a Blum integer, raising  $c_i$  to secret key  $sk^{\text{GM}}$  is sufficient, i.e., you compute  $M = \text{Dec}_{sk^{\text{GM}}}^{\text{GM}}(c_1,...,c_{\eta}) = (1 - c_1^{sk^{\text{GM}}} \mod n,...,1 - c_{\eta}^{sk^{\text{GM}}} \mod n)$ . Recall GM's homomorphic properties for encryptions of two bits  $b_1, b_2$  (when ob-

vious, we omit public-/private keys in this paper for better readability):

- $\text{Dec}^{\text{GM}}(\text{Enc}^{\text{GM}}(b_1) \cdot \text{Enc}^{\text{GM}}(b_2)) = b_1 \oplus b_2$  (plaintext XOR)  $\text{Dec}^{\text{GM}}(\text{Enc}^{\text{GM}}(b_1) \cdot z) = 1 b_1$  (flip plaintext bit  $b_1$ )
- For a GM ciphertext c, re-encryption is ReEnc<sup>GM</sup> $(c) \leftarrow c \cdot \text{Enc}^{\text{GM}}(0)$ .

AND-Homomorphic GM Encryption. GM encryption can be modified to support AND-homomorphism [20, 32]. Specifically, let  $\lambda'$  be the soundness parameter of the Sander et al. [32] technique that works as follows.

A single bit b=1 is encrypted to  $\lambda'$ -many random quadratic residues mod n, i.e.,  $\lambda'$  separate GM encryptions of 0. A bit b=0 is encrypted to a sequence of random elements x with  $J_n(x)=1$ , i.e.,  $\lambda'$  encryptions of randomly chosen bits  $a_1,...,a_{\lambda'}$ . More formally,  $\operatorname{Enc}^{\operatorname{AND}}(1) = (\operatorname{Enc}^{\operatorname{GM}}(0),...,\operatorname{Enc}^{\operatorname{GM}}(0))$  and  $\operatorname{Enc}^{\operatorname{AND}}(0) = (\operatorname{Enc}^{\operatorname{GM}}(a_1),...,\operatorname{Enc}^{\operatorname{GM}}(a_{\lambda'}))$ . Decryption of a sequence of a  $\lambda'$ -element ciphertext checks whether all elements

are in  $QR_n$ . That is,  $Dec^{AND}(c_1,...,c_{\lambda'}) = 1$ , if  $\forall c_i : c_i \in QR_n$ , and 0 otherwise.

As an AND-encryption of 0 can result in  $\lambda'$  elements of  $QR_n$ , decryption is correct with probability  $1-2^{-\lambda'}$ .

Enc<sup>AND</sup> is homomorphic with respect to Boolean AND. For two ciphertexts  $\operatorname{Enc}^{AND}(b) = (c_1, \ldots, c_{\lambda'})$  and  $\operatorname{Enc}^{AND}(b') = (c'_1, \ldots, c'_{\lambda'})$ ,  $\operatorname{Dec}^{AND}(c_1 \cdot c'_1, \ldots, c_{\lambda'} \cdot c'_{\lambda'}) = b \wedge b'$ . If the  $c_i$  and  $c'_i$  are all in  $QR_n$ , so is their product. If one is in  $QR_n$  and the other in  $QNR_n^1$ , their product is in  $QNR_n^1$ . Yet, if both  $c_i$  and  $c'_i$  are in  $QNR_n^1$ , their product is in  $QR_n$ . For example, if all  $c_i$  and  $c'_i$  are in  $QNR_n^1$ , b = b' = 0, but  $\operatorname{Dec}^{AND}$  after their homomorphic combincation will output 1. So,  $\operatorname{Dec}^{AND}$  is correct with probability  $1 - 2^{-\lambda'}$ . Re-encryption for AND-encryption is simply defined as  $\operatorname{ReEnc}^{AND}(c_1, \ldots, c_{\lambda'}) \leftarrow (\operatorname{ReEnc}^{GM}(c_1), \ldots, \operatorname{ReEnc}^{GM}(c_{\lambda'}))$ .

Finally, we can embed an existing GM ciphertext  $\gamma = \text{Enc}^{\text{GM}}(b)$  of bit *b* into an a ciphertext  $\text{Enc}^{\text{AND}}(b) = (c_1, ..., c_{\lambda'})$  without decryption. First, we choose  $\lambda'$  random bits  $a_1, ..., a_{\lambda'}$ . Now, if  $a_i = 1$ , then set  $c_i = \text{Enc}^{\text{GM}}(0)$ . Otherwise, set  $c_i = \text{Enc}^{\text{GM}}(0) \cdot \gamma \cdot z \mod n$ . In the first case,  $c_i$  is a quadratic residue independently of *b* ( $c_i = \text{Enc}^{\text{GM}}(0)$ ). In the second case, we flip bit *b* by multiplying with *z* (and re-encrypt the result). So, a quadratic residue  $c_i$  becomes a non-residue and the other way around. If b = 1, all  $\lambda'$  elements  $c_i$  will be quadratic residues. If b = 0, all  $\lambda'$  elements  $c_i$  will be quadratic residues only with probability  $2^{-\lambda'}$ , such that the embedding is correct with probability  $1-2^{-\lambda'}$ .

#### 2.2 Blockchain

There exist several detailed introductions to blockchain and smart contract technology such as Ethereum [17]. Here, we only briefly and informally summarize properties relevant for Strain.

A blockchain is a distributed network implementing a ledger functionality. Parties can append transactions to the ledger, if the network validates transactions in a distributed fashion. Surprisingly, such a distributed ledger is sufficient to realize distributed execution of programs that are called smart contracts. Using transactions, one party uploads code and state into the blockchain, and other parties modify state by stipulating code execution. For a procurement auction, auctioneer A would upload a new smart contract and allow other parties to bid. That is, the smart contract could just implement a simple, initially empty mailbox as state, and suppliers could only append data (bids and anything else) to that mailbox by transactions. All blockchain transactions are automatically signed by their generating party, and so would be the data they carry. Such a simple mailbox smart contract provides the following properties that we will need.

First, the blockchain guarantees *reliable broadcast*. Each signed transaction appending a message to the mailbox is public. Based on the blockchain's consensus, everybody

```
1 forall S_i do

2 if Pseudonymity then S_i \rightarrow TTP: \mathcal{F}_{Pseu}(v_i); else S_i \rightarrow TTP: \mathcal{F}_{Auth}(v_i);

3 end

4 for i=1 to s do

5 forall j \neq i do

6 TTP: Let cmp_{i,j}=1, if v_i > v_j and cmp_{i,j}=0 otherwise;

7 end

8 end

9 TTP \rightarrow \{A, S_1, ..., S_s\}: \mathcal{F}_{BC}(\{cmp_{i,j} | \forall i, j \in \{1, ..., s\}\});

10 TTP \rightarrow A: \{v_w | v_w = \min(v_1, ..., v_s)\};
```

Algorithm 1: Ideal Functionality  $\mathcal{F}_{\mathsf{Bid}}$  of the bidding algorithm

in the network observes the same message appended (if valid). Being the blockchain's core feature, reliable broadcast takes one block latency. Along the same lines, we can introduce *personal messages* between parties over the blockchain. A broadcast to supplier  $S_i$  encrypted with  $S_i$ 's public key realizes a secure, reliable channel to  $S_i$ .

Moreover, a blockchain automatically allows for *deadlines*. Parties participating in the blockchain receive new blocks and therefore have (weakly) synchronized clocks. Based on the current block, an auction smart contract can specify a deadline as a function of the number of future blocks.

Note that with, e.g., Ethereum, there is essentially no limit for the number of transactions per block. Miners have an incentive to include as many transactions as possible in their block to receive transaction fees. Thus, large messages can therefore be split into multiple transactions and still sent as "one message". Consequently in this paper, we silently assume that the blockchain accepts any number of messages of arbitrary length per block. In practice with Ethereum, the GasLimit upper bounds transactions and their size, but one could imagine that a long messages m is stored in a public bulletin board system, and the blockchain only stores hash of m.

# **3** Security Definition

We define security following the standard ideal vs. real world paradigm. First, we specify an ideal functionality  $\mathcal{F}_{Bid}$  of our bidding protocol, see Algorithm 1.

**Ideal Functionality** Our protocol emulates a trusted third party TTP that, first, receives all bids from all suppliers. If supplier pseudonymity is required, all participating suppliers  $S_i$  send their bids  $v_i$  via a pseudonymous channel, or else they send it via an authenticated channel. The trusted third party then computes result  $cmp_{i,j}$  of the comparsion between each bid. Finally, the trusted third party announces (broadcasts) the results of all comparisons to auctioneer A, each Supplier  $S_i$ , and all other participants of the blockchain. Similar to order preserving encryption, this reveals the total order of bids and hence the winner of the auction, but does not reveal the bids themselves.

Adversary Model We consider two adversaries  $A_1$  and  $A_2$ . These adversaries have different capabilities, are non-colluding, and control different parties. The following Theorem 1 summarizes our main contribution, and we will prove it later in the paper.

**Theorem 1.** If adversary  $A_1$  is a static, active adversary which may control up to a threshold<sup>3</sup>  $\tau$  of suppliers  $S_i$ , and if Adversary  $A_2$  is a passive adversary which may control auctioneer A, and if  $A_1$  and  $A_2$  do not collude, then protocol Strain implements functionality  $\mathcal{F}_{Bid}$ .

The order of bids is revealed to the adversary, and the auctioneer, but not the suppliers, must be only semi-honest. While this results in slightly weaker security than offered by MPC, it allows for optimally low latency. Moreover, we conjecture that this adversary model is practical in a variety of real-world scenarios.

#### 4 Maliciously-Secure Comparisons

The first ingredient to our main contribution of secure auctions is a generic comparison construction. It allows two parties  $S_i$  and  $S_j$  (the suppliers in our application) with inputs  $v_i$  and  $v_j$  to obliviously evaluate whether or not  $v_i > v_j$  without disclosing anything else to the other party. In contrast to related work, the novelty of our construction is its efficiency in the face of fully malicious adversaries. We do not rely on general MPC primitives and have asymptotically optimal complexity (3 blocks and  $O(\eta)$  computation and communication cost per comparison). This allows us to easily integrate our comparison into the auction framework of Section 5 and, e.g., tolerate parties aborting the auction without restarting comparisons.

To realize maliciously-secure comparisons, we rely on the existence of a *judge* A (the auctioneer in our application).  $S_i$  and  $S_j$  can be fully malicious, but A must be semi-honest and moreover not collude with  $S_i, S_j$ , see Section 10. As long as A does not collude with  $S_i, S_j$ , neither A nor a malicious supplier learn bids of honest suppliers. An important property of our solution is that knowledge of  $S_i$ 's,  $S_j$ 's, and A's public keys is sufficient to verify whether  $v_i > v_j$ , again without learning anything else about  $v_i$  and  $v_j$ .

#### 4.1 Secure Comparisons Against Semi-Honest Adversaries

We begin by presenting Fischlin [20]'s technique for comparisons, secure against semihonest adversaries. Subsequently, we extend comparisons to be secure against fully malicious adversaries.

Given bit representations  $v_i = v_{i,1} \dots v_{i,\eta}$  and  $v_j = v_{j,1} \dots v_{j,\eta}$ , we can compute  $v_i > v_j$ by evaluating Boolean circuit  $F = \bigvee_{\ell=1}^{\eta} (v_{i,\ell} \wedge \neg v_{j,\ell} \wedge \bigwedge_{u=\ell+1}^{\eta} (v_{i,u} = v_{j,u}))$ . We have F = 1 *iff*  $v_i > v_j$ . Observe that the main  $\bigvee_{t=1}^{\eta}$  is actually an XOR: if  $v_i > v_j$ , exactly one term will be 1, and all other terms are 0. If  $v_i \leq v_j$ , all terms will be 0. Moreover,  $(v_{i,u} = v_{j,u})$  equals  $\neg (v_{i,u} \oplus v_{j,u})$ . That can be exploited to homomorphically evaluate F using GM encryption.

- 1.  $S_i$  sends its GM public key  $pk_i^{\text{GM}} = (z_i, n_i)$  and encrypted value  $C_i = \text{Enc}_{pk_i^{\text{GM}}}^{\text{GM}}(v_i)$ , a sequence of GM ciphertexts, to  $S_j$ .
- 2.  $S_j$  encrypts its own value  $v_j$  with  $S_i$ 's public key,  $C_{i,j} = \mathsf{Enc}_{pk_i^{\mathsf{GM}}}^{\mathsf{GM}}(v_j)$ .  $S_j$  then homomorphically computes all  $\neg(v_{i,u} \oplus v_{j,u})$  and  $\neg v_{j,\ell}$  from F.

<sup>&</sup>lt;sup>3</sup> Threshold  $\tau$  will later be used to open commitments using Shamir's secret sharing of the key, cf. Section 5.1.

- S<sub>j</sub> embeds C<sub>i</sub> and its own sequence of ciphertexts C<sub>i,j</sub> into AND-homomorphic GM ciphertexts as described in Section 2.1. Using AND-homomorphism, S<sub>j</sub> computes a sequence ℓ = {1,...,η} of ciphertexts c<sub>ℓ</sub> = (v<sub>i,ℓ</sub> ∧ ¬v<sub>j,ℓ</sub> ∧ ∧<sup>η</sup><sub>u=ℓ+1</sub>(v<sub>i,u</sub> = v<sub>ju</sub>)). Finally, S<sub>j</sub> randomly shuffles the order of ciphertexts c<sub>ℓ</sub> and sends resulting permutation res<sub>i,j</sub> = π(c<sub>1</sub>,...,c<sub>η</sub>) back to S<sub>i</sub>.
- 4.  $S_i$  can decrypt the  $c_{\ell}$  in  $res_{i,j}$  and learns whether  $v_i \leq v_j$ , if all  $c_{\ell}$  decrypt to 0, or  $v_i > v_j$ , if exactly one ciphertext decrypts to 1 and all other to 0.

The purpose of  $S_j$  shuffling ciphertexts is to hide the position of the potential 1 decryption, thereby not leaking the position of the lowest bit differing between  $v_i$  and  $v_j$ .

Steps 2 and 3 implement a functionality which we call  $Eval(C_i, v_j)$  from now on.

#### 4.2 Secure Comparisons Between Two Malicious Adversaries

Fischlin's protocol is only secure against semi-honest adversaries. However, one or *even* both parties may have behaved maliciously during comparison. Both suppliers  $S_i$  and  $S_j$  may submit different bids to distinct comparisons and supplier  $S_j$  could just encrypt any result of their choice using  $S_i$ 's public key. That is, Fischlin's protocol does not ensure that  $res_{i,j}$  has been computed according to the protocol specification and the fixed inputs of the suppliers.

We tackle this problem by, first, requiring both  $S_i$  and  $S_j$  to commit to their own input, simply by publishing GM encryptions  $C_i, C_j$  of  $v_i, v_j$  with their public key including a proof of knowledge of the plaintext. During comparison,  $S_j$  will prove to a judge A in zero-knowledge that  $S_j$  used the same value  $v_j$  in  $C_{i,j}$  as in commitment  $C_j$ , and that  $S_j$  has performed homomorphic computation of  $res_{i,j}$  according to Fischlin's algorithm. Therewith,  $S_i$  is sure that  $res_{i,j}$  contains the result of comparing inputs behind ciphertexts  $C_i$  and  $C_j$ .

In the following description, we allow parties to either *publish* data or to send data from one to another. In reality, one could use the blockchain's broadcast feature to efficiently and reliably publish data to all parties or to just send a private (automatically signed) message, see Section 2.2.

**Details** First, party  $S_i$  commits to  $v_i$  by publishing  $\{pk_i^{\text{GM}}, C_i = \text{Enc}_{pk_i^{\text{GM}}}^{\text{GM}}(v_i)\}$ , and party  $S_j$  commits to  $v_j$  by publishing  $\{pk_j^{\text{GM}}, C_j = \text{Enc}_{pk_j^{\text{GM}}}^{\text{GM}}(v_j)\}$ . Then,  $S_i$  and  $S_j$  compare their  $v_i, v_j$  following Fischlin [20]'s homomorphic circuit evaluation above. After  $S_j$  has computed  $res_{i,j}, S_j$  additionally computes a ZK proof  $P_{i,j}^{\text{eval}}$  as follows.

1.  $S_j$  adds  $C_{i,j}$  and random coins for both the shuffle of  $res_{i,j}$  and the AND-homomorphic embeddings to initially empty proof  $P_{i,j}^{eval}$ .

Let  $v_{j,\ell}$  be the  $\ell^{\text{th}}$  bit of  $v_j$ . Let  $(C_j)_{\ell}$  be the  $\ell^{\text{th}}$  ciphertext of GM commitment  $C_j$ , i.e., the encryption of  $v_{j,\ell}$  (the  $\ell^{\text{th}}$  bit of  $v_j$ ). Let  $(C_{i,j})_{\ell}$  be the  $\ell^{\text{th}}$  ciphertext of  $C_{i,j}$ .

- 2. Let  $\lambda''$  be the soundness parameter of our ZK proof.  $S_j$  flips  $\eta \cdot \lambda''$  coins  $\delta_{\ell,m}$ ,  $1 \le \ell \le \eta, 1 \le m \le \lambda''$ .
- 3.  $S_j$  computes  $\eta \cdot \lambda''$  encryptions  $\gamma_{\ell,m} \leftarrow \mathsf{Enc}_{pk_j^{\mathsf{GM}}}^{\mathsf{GM}}(\delta_{\ell,m})$  and  $\gamma'_{\ell,m} \leftarrow \mathsf{Enc}_{pk_i^{\mathsf{GM}}}^{\mathsf{GM}}(\delta_{\ell,m})$ and appends them to proof  $P_{i,j}^{\mathsf{eval}}$ .
- 4.  $S_j$  also computes  $\eta \cdot \lambda''$  products  $\Gamma_{\ell,m} = (C_j)_{\ell} \cdot \gamma_{\ell,m} \mod n_j$  and  $\Gamma'_{\ell,m} = (C_{i,j})_{\ell} \cdot \gamma'_{\ell,m} \mod n_i$  and appends them to proof  $P_{i,j}^{\text{eval}}$ . A product  $\Gamma_{\ell,m}$  is an encryption of  $\delta_{\ell,m} \oplus v_{j,\ell}$  under key  $pk_j^{\text{GM}}$ , and  $\Gamma'_{\ell,m}$  is an encryption of  $\delta_{\ell,m} \oplus v_{j,\ell}$  under key  $pk_i^{\text{GM}}$ .

- 5.  $S_j$  sends  $P_{i,j}^{\text{eval}}$  to judge A.
- Our ZK proof can either be interactive or non-interactive. We first consider the interactive version of our proof. Here, A sends back the challenge h, a sequence of η·λ" bits b<sub>l,m</sub>, to S<sub>j</sub>.
- 7. If  $b_{\ell,m} = 0$ ,  $S_j$  sends plaintext and random coins of  $\gamma_{\ell,m}$  and  $\gamma'_{\ell,m}$  to A. If  $b_{\ell,m} = 1$ ,  $S_j$  sends plaintext and random coins of  $\Gamma_{\ell,m}$  and  $\Gamma'_{\ell,m}$  to A.

The non-interactive version of our proof is a standard application of Fiat-Shamir's heuristic [19] to  $\Sigma$ -protocols and imposes slight changes to steps 5 to 7. So, let  $h = H((\gamma_{1,1},\gamma'_{1,1},\Gamma_{1,1}\Gamma'_{1,1}),...,(\gamma_{\eta,\lambda''},\gamma'_{\eta,\lambda''},\Gamma_{\eta,\lambda''}),C_i,C_j,C_{i,j})$  for random oracle  $H: \{0,1\}^* \to \{0,1\}^{\eta\cdot\lambda''}$ . Instead of sending  $P_{i,j}^{\text{eval}}$  to A, receiving the challenge, and replying to the challenge,  $S_j$  parses h as a series of  $\eta\cdot\lambda''$  bits  $b_{\ell,m}$ .  $S_j$  does not send plaintexts and random coins of either  $(\gamma_{\ell,m},\gamma'_{\ell,m})$  or  $(\Gamma_{\ell,m},\Gamma'_{\ell,m})$  as above to A, but simply appends them to  $P_{i,j}^{\text{eval}}$  and then sends  $P_{i,j}^{\text{eval}}$  to A. In practice, we implement H by a cryptographic hash function.

So in conclusion,  $S_j$  sends proof  $P_{i,j}^{\text{eval}}$  to judge A who has to verify it. Note that  $P_{i,j}^{\text{eval}}$  contains ciphertext  $C_{i,j}$  of  $S_j$ 's input  $v_j$  under  $S_i$ 's public key. The proof is zero-knowledge for judge A and very efficient, but must not be shared with party  $S_i$ . A's verification steps are as follows:

- 8. Judge A verifies that homomorphic computations for  $res_{i,j}$  have been computed correctly, according to  $C_{i,j}, C_j$ , and random coins of  $res_{i,j}$ 's shuffle, simply by reperforming the computation.
- For ℓ = {1,...,η} and m = {1,...,}, A verifies that homomorphic relations between (C<sub>i</sub>)<sub>ℓ</sub>, γ<sub>ℓ,m</sub>, Γ<sub>ℓ,m</sub> as well as for (C<sub>i,j</sub>)<sub>ℓ</sub>, γ'<sub>ℓ,m</sub>, Γ'<sub>ℓ,m</sub> hold.
- 10. For each triple of plaintext, random coins, and ciphertexts of either  $\gamma_{\ell,m}$  and  $\gamma'_{\ell,m}$  or  $\Gamma_{\ell,m}$  and  $\Gamma'_{\ell,m}$ , A checks that ciphertext results from the plaintext and random coins and that the plaintexts are the same.
- 11. If all checks pass, the judge A outputs  $\top$ , else  $\perp$ .

If A outputs  $\top$ ,  $S_i$  decrypts  $res_{i,j}$  and learns the outcome of the comparison, i.e., whether  $v_i > v_j$ .

Steps 1 to 7 implement a functionality that we call  $ProofEval(C_i, C_j, C_{i,j}, res_{i,j}, v_j)$ from now on. ProofEval is executed by  $S_j$  and uses commitments  $C_i$  and  $C_j$  and  $S_j$ 's input  $v_j$  and outputs  $\{C_{i,j}, res_{i,j}\}$  of  $Eval(C_i, v_j)$ . Similarly, steps 8 to 11 realize functionality  $VerifyEval(P_{i,j}^{eval}, res_{i,j}, C_i, C_j)$ . Executed by judge A, it outputs either  $\top$  or  $\bot$ .

**Lemma 1.** The above scheme of computing and verifying proof  $P_{i,j}^{\text{eval}}$  with ProofEval and VerifyEval is a ZK proof of knowledge of  $v_j$ , such that  $C_j = \text{Enc}_{PK_j}^{\text{GM}}(v_j), \{C_{i,j}, res_{i,j}\} = \text{Eval}(C_i, v_j)$ , and if it is performed in  $\lambda''$  rounds, the probability that  $S_j$  has cheated, but A outputs  $\top$ , is  $2^{-\lambda''}$ .

*Proof.* As completeness follows directly from our description, we focus on soundness (extractability) and zero-knowledge.

(1) Knowledge Soundness. Judge A can extract  $v_j$  from  $S_j$  with rewinding access. Let  $tr1(C_{i,j}, res_{i,j}, \gamma_{\ell,m}, \gamma'_{\ell,m}, \Gamma_{\ell,m}, \Gamma'_{\ell,m}, b_{\ell,m}, ...)$  be the trace of the first execution of  $P_{i,j}^{\text{eval}}$ . Then judge A rewinds  $S_j$  to Step 5 and continues the protocol. Let  $tr2(C_{i,j}, res_{i,j}, \gamma_{\ell,m}, \gamma'_{\ell,m}, \Gamma'_{\ell,m}, b_{\ell,m}, \ldots)$  be the trace of the second execution of  $P_{i,j}^{\text{eval}}$ . If  $tr1(b_{\ell,m}) = 0$  and  $tr2(b_{\ell,m}) = 1$ , then A learns  $tr1(\delta_{\ell,m})$  and  $tr2(\delta_{\ell,m} \oplus v_{j,\ell})$ . Therewith, A computes  $v_{j,\ell}$ . As  $v_{j,\ell}$  can be extracted, our  $\Sigma$ -protocol achieves special soundness. With challenge length  $\lambda''$  for each bit of  $v_j$ , it is moreover a proof of knowledge with knowledge error  $2^{-\lambda''}$  [13].

(2) Zero-Knowledge. Intuitively, the auctioneer learns nothing from the opening of either  $\gamma_{\ell,m}$  and  $\gamma'_{\ell,m}$  or  $\Gamma_{\ell,m}$  and  $\Gamma'_{\ell,m}$ , since the plaintext value is always chosen uniformly random due to the uniform distribution of  $\delta_{\ell,m}$ . More formally, in the interactive case, we can construct a simulator  $\operatorname{Sim}_{P_{i,j}^{\operatorname{eval}}}^{A(\{C_i, C_j\})}(\operatorname{res}_{i,j})$  with rewinding access to judge  $A(\{C_i, C_j\})$  following a standard simulation paradigm [25]. This ensures that we can construct a simulation of the ZK proof in the malicious model of secure computation even if bid  $v_j$  does not correspond to ciphertext  $C_{i,j}$  and commitments  $C_i, C_j$ , since the simulator generates an accepting, indistinguishable output even if  $v_j$  is unknown. In the non-interactive case with Fiat-Shamir's heuristic, our ZK proof is secure in the random oracle model.

**Note:** Our proof here shows something stronger than required by the general auction protocol. We show our ZK proof to be secure even against malicious verifiers. However, auctioneer A, serving as the judge in the main protocol, is supposed to be semi-honest.

#### **5** Blockchain Auction Protocol

After having presented our core technique for secure comparisons, we now turn to our main auction protocol Strain. Imagine that, at some point, A announces a new auction and uploads a smart contract to the blockchain. The smart contract is very simple and allows parties to comfortably exchange messages as mentioned before. The contract is signed by  $sk_A$ , so everybody understands that this is a valid procurement auction.

*Overview.* With the smart contract posted, the actual auction starts. In Strain, each supplier must first publicly commit to their bid. For this, we use a new verifiable commitment scheme which allows a majority of honest suppliers to open other suppliers' commitments. Therewith, we can at any time open commitments of malicious suppliers blocking or aborting the auction's progress.

After suppliers have committed to their bids (or after a deadline has passed), the protocol to determine the winning bid starts. Strain uses the new comparison technique from Section 4.2 to compare bids of any two parties. Auctioneer A serves as the judge. However, using our new comparison in the auctions turns out to be a challenge. Recall that, when  $S_i$  and  $S_j$  compare their bids, only  $S_i$  knows the outcome of the comparison, but nobody else. We therefore augment our comparison such that  $S_i$  can publish the outcome of the comparison, together with a (zero knowledge) proof of correctness.

To improve readability, we present Strain without optional pseudonymity and postpone pseudonymity to Section 5.4. For now, assume that a subset  $S' \subset S$ ,  $|S'| = s' \leq s$ participates in the auction. Either a pseudonymous subset or all suppliers participate.

#### 5.1 Verifiable Key Distribution for Commitments

To be able to commit to their bids, suppliers in Strain initially distribute their keying material. In the following, we devise a new key distribution technique for our specific setting. It permits supplier  $S_i$  to publish a GM public key and verifiably secret share the corresponding secret key. The crucial property of our key distribution is that a majority of honest suppliers can decrypt ciphertexts encrypted with  $S_i$ 's public key. To then later commit to a value  $v_i$ ,  $S_i$  encrypts  $v_i$  with their public key. For ease of exposition, we describe our key distribution with s-out-of-s threshold secret sharing. However, we stress that many different schemes exist for s'-out-of-s sharing modulo an RSA integer. For example, one could adopt and employ the schemes by Desmedt and Frankel [15] or Katz and Yung [23]. See also Shoup [33] for an overview.

Key Distribution Each supplier  $S_i$  generates a GM key pair  $(pk_i^{GM} = (n_i = p_i \cdot q_i, q_i)$  $z_i = n_i - 1$ ,  $sk_i^{\mathsf{GM}} = \frac{(p_i - 1) \cdot (q_i - 1)}{4}$ ). To allow other suppliers  $S_j$  to open commitments from supplier  $S_i$ ,  $S_i$  first computes a non-interactive ZK proof  $P_i^{\mathsf{Blum}}$  that  $n_i$  is a Blum  $(q_i - 1) \cdot (q_i - 1)$ integer, see Blum [4] for details. Moreover,  $S_i$  computes secret shares of  $\frac{(p_i-1)\cdot(q_i-1)}{4}$ for all suppliers as follows:  $S_i$  computes s' - 1 random shares  $r_{i,1}, \ldots, r_{i,s'-1} \xleftarrow{\$} \{0, \dots, n_{i,s'-1} \xleftarrow{\$} \}$  $(p_i-1)\cdot(q_i-1)$  such that  $\sum_{j=1}^{s'-1}r_{i,j} = \frac{(p_i-1)\cdot(q_i-1)}{4} \mod (p_i-1)\cdot(q_i-1)$ . This can easily be converted into a threshold scheme using Shamir's secret shares where  $\tau$  is the threshold for reconstructing a secret. Supplier  $S_i$  computes signature  $sig_{sk_i}(r_{i,j})$  and encrypts share  $r_{i,j}$  and signature  $sig_{sk_i}(r_{i,j})$  for supplier  $S_j$  using  $S_j$ 's public key  $pk_j$ . Finally,  $S_i$  broadcasts resulting s'-1 ciphertexts of share and signature pairs as well as  $pk_i^{\sf GM}$  and  $P_i^{\sf Blum}$  on the blockchain.

All suppliers can send their broadcasts in parallel, requiring only one block latency. Key Verification All s' participating suppliers start a sub-protocol to verify all s' public keys  $pk_i^{\text{GM}}$ . For each  $pk_i^{\text{GM}}$ :

- 1. All suppliers check proof  $P_i^{\mathsf{Blum}}$ . If supplier  $S_i$  fails to verify the proof,  $S_i$  publishes  $(i, \perp)$  on the blockchain.
- 2. Each supplier  $S_j$  selects a random  $\rho_{i,j} \stackrel{\$}{\leftarrow} \mathbb{Z}_{n_i}^*$  and employs a traditional commitment scheme commit to commit to  $\rho_{i,j}$ . That is, each supplier  $S_j$  publishes commit $(\rho_{i,j})$ on the blockchain.
- 3. After a deadline has passed, all suppliers open their commitments, by publishing  $\rho_{i,j}$ and the random nonce used for the commitment. All suppliers compute  $x_i = \sum_{j \neq i} \rho_{i,j} \mod n_i$  and  $y_i = x_i^2$ .
- All suppliers compute x<sub>i</sub> = ∑<sub>j≠i</sub>ρ<sub>i,j</sub> mod n<sub>i</sub> and y<sub>i</sub> = x<sub>i</sub><sup>\*</sup>.
  4. Each supplier S<sub>j</sub> raises y<sub>i</sub> to their share r<sub>i,j</sub> of (p<sub>i</sub>-1)·(q<sub>i</sub>-1)/4 and publishes γ<sub>i,j</sub> = y<sub>i</sub><sup>r<sub>i,j</sub> on the blockchain. S<sub>j</sub> also raises z<sub>i</sub> to their r<sub>i,j</sub>, i.e., ζ<sub>i,j</sub> = z<sub>i</sub><sup>r<sub>i,j</sup></sup>. S<sub>j</sub> then prepares a non-interactive ZK proof P<sub>i,j</sub><sup>DLOG</sup> of statement log<sub>yi</sub> γ<sub>i,j</sub> = log<sub>zi</sub> ζ<sub>i,j</sub>, see Appendix A for details. Supplier S<sub>j</sub> publishes {γ<sub>i,j</sub>, ζ<sub>i,j</sub>, P<sub>i,j</sub><sup>DLOG</sup>} on the blockchain.
  5. Finally, all s' 1 suppliers verify soundness of pk<sub>i</sub><sup>GM</sup>. Each supplier S<sub>j</sub> computes b<sub>i</sub> = ∏<sub>j≠i</sub> γ<sub>i,j</sub> = y<sub>i</sub><sup>S'-1</sup>r<sub>i,j</sub> = y<sub>i</sub><sup>(p<sub>i</sub>-1)·(q<sub>i</sub>-1)</sup>/4 mod n<sub>i</sub> and b'<sub>i</sub> = ∏<sub>j≠i</sub> ζ<sub>i</sub> = z<sub>i</sub><sup>S'-1</sup>r<sub>i,j</sub> = z<sub>i</sub><sup>(p<sub>i</sub>-1)·(q<sub>i</sub>-1)</sup>/4 mod n<sub>i</sub>. If S<sub>j</sub> detects that b<sub>i</sub> ≠ 1 or b'<sub>i</sub> ≠ -1 mod n<sub>i</sub>, S<sub>j</sub> publishes (i,⊥) on the blockchain. Supplier S<sub>j</sub> also checks s'-1 proofs P<sub>i,k</sub><sup>DLOG</sup>. If one of the rounds outputs ⊥ during verification S<sub>i</sub> publishes (k ⊥) on the blockchain
  </sup></sup></sub>  $\kappa$  rounds outputs  $\perp$  during verification,  $S_j$  publishes  $(k, \perp)$  on the blockchain.

**Lemma 2.** Let  $n_i$  be a Blum integer and  $\alpha$  the sum of shares distributed by  $S_i$ . If no honest supplier publishes  $(i, \perp)$ , then  $Pr[\alpha \neq \frac{(p_i-1)\cdot(q_i-1)}{4}] \in O(2^{-\lambda})$ .

*Proof.* Let  $y_i$  have no roots in  $\mathbb{Z}_{n_i}$  that divide  $\frac{(p_i-1)(q_i-1)}{4}$ . For an uniformly chosen  $y_i$  this happens with overwhelming probability  $\in O(1-2^{-\lambda})$ .

As  $y_i \in QR_{n_i}$ , it has order  $\frac{(p_i-1)(q_i-1)}{4}$ . So,  $b_i = 1$  implies that (I)  $\alpha \mod \frac{(p_i-1)(q_i-1)}{4} = 0$ . Further, since  $z_i = -1 \mod n_i$ , we have  $z_i^{\frac{(p_i-1)(q_i-1)}{4}} \in \{-1,1\}$ , and therefore (II)  $z_i^{\frac{(p_i-1)(q_i-1)}{2}} = 1$ . Hence  $b'_i = -1$  means that  $\alpha \mod \frac{(p_i-1)(q_i-1)}{2} \neq 0$ . From (I) and (II) we conclude ( $\alpha \mod \frac{(p_i-1)(q_i-1)}{4}$ ) mod 2=1.

However, all those values will serve as private keys in GM encryption.

In conclusion, supplier  $S_i$  can verify whether their shares for supplier  $S_j$ 's secret key  $sk_j^{\text{GM}}$  matches public key  $pk_j^{\text{GM}}$ . Therewith, an honest majority of suppliers will later be able to open commitments of malicious suppliers trying to block the smart contract or cheat.

**Excluding malicious suppliers** Strain's key verification easily allows detection and exclusion of malicious suppliers. First, as all suppliers can verify proofs  $P_i^{\text{Blum}}$  and  $P_{i,j}^{\text{DLOG}}$  of a supplier  $S_i$ , honest suppliers can exclude  $S_i$  or  $S_j$  from further participating in the protocol in case of a bad proof.

Moreover, following our assumption of up to  $\tau$  malicious suppliers, Strain allows to systematically detect and exclude malicious suppliers. Supplier  $S_j$  will reconstruct  $b_i = 1$  and  $b'_i = -1$  from the set of secret shares  $(\gamma_{i,j}, \zeta_{i,j})$ . If no subset reconstructs the correct plaintexts,  $S_j$  deduces that distributor  $S_i$  is malicious and excludes  $S_i$ . Otherwise,  $S_j$  checks that each supplier  $S_k$ 's share reconstructs the correct plaintext. If any does not,  $S_j$  asks  $S_k$  publicly on the blockchain to reveal their exponent  $r_{i,k}$  and signature  $\operatorname{sig}_{sk_i}(r_{i,k})$ . If at least  $\tau + 1$  suppliers ask  $S_k$  to reveal,  $S_k$  will reveal, and honest suppliers can detect whether  $S_k$  should be excluded (signature does not verify or exponent does not match secret shares) or  $S_i$  (signature verifies and exponent matches secret shares).

#### 5.2 Determining the Winning Bid

Strain's main protocol  $\Pi_{\text{Strain}}$  to determine the winning bid is depicted in Algorithm 2. Within Algorithm 2, we use three ZK proofs as sub-protocols.

- ProofEnc $(C_i, v_i)$  proves in zero-knowledge the knowledge of  $v_i$ , such that  $C_i = \text{Enc}_{PK_i}^{\text{GM}}(v_i)$ . For an exemplary implementation we refer to Katz [22].
- ProofEval $(C_j, C_i, C_{i,j}, res_{i,j}, v_j)$  has been introduced in Section 4.2.
- ProofShuffle( $shuffle_{i,j}, res_{i,j}$ ) proves in zero-knowledge the knowledge of a permutation Shuffle with  $shuffle_{i,j} = Shuffle(res_{i,j})$ . There exist a large number of implementations of shuffle proofs. For one that is straightforward to adapt to GM encryption, see Ogata et al. [29]. Using this technique, one can even create shuffles with a restricted structure [30]. That is, the shuffle is only chosen from a pre-defined subset of all possible shuffles. In our case this is necessary, since we do not randomly shuffle all GM ciphertexts, but only AND-homomorphic blocks of GM ciphertexts.

1 for i=1 to s' do  $S_i$ : publish  $\{C_i \leftarrow \mathsf{Enc}_{PK_i}^{\mathsf{GM}}(v_i), P_i^{\mathsf{enc}} \leftarrow \mathsf{ProofEnc}(C_i, v_i)\}$  on blockchain; 2 3 end 4 for i=1 to s' do forall  $j \neq i$  do 5 
$$\begin{split} S_j : & \{C_{i,j}, res_{i,j}\} \leftarrow \mathsf{Eval}(C_i, v_j); \\ & S_j : P_{i,j}^{\mathsf{eval}} \leftarrow \mathsf{ProofEval}(C_j, C_i, C_{i,j}, res_{i,j}, v_j); \end{split}$$
6 7  $S_j$ : publish { $Enc_{pk_A}(P_{i,j}^{eval}), res_{i,j}$ } on blockchain; 8 A: publish VerifyEval $(P_{i,j}^{eval}, res_{i,j}, C_i, C_j)$  on blockchain; 9  $S_i: bitset_{i,j} = \mathsf{Dec}_{pk_j^{\mathsf{GM}}}^{\mathsf{AND}}(res_{i,j});$ 10  $S_i: shuffle_{i,j} \leftarrow Shuffle(res_{i,j});$ 11  $S_i: P_{i,j}^{\mathsf{shuffle}} \leftarrow \mathsf{ProofShuffle}(shuffle_{i,j}, res_{i,j});$ 12  $S_i: \text{let } \gamma_{\ell,m} \leftarrow \text{Enc}_{PK_i}^{\text{GM}}(\beta_{\ell,m}) \in shuffle_{i,j}$  be the shuffled ciphertexts 13 with their random coins  $r_{\ell,m}$ . Publish { $P_{i,j}^{\text{shuffle}}$ ,  $shuffle_{i,j}, \beta_{\ell,m}, r_{\ell,m}$ }; 14 15 end 16 end

ZK proofs ProofEnc and ProofShuffle are verified by all suppliers active in the auction, and, hence, verification is not explicitly shown. ZK proof ProofEval, however, is verified only by the semi-honest judge and auctioneer A.

Let  $\eta \ll \lambda$  be a public system parameter determining the bit length of each bid. That is, any bid  $v_i = v_{i,1}...v_{i,n}$  can take values from  $\{0,...,2^{\eta}-1\}$ .

 $\Pi_{\text{Strain}}$  starts with each supplier  $S_i$  committing to their bid  $v_i$  by publishing GMencryption  $C_i = (\text{Enc}_{pk_i^{\text{GM}}}^{\text{GM}}(v_{i,1}), \dots, \text{Enc}_{pk_i^{\text{GM}}}^{\text{GM}}(v_{i,\eta}))$  on the blockchain. Recall that all messages on the blockchain are automatically signed by their generating party.

After a deadline has passed, suppliers determine index w of winning bid  $v_w$  by running our maliciously-secure comparison mechanism of Section 4.2. Any pair  $(S_i, S_j)$  of suppliers computes the comparison and publishes the result on the blockchain.

Specifically, after judge/auctioneer A has published whether  $S_j$ 's computation of  $C_{i,j}$  corresponds to  $S_j$ 's commitment  $C_j$ , supplier  $S_i$  can decrypt  $res_{i,j}$  and learn whether  $v_i > v_j$ . To publish whether  $v_i > v_j$ ,  $S_i$  shuffles  $res_{i,j}$  to  $shuffle_{i,j}$ , publishes a ZK proof of shuffle, and publicly decrypts  $shuffle_{i,j}$ . Therewith, everybody can verify  $v_i > v_j$ . If A has output  $\top$ , if the proof of shuffle is correct, and if  $shuffle_{i,j}$  contains exactly a single 1, then  $v_i > v_j$ . If A has output  $\top$ , the shuffle proof is correct, and if  $shuffle_{i,j}$  contains only 0s, then  $v_i > v_j$ .

A supplier  $S_i$  is the winner of the auction, if all their shuffles prove that their bid is the lowest among all suppliers.  $S_i$  can prove this by opening the plaintext and random coins of  $shuffle_{i,j}$ . If  $v_i \le v_j$ , at least one plaintext in each consecutive sequence of  $\lambda'$  plaintexts is 0. If  $v_i > v_j$ , a consecutive sequence of  $\lambda'$  plaintexts is 1. Strain concludes with auction winner  $S_w$  revealing bid  $v_w$  and a plaintext equality ZK proof that commitment  $C_w$  is for  $v_w$  to auctioneer A.

#### 5.3 Latency Evaluation

The performance of any interactive protocol or application running on top of a blockchain is dominated by block interval times. With today's block interval times in the order of several seconds, protocols requiring a lot of party interaction significantly in-

Table 1. Execution time for Strain's main cryptographic operations

	$Enc^{GM}$	$Dec^{GM}$	$Enc^{AND}$	Dec	AND	ProofEn	c	VerifyEnc	Eval	ProofEv	al	VerifyEval
	0.08 ms	46 ms	60 ms	980 ms		10 ms		9 ms	390 ms	107 ms	3	15 ms
ProofDLOG VerifyDLOG ProofShuffle VerifyShuffle												
		_	154 ms			339 ms		633 ms	198	198 ms		

crease the protocol's total latency, i.e., its total run time. A secure auction protocol with high latency is useless in many scenarios with automated, short-living auctions.

As a crucial performance metric, we therefore investigate Strain's latency. As key distribution is a setup-like initial process, necessary only once, and independent of actual auctions, we focus on  $\Pi_{\text{Strain}}$ 's latency.

Asymptotic Analysis In Algorithm 2,  $\Pi_{\text{Strain}}$  starts in Line 2 by all suppliers sending a commitment to their bid together with  $P^{\text{enc}}$ . There is no interactivity between by suppliers, so all suppliers can send in parallel, requiring one block latency.

After that first block has been mined, all suppliers send their  $P^{\text{eval}}$  for each other supplier to A, lines 6 to 8. Each supplier can send all  $P^{\text{eval}}$  for all other suppliers at once. Again, there is no interactivity between suppliers, so all suppliers send in parallel in one block. Then, auctioneer A sends all VerifyEval for all comparisons at once, Line 9, in another block. In a final block, all suppliers disclose in parallel their shuffles, random coins, and corresponding  $P^{\text{shuffle}}$  (Line 14).

In conclusion, one run of  $\Pi_{\text{Strain}}$  requires a total of 4 blocks latency: 1 block for suppliers to commit, and then 3 blocks for core comparisons and computation of the winning bid. This number is constant in both bit length  $\eta$  of each bid and the number of suppliers *s*. In contrast, practical MPC protocols require at least  $\Omega(\eta)$  rounds. Although Fischlin's protocol only evaluates a circuit of constant multiplicative depth, it is capable of evaluating a comparison due to the shuffle of the ciphertexts before decryption.

**Prototypical Implementation** To indicate its real-world practicality, we have prototypically implemented and benchmarked  $\Pi_{\text{Strain}}$ 's core cryptographic operations in Python. The source code is available for download [34].

In our measurements, we have set bid length  $\eta$  to 32 bit, allowing for either large bids or very fine-grained bids. For good security, we set the bit length of primes for Blum integers *n* to |p| = |q| = 768 bit. To achieve a small probability for soundness errors of  $2^{-40}$ , we choose  $\lambda' = \lambda'' = \kappa = 40$ . We have implemented the non-interactive versions of our ZK proofs and used SHA256 as hash function. All experiments were performed on a mostly idle Linux laptop with Intel i7-6560U CPU, clocked at 2.20 GHz. Our prototypical implementation uses only one core of the CPU's four virtual cores available, but we emphasize that our cryptographic operations can run independently in parallel, e.g., for each supplier. They scale linearly in the number of (virtual) cores.

Table 1 summarizes timings for cryptographic operations. All values are the average of ten runs. Relative standard deviation for each average was low with less than 9%. *Eval.* Inside the main for-loop in  $\Pi_{\text{Strain}}$ , operation Eval and computation of ZK proof ProofEval for A take roughly 0.5 s. Taking Ethereum's 15 s blockchain interval, a supplier could compute proofs for up to 30 other suppliers using a single core. Again, with the availability of x many cores, this number multiplies by x.

Auctioneer A executes VerifyEval for which we have implemented verification of homomorphic relations between Cs,  $\gamma$ s, and  $\Gamma$ s and (expensive) verification of encryptions for given random coins. Yet, verification is just (re-)computing GM encryptions with fixed coins which are included in  $P^{\text{Eval}}$ . As you can see, VerifyEval is very fast (15 ms), allowing roughly thousand comparisons in one Ethereum block interval.

*ProofShuffle.* As a supplier needs to compute ProofShuffle, we have modified Ogata et al. [29]'s standard shuffle to our setting. Very briefly, the idea of proving shuffle to be a re-encrypted shuffle of res in zero-knowledge is to generate  $\kappa$  re-encrypted intermediate shuffles  $shuffle'_i$  of res. For each intermediate shuffle  $shuffle'_i$ , the verifier ask *either* to show the permutation between res and  $shuffle'_i$  and all random coins used during re-encryption *or* to show the permutation between  $shuffle'_i$  and shuffle and shuffle and random coins used during re-encryption. Recall that re-encryption in our setting is simply multiplication with a random quadratic residue. Computing ProofShuffle is an expensive operation, taking 600 ms. Thus, in our non-optimized implementation, a supplier could prepare  $\approx 25$  proofs of shuffle per CPU core in one block interval. We stress that our modification to Ogata et al. [29]'s shuffle is straightforward and leave the design of more performance optimized shuffles for future work.

Note that  $Enc_{pk_A}$  is not GM encryption, but a regular hybrid encryption for auctioneer A, e.g., AES-ECC. As hybrid encryption is extremely fast compared to computation of our ZK proofs, we ignore it in our latency analysis.

*ProofEnc.* For the initial commitment of each supplier, we have adopted Katz [22]'s standard technique for proving plaintext knowledge to GM encryption. Again, we only summarize the main idea of our (straightforward) adoption. To prove knowledge of a single plaintext bit m, encrypted to GM ciphertext  $C = r^2 \cdot z^m$ , prover and verifier engage in a  $\kappa$ -round  $\Sigma$ -protocol. In each round i, the prover randomly chooses  $r_i$  and sends  $A_i = r_i^4$  to the verifier. The verifier replies by sending random bit  $q_i$ , and the prover concludes the proof by sending  $R_i = r^{q_i} \cdot r_i$ . The verifier accepts the round, if  $R_i^4 = A_i \cdot C^{2 \cdot q_i}$ . For our evaluation, we have implemented a non-interactive version of this  $\Sigma$ -protocol. Both, computation of the ZK proof (VerifyEnc) as well as its verification (VerifyEnc) are extremely fast, taking only 10 ms for all rounds and all encrypted bits together. Note that computation of this proof is independent of the number of suppliers and has to be performed only once per auction.

*ProofDLOG*. Albeit part of only the initial key distribution phase, we also include computation times for computation and verification of proof  $P^{\text{DLOG}}$ . In Table 1, ProofDLOG denotes the algorithm computing proof  $P^{\text{DLOG}}$ , and VerifyDLOG is the algorithm verifying  $P^{\text{DLOG}}$ , see Appendix A for details. These computations are efficient: within one block interval, a supplier can generate  $\approx 100$  shares for other suppliers and verify  $\approx 45$ .

Having in mind that our Python implementation is prototypical and not optimized for speed, we conclude that  $\Pi_{\text{Strain}}$ 's cryptographic operations are very efficient, allowing Strain's deployment in many short-term auction scenarios with dozens of suppliers.

#### 5.4 Optional: Preparation of Pseudonyms

To pseudonymously place a bid in Strain, suppliers must decouple their blockchain transactions from their regular key pair  $(pk_i, sk_i)$ . Ideally for each auction, supplier  $S_i$  generates a fresh random key pair  $(rpk_i, rsk_i)$  for bidding. In practice, e.g., with

Ethereum, this turns out to be a challenge. To interact with a smart contract,  $S_i$  must send a transaction. Yet, to mitigate DoS attacks in Ethereum, transactions cost money of the blockchain's virtual currency. If a fresh key pair wants to send a transaction, someone must send funds to it.  $S_i$  cannot send funds to their fresh key, as this would create a visible link between  $S_i$  and  $(rpk_i, rsk_i)$ .

Our idea is that A sends funds to keys that have previously been registered. To do so,  $S_i$  will register their fresh key pair  $(rpk_i, rsk_i)$  using a blind RSA signature. As a result,  $S_i$  has received a valid signature  $sig'_i$  of its random key  $rpk_i$ . Besides s, the adversary learns nothing about the  $rpk_i$ s.

All suppliers send their blinded  $rpk_i$  in parallel, and A then replies with blind signatures in parallel, too. Communication latency is constant in the number of suppliers s. Note that all suppliers must request a blind signature for a random  $rpk_i$ , regardless of whether a supplier is interested in an auction or not. If a supplier does not request a blind signature, the adversary knows that they will not participate in the auction.

After a supplier has recovered their key pair  $(rpk_i, rsk_i)$ , they broadcast it to the blockchain. All suppliers run a Dining Cryptographer network in parallel, see Appendix C. A supplier  $S_i$  interested in participating in the auction will broadcast  $(rpk_i, sig'_i)$ , and a supplier not interested will broadcast 0s.

As a result of the DC network, everybody knows fresh, random public keys of a list of suppliers participating in the auction. Due to A's signature, everybody knows that these suppliers are valid suppliers, but nobody can link a key  $rpk_i$  to supplier  $S_i$ . Starting from now, only suppliers interested in the auction will continue by submitting a bid and determining the winning bid. Running a DC network is communication efficient. That is, all suppliers submit their s powers of  $rpk_i$  in parallel in O(1) blocks.

Finally, A transfers money to each public key  $rpk_i$ , just enough such that suppliers can use their  $(rpk_i, rsk_i)$  keys to interact with the smart contract. Supplier  $S_i$  will use their new key pair  $(rpk_i, rsk_i)$  to pseudonymously participate in the rest of the protocol.

# 5.5 Security

For space reasons, we move the security analysis to Appendix B.

#### 6 Related Work

**MPC** Current maliciously-secure protocols of practical performance for *more than two* parties are based on secret shares [2]. They require at least as many rounds of interaction as the multiplicative depth of the circuit evaluated [26]. For comparisons this is the bit length  $\eta$  of the bids. Even for tiny auctions this will exceed Strain's total of four blocks. Constant-round MPC protocols, e.g. [26, 27], exceed four blocks already in their pre-computation phase before any comparison has taken place.

**Dedicated auction protocols** There exists a large number of specialized secure auctions protocols; for a survey see Brandt [8]. Among them, the one that compares closely to Strain is Brandt's very own auction protocol [7]. There, suppliers compute the winner of the auction, as with Strain, and the protocol requires a constant number of party interactions – as does Strain. However, Brandt encodes bids in unary notation making the protocol impractical for all but the simplest auctions. Instead, Strain encodes bids in binary notation, thus enabling efficient auctions for realistic bid values. Brandt cannot

guarantee output delivery which Strain does and which we consider crucially important in practice. Brandt claims full privacy in the malicious model, but formal verification has shown that this does not necessarily hold, cf. Dreier et al. [16].

Fischlin [20] also presents a variant of his main protocol which is secure against a malicious adversary. However, that variant requires an oblivious third party A providing a public/private key pair. All homomorphic computations in Fischlin's protocol are then performed under A's public key. Simulating A on the blockchain requires distributing the private key over multiple parties. As a result, one would need a secure, distributed computation of a Goldwasser-Micali key pair. Even for the case of RSA, this is complex and requires many rounds of interactions [5], rendering it impractical on a blockchain. Instead in Strain, each party creates its own key pair and only proves correct key sharing. Furthermore, even in case A's key has been set up, Fischlin's protocol still requires six rounds for each core comparison, whereas Strain requires only three (plus one for commitments) – a noticeable difference on the blockchain. We also stress that Fischlin's protocol targets a setup with 2 parties and cannot trivially be extended to multiple parties: 2 colluding malicious parties can convince oblivious party A of any outcome of the comparison they desire. In a multi-party setting, this allows an adversary to undermine the result of an auction, even after bids have been placed. Instead in this paper, we prove that Strain is secure against a collusion of up to  $\tau$  suppliers.

Cachin [9] presents a protocol for secure auctions based on the  $\Phi$ -hiding assumption. A variant secure against *one* malicious party (§3.3 in [9]) requires at least 7 blocks per comparison. Instead, Strain compares in only three blocks and supports both parties to be malicious during comparisons. Moreover similar to Fischlin [20]'s protocol, it is not trivial to extend [9] to support more than one fully malicious party. The auction protocol by Naor et al. [28] requires another trusted party (the auction issuer), is based on garbled circuits, therefore communication and computation inefficient, and secure only in the semi-honest model. Damgård et al. [14]'s auction considers the very different scenario of comparing a secret value m with a public integer m. The fully malicious party. Another version (§5.1 in [14]) only copes with up to one fully malicious party. Another version (§5.1 in [14]) addresses comparing secret inputs m and x, but only with semi-honest security.

# 7 Conclusion

Strain is a new protocol for secure auctions on blockchains. Strain allows, for the first time, to execute a sealed bid auction on a blockchain, secure against malicious bidders, with optional bidder anonymity, and guaranteed output delivery. Strain is efficient, and its main auction part runs in a constant number of blocks. Such low latency is crucial for practical adoption and a basis for a new implementation of sealed-bid auctions over blockchains where auction results can be observed by all participants.

# A Proofs of DLOG Equivalence

As the DDH assumption holds in group  $(\mathbb{J}_n, \cdot)$  for Blum integers *n* [12], we adopt standard ZK proofs of DLOG equivalence to our setting.

Let  $y, z \in \mathbb{J}_n$  and z be a generator of group  $(\mathbb{J}_n, \cdot)$ . A prover knows an integer  $\sigma$  such that  $y^{\sigma} = \gamma \mod n$  and  $z^{\sigma} = \zeta \mod n$ . For public values  $\{y, z, \gamma, \zeta\}$ , the prover wants to compute the statement  $\log_y \gamma = \log_z \zeta$  to a verifier in zero-knowledge, i.e., without revealing any additional information about  $\sigma$ . This boils down to Chaum and Pedersen's ZK proof that  $(y, z, Y = y^{\sigma}, Z = z^{\sigma})$  is a DDH tuple [11]. The protocol runs in  $\kappa$  rounds.

In each round, (1) The prover computes  $r \stackrel{\$}{\leftarrow} \mathbb{J}_n$  and sends  $(t_1 = y^r, t_2 = z^r)$  to the verifier. (2) The verifier sends challenge  $c \stackrel{\$}{\leftarrow} \mathbb{J}_n$  to the prover. (3) The prover sends  $s = r + c \cdot \sigma$  to the verifier. (4) The verifier checks  $y^s \stackrel{?}{=} t_1 \cdot Y^c \wedge z^s \stackrel{?}{=} t_2 \cdot Z^c$ . If the check fails, the verifier outputs  $\bot$ .

We target non-interactive ZK proofs, so challenge c can be replaced in round  $i \le \kappa$ by a random oracle call  $c = H(y, z, Y, Z, t_1, t_2, i)$  [19]. Let  $P^{\mathsf{DLOG}}$  be an initially empty proof. For each round, the prover would add  $t_1, t_2$ , and s to  $P^{\mathsf{DLOG}}$ , and then send  $P^{\mathsf{DLOG}}$ to the verifier. Note that, if  $z = -1 \mod n$ , as in our main protocol, then  $z = -(1^2)$  is indeed a generator of  $\mathbb{J}_n$ . This ZK proof is secure in the random oracle model.

# **B** Security Analysis

We now prove Theorem 1. Our proof is a simulation-based proof in the hybrid model [25]. In the hybrid model, simulator S generates messages of honest parties interacting with malicious parties and the trusted third party TTP. Since the simulator does not use inputs of honest parties (except for forwarding to the TTP which does not leak any information), it is ensured that the protocol does not reveal any information except the result, i.e., the output of the TTP. Messages generated by the simulator must be indistinguishable from messages in the real execution of the protocol.

*Proof.* Let S be the set of all suppliers and  $\overline{S}$  be the suppliers controlled by adversary  $\mathcal{A}_1$ . We prove  $IDEAL_{\mathcal{F}_{Bid},\mathcal{S},\overline{S}}(v_1,...,v_s) \equiv REAL_{\Pi_{\text{Strain}},\mathcal{A},\overline{S}}(v_1,...,v_s)$ .

We either establish pseudonymous (broadcast) channels over the blockchain using the protocol of Section 5.4 or use regular authenticated channels.

I) In the first step of the protocol, honest suppliers  $S \setminus \overline{S}$  commit to random bids  $r_i$  and publish corresponding ZK proofs  $P_i^{\text{enc}}$  on the blockchain. The simulator reads  $P_{\overline{i}}^{\text{enc}}$  of the malicious parties  $\overline{S}$  from the blockchain. Using the extractor for the zero-knowledge argument, the simulator extracts  $v_{\overline{i}}$ . The simulator sends all  $v_i$ (including those of the honest parties) to the TTP. The simulator receives from the TTP results  $cmp_{i,i}$  of all comparisons and winning bid  $v_w$  for auctioneer A.

II) For each honest party  $S_i \in S \setminus \overline{S}$ , the simulator prepares a message of random AND-homomorphic encryptions  $res_{j,i}$  following Fischlin's circuit output and the result of the comparison  $cmp_{j,i}$ . The simulator also invokes the simulator  $\operatorname{Sim}_{P_{j,i}^{\operatorname{eval}}}^{A(\{C_i,C_j\})}(res_{j,i})$  which is guaranteed to exist. Then, the simulator sends the messages to the blockchain. For each malicious party  $S_{\overline{i}} \in \overline{S}$  that is still active, the simulator reads  $P_{j,\overline{i}}^{\operatorname{eval}}$  and  $res_{j,\overline{i}}$  from the blockchain. If judge A determines that  $\operatorname{VerifyEval}(P_{j,\overline{i}}^{\operatorname{eval}}, res_{j,\overline{i}}, C_j, C_{\overline{i}})$  does not check, it publishes  $\bot$  on the blockchain, and supplier  $S_{\overline{i}}$  is dropped from the auction. We describe later how we deal with suppliers aborting the protocol.

III) For each honest party  $S_i \in S \setminus \overline{S}$ , the simulator prepares a message of random AND-homomorphic encryptions  $shuffle_{i,j}$  following Fischlin's circuit output and the result of the comparison  $cmp_{i,j}$ . The simulator also invokes simulator  $Sim_{P^{shuffle}}(shuffle_{i,j})$  for the shuffle ZK proof. It also opens the corresponding ciphertexts  $\gamma_{\ell,m} \in shuffle_{i,j}$ . Then the simulator sends the messages to the blockchain. For each malicious party  $S_{\overline{i}} \in \overline{S}$ , the simulator reads  $P^{\text{shuffle}}_{\overline{i},j}$ ,  $shuffle_{\overline{i},j}$ ,  $\beta_{\ell,m}$ , and  $r_{\ell,m}$ from the blockchain. In case VerifyShuffle $(P^{\text{shuffle}}_{\overline{i},j}, shuffle_{\overline{i},j}, res_{\overline{i},j})$  does not check, the supplier  $S_{\overline{i}}$  is dropped from the auction. If encrypting plaintexts  $\beta_{\ell,m}$  and random coins  $r_{\ell,m}$  do not result in  $shuffle_{\overline{i},j}$ , supplier  $S_{\overline{i}}$  is dropped from the auction.

*IV*) If the winner  $S_w$  of the auction is honest, i.e.,  $S_w \in S \setminus \overline{S}$ , then the simulator invokes the simulator for the ZK proof and sends it and  $v_w$  (received from the TTP) to auctioneer A. In case the ZK proof does not check,  $S_w$  is removed from the auction. If the winner  $S_w$  of the auction is malicious, i.e.,  $S_w \in \overline{S}$ , then the simulator receives the winning bid value  $v_w$  and the ZK proof that it corresponds to commitment  $C_w$ . If the ZK proof does not check,  $S_w$  is removed from the auction.

It remains to show that there exists is a simulator for the view of  $\mathcal{A}_2$  (the semi-honest auctioneer/judge A): in the first step of the protocol,  $\mathcal{A}_2$  receives IND-CPA secure ciphertexts and zero-knowledge proofs  $P^{\text{enc}}$ . In the second step  $\mathcal{A}_2$  receives further IND-CPA secure ciphertexts and zero-knowledge proofs  $P^{\text{eval}}$ . We have shown in Section 4.2 that  $P^{\text{eval}}$  is zero-knowledge for the auctioneer. In the third step  $\mathcal{A}_2$  receives IND-CPA secure ciphertexts, ZK proofs  $P^{\text{shuffle}}$  and the opened plaintext and randomness of some ciphertexts. The plaintexts are either all 1 or all 0 depending on  $cmp_{i,j}$ , and the randomness can be chosen consistently for each ciphertext. Finally,  $\mathcal{A}_2$  receives  $v_w$  and the ZK proof of plaintext equality to  $C_w$ . Hence the view of  $\mathcal{A}_2$  is simulatable from the TTP's output, i.e., the set of results of comparisons  $\{cmp_{i,j}\}$  and winning bid  $v_w$ .  $\Box$ 

*Dealing with Early Aborts.* Strain is particularly suitable for the blockchain, as it can handle any early abort after bids have been committed. Assume supplier  $S_{\overline{i}}$  has aborted the protocol or has been caught cheating. Then, all others suppliers  $S_i$  can recover its

bid  $v_{\overline{i}}$  using the shares of its private key  $sk_{\overline{i}}^{\text{GM}}$  from commitment  $C_{\overline{i}} = \text{Enc}_{PK_{\overline{i}}}^{\text{GM}}(v_{\overline{i}})$ . We emphasize that our bid opening is secure against malicious suppliers due to ZK-proof  $P^{\text{DLOG}}$ . Suppliers publish  $v_{\overline{i}}$  on the blockchain, and, after the bidding protocol, winning supplier  $S_w$  reveals bid  $v_w$  to semi-honest auctioneer A (proving plaintext equality to commitment  $C_w$  in zero-knowledge). The auctioneer compares  $v_w$  to all opened bids  $v_{\overline{i}}$  and, in case, chooses a different winner w'. Hence, after commitments have been sent to the blockchain, no supplier can abort the auction. Even worse, aborting the auction reveals one's bid to all other suppliers.

### C Dining Cryptographer Networks

A standard technique we use as an ingredient in Strain is a Dining Cryptographer (DC) network [10]. If out of a set of s parties (suppliers)  $\{S_1, ..., S_s\}$  exactly one party  $S_i$  wants to broadcast their message  $m_i$  to all other parties, a DC network guarantees delivery of  $m_i$  to all other parties without revealing i, i.e., who has sent  $m_i$ .

Assume that all parties have exchanged pairwise secret keys  $k_{i,j}$  with each other. In a single round of a DC network, parties communicate in a daisy chain where party  $S_i$  sends a sum  $sum_i$  to party  $S_{i+1}$ . Upon receipt,  $S_{i+1}$  superposes  $sum_i$  with their own data and sends  $sum_{i+1}$  to  $S_{i+2}$ . Again,  $S_{i+2}$  superposes  $sum_{i+1}$  with their own data and sends  $sum_{i+2}$  to  $S_3$  and so on. Superposing in our case is simple: each party  $S_i$  XORs all pairwise keys  $k_{i,j}$  of all other parties  $S_j$  to whatever previous party  $S_{i-1}$  has broadcast. Only the one party  $S_*$  that wants to publish message  $m_*$  additionally XORs  $m_*$  to the previous sum. The last XOR of all data sent cancels out keys  $k_{i,j}$ , and  $m_*$  remains. So, a one round DC network allows one party to disseminate a single message, protected by the DC network. Message  $m_*$  is public, but the sender's identity is protected. Therewith, one supplier can anonymously disseminate their public key, and everybody knows that this is a new valid key from one of the suppliers.

Daisy chain communication can trivially be replaced by per party broadcasts, e.g., publishing to the blockchain. The advantage of using the blockchain is efficiency: all parties can broadcast their sums at the same time.

Multiple messages. To disseminate multiple parties' messages, several different strategies exist to resolve collisions in DC networks [10]. In Strain, we employ the approach by Bos and den Boer [6]. Assume that each party  $S_i$  has exchanged s-1 different pairwise keys  $k_{i,j,u}, 1 \le u \le s-1$  with each other party  $S_j$ . Now, party  $S_i$  broadcasts all s powers  $< m_i^1, ..., m_i^n >$  of their message  $m_i$  protected by the DC network. Instead of XORing messages broadcast with keys for protection, we now operate over  $GF(2^q), q \ge$ |m|, and use the following trick to cancel out keys. To protect the  $u^{\text{th}}$  power  $m_i^u$  of  $m_i$ ,  $S_i$  adds all keys  $k_{i,j,u}$  for j > i to  $K_{i,u}$  and subtracts keys  $k_{i,j,u}$  for j < i from  $K_{i,u}$ .  $S_i$ broadcasts  $m_i^u + K_{i,u}$ . All parties compute power sums  $p_u(m_1,...,m_s) = \sum_{i=1}^s m_i^u, 1 \le$  $u \le s$ . Each party uses Newton identities to compute  $m_i$  from power sums. All parties publish their output at the same time in parallel which is very efficient on a blockchain.

For space reasons, we do not discuss standard approaches realizing fully-malicious security for DC networks. These approaches use "traps" to identify and blame other parties, see, e.g., [6, 37, 38] for an overview.
