May 19, 2017

Abstract

In this work, we present two new universally composable, actively secure, constant round multi-party protocols for generating BMR garbled circuits with free-XOR and reduced costs.

1. Our first protocol takes a generic approach using any secret-sharing based MPC protocol for binary circuits, and a correlated oblivious transfer functionality.
2. Our specialized protocol uses secret-sharing based MPC with information-theoretic MACs. This approach is less general, but requires no additional correlated OTs to compute the garbled circuit.

In both approaches, the underlying secret-sharing based protocol is only used for *one secure \mathbb{F}_2 multiplication per AND gate*. An interesting consequence of this is that, with current techniques, constant round MPC for binary circuits is not much more expensive than practical, non-constant round protocols.

We demonstrate the practicality of our second protocol with an implementation, and perform experiments with up to 9 parties securely computing the AES and SHA-256 circuits. Our running times improve upon the best possible performance with previous BMR-based protocols by 60 times.

1 Introduction

Secure multi-party computation (MPC) protocols allow a group of n parties to compute some function f on the parties' private inputs, while preserving a number of security properties such as *privacy* and *correctness*. The former property implies data confidentiality, namely, nothing leaks from the protocol execution but the computed output. The latter requirement implies that the protocol enforces the integrity of the computations made by the parties, namely, honest parties learn the correct output. Modern, practical MPC protocols typically fall into two main categories: those based on secret-sharing [GMW87, RBO89, BOGW88, DN07, IPS09, DPSZ12], and those based on garbled circuits [Yao86, BMR90, LP07, KS08, LP09, LP11, CKMZ14, MRZ15]. When it comes to choosing a protocol, many different factors need to be taken into account, such as the function being evaluated, the latency and bandwidth of the network and the adversary model.

Secret-sharing based protocols such as [GMW87, BOGW88, DPSZ12] tend to have lower communication requirements in terms of bandwidth, but require a large number of rounds of communication, which increases with the complexity of the function. In this approach the parties first secret-share their inputs and then evaluate the circuit gate by gate while preserving privacy and correctness. In low-latency networks, they can have an extremely fast online evaluation stage, but the round complexity makes them much less suited to high-latency networks, when the parties may be far apart.

Garbled circuits, introduced in Yao's protocol [Yao86], are the core behind all practical, constant round protocols for secure computation. In the two-party setting, one of the parties "encrypts" the circuit being evaluated, whereas the other party privately evaluates it. Garbled circuit-based protocols have recently become much more efficient, and currently give the most practical approach for actively secure computation of binary circuits [RR16, NST17]. With more than two parties, the situation is more complex, as the garbled circuit must be computed by all parties in a distributed manner using another (non-constant-round) MPC protocol, as in the BMR protocol from [BMR90]. This still leads to a low depth circuit, hence a constant round protocol overall, because all gates can be garbled in parallel. We note that this paradigm has received very little attention, compared with two-party protocols. The original BMR construction uses generic zero-knowledge techniques for proving correct computation of PRG values, so is impractical. A different protocol, but only for three parties, was designed by Choi et al. [CKMZ14] in the dishonest majority setting. More practical, actively secure protocols for any number of parties are the recent works of Lindell et al. [LPSY15, LSS16], which use somewhat homomorphic encryption (SHE) or generic MPC to garble a circuit. Ben-Efraim et al. [BLO16] recently presented and implemented an efficient multi-party garbling protocol based on oblivious transfer, but with only semi-honest security. Very recently, Katz et al. introduced in [KRW17] protocols based on authenticated garbling, with a preprocessing phase that can be instantiated based on TinyOT [NNOB12].

1.1 Our Contributions

In this work, we present a practical, actively secure, constant round multi-party protocol for generating BMR garbled circuits with free-XOR in the presence of up to $n - 1$ out of n corruptions. As in prior constructions, our approach has two phases: a preprocessing phase where the garbled circuit is mutually generated by all parties, and an online phase where the parties obtain the output of the computation. While the online phase is typically efficient and incurs no cost to achieve active security, the focus of recent works was on optimizing the preprocessing complexity, where the main bottleneck is with respect to garbling AND gates. In that context, we present two new constant-round protocols for securely generating the garbled circuit:

1. A generic approach using any secret-sharing based MPC protocol for binary circuits, and a correlated

oblivious transfer functionality.

2. A specialized protocol which uses secret-sharing based MPC with information-theoretic MACs, such as TinyOT [NNOB12, FKOS15]. This approach is less general, but requires no additional correlated OTs to compute the garbled circuit.

In both approaches, the underlying secret-sharing based protocol is only used for *one secure* \mathbb{F}_2 multiplication per AND gate.

In the first, more general method, every pair of parties needs to run one correlated OT per AND gate, which costs $O(\kappa)$ communication. This gives an overall communication cost of $O(|C|(M + \kappa n^2))$ to evaluate a circuit C , where M is the cost of evaluating an AND gate in the secret-sharing based protocol, Π . Instantiating Π with GMW and the IPS compiler [IPS08] gives total complexity $O(|C|\kappa n^2)$, assuming only symmetric primitives and $O(\kappa)$ seed OTs between every pair of parties. To the best of our knowledge, this is the *first* protocol with this complexity under these general assumptions.¹ Another interesting candidate for instantiating Π would be to use an MPC protocol optimized for SIMD binary circuits such as MiniMAC [DZ13]. This is because in our construction, all the AND gates can be computed in parallel. Currently, the only known preprocessing methods [FKOS15] for MiniMAC are not practical, but this seems to be an interesting future direction to explore.

TinyOT is currently the most practical approach to secret-sharing based MPC on binary circuits, so the second method leads to a highly practical protocol for constant-round secure computation. The complexity is essentially the same as TinyOT, as here we do not require any additional OTs. However, the protocol is less general and has worse asymptotic complexity, since TinyOT costs either $O(|C|B\kappa n^2)$ (with 2 parties or the recent protocol of [WRK17]), or $O(|C|B^2\kappa n^2)$ (with [FKOS15]), where $B = O(1 + s/\log |C|)$ (and in practice is between 3–5), and s is the statistical security parameter.

Our constructions employ several very appealing features. For a start, we embed into the modeling of the preprocessing functionality, which computes the garbled circuit, an additive error introduced into the garbling by the adversary. Concretely, we extend the functionality from [LPSY15] so that it obtains a vector of additive errors from the adversary to be applied to each garbled gate, which captures the fact that the adversary may submit inconsistent keys and pseudorandom function (PRF) values. We further strengthen this by allowing the adversary to pick the error *adaptively* after seeing the garbled circuit (in prior constructions this error is independent of the garbling) and allowing corrupt parties to choose their own PRF keys, possibly not at random. This requires a new analysis and proof of the online phase.

Secondly, we devise a new consistency check to enforce correctness of inputs to correlated OT, which is based on very efficient linear operations similar to recent advances in homomorphic commitments [CDD⁺16]. This check, combined with our improved error analysis for the online phase, allows the garbled circuit to be created without authenticating any of the parties' keys or PRF values, which removes a significant cost from previous works (saving a factor of $\Omega(n)$).

Implementation. We demonstrate the practicality of our TinyOT-based protocol with an implementation, and perform experiments with up to 9 parties securely computing the AES and SHA-256 circuits. In a 1Gbps LAN setting, we can securely compute the AES circuit with 9 parties in just 620ms. This improves upon the best possible performance that would be attainable using [LPSY15] by around 60 times. The details of our implementation can be found in Section 6.

¹This is with exception to the concurrent work by Katz et al. [KRW17]; see more discussion in Section 1.2.1.

Protocol	Based on	Free XOR	Comms. per Garbled Gate
SPDZ-BMR [LPSY15]	SHE + ZKPoPK	✗	$O(n^4\kappa)$
SHE-BMR [LSS16]	SHE (depth 4) + ZKPoPK	✗	$O(n^3\kappa)$
MASCOT-BMR-FX	OT	✓	$O(n^3\kappa^2)$
This work §3	OT + [IPS08]	✓	$O(n^2\kappa)$
This work §4	TinyOT	✓	$O(n^2B^2\kappa)$
[KRW17] (concurrent)	Optimized TinyOT	✓	$O(n^2B\kappa)$

Table 1: Comparison of actively secure, constant round MPC protocols. $B = O(1 + s/\log |C|)$ is a cut-and-choose parameter, which in practice is between 3–5. Our second protocol can also be based upon optimized TinyOT to obtain the same complexity as [KRW17].

1.1.1 Comparison with Other Approaches

Table 1 shows how our work compares with other actively secure, constant-round protocols. As mentioned earlier, most previous constructions express the garbling function as an arithmetic circuit over a large finite field. In these protocols, garbling even a single AND gate requires computing $O(n)$ multiplications over a large field with SHE or MPC. This means they scale at least cubically in the number of parties. In contrast, our protocol only requires one \mathbb{F}_2 multiplication per AND gate, so scales with $O(n^2)$. Previous SHE-based protocols also require zero-knowledge proofs of plaintext knowledge of SHE ciphertexts, which in practice are very costly. Note that the recent MASCOT protocol [KOS16] for secure computation of arithmetic circuits could also be used in [LPSY15], instead of SHE, but this still has very high communication costs. We denote by MASCOT-BMR-FX an optimized variant of [LPSY15], modified to use free-XOR as in our protocol, with multiplications in \mathbb{F}_{2^κ} done using MASCOT. Finally, the recent concurrent work by Katz et al. [KRW17] is based on an optimized variant of TinyOT, with comparable performance to our approach.

None of these previous works have reported implementations at the time of writing, but our implementation of the TinyOT-based protocol improves upon the best times that would be achievable with SPDZ-BMR and MASCOT by up to 60x. This is because our protocol has lower communication costs than [LPSY15] (by at least 2 orders of magnitude) and the main computational costs are from standard symmetric primitives, so far cheaper than using SHE.

Overall, our protocols significantly narrow the gap between the cost of constant-round and many-round MPC protocols for binary circuits. More specifically, this implies that, with current techniques, constant round MPC for binary circuits is not much more expensive than practical, non-constant round protocols. Additionally, both of our protocols have potential for future improvement by optimizing existing non-constant round protocols: a practical implementation of MiniMAC [DZ13] would lead to a very efficient approach with our generic protocol, whilst any future improvements to multi-party TinyOT would directly give a similar improvement to our second protocol.

1.2 Technical Overview

Our protocol is based on the recent free-XOR variant of BMR garbling used for semi-honest MPC in [BLO16]. In that scheme, a garbling of the g -th AND gate with input wires u, v and output wire w , consists of the $4n$ values (where n is the number of parties):

$$\tilde{g}_{a,b}^j = \left(\bigoplus_{i=1}^n F_{k_{u,a}^i, k_{v,b}^i}(g\|j) \right) \oplus k_{w,0}^j \quad (1)$$

$$\oplus (R^j \cdot ((\lambda_u \oplus a) \cdot (\lambda_v \oplus b) \oplus \lambda_w)), \quad (a, b) \in \{0, 1\}^2, j \in [n]$$

Here, F is a double-key PRF, $R^j \in \{0, 1\}^\kappa$ is a fixed correlation string for free-XOR known to party P_j , and the keys $k_{u,a}^j, k_{v,b}^j \in \{0, 1\}^\kappa$ are also known to P_j . Furthermore, the wire masks $\lambda_u, \lambda_v, \lambda_w \in \{0, 1\}^\kappa$ are random, additively secret-shared bits known by no single party.

The main idea behind BMR is to compute the garbling, except for the PRF values, with a general MPC protocol. The analysis of [LPSY15] showed that it is not necessary to prove in zero-knowledge that every party inputs the correct PRF values to the MPC protocol that computes the garbling. This is because when evaluating the garbled circuit, each party P_j can check that the decryption of the j -th entry in every garbled gate gives one of the keys $k_{w,b}^j$, and this check would overwhelmingly fail if any PRF value was incorrect. It further implies that the adversary cannot flip the value transmitted through some wire as that would require from it to guess a key.

Our garbling protocol proceeds by computing a random, *unauthenticated*, additive secret sharing of the garbled circuit. This differs from previous works [LPSY15, LSS16], which obtain *authenticated* (with MACs, or SHE ciphertexts) sharings of the entire garbled circuit. Our protocol greatly reduces this complexity, since the PRF values and keys (on the first line of equation (1)) do not need to be authenticated. The main challenge, therefore, is to compute shares of the products on the second line of (1). Similarly to [BLO16], a key observation that allows efficiency is the fact that these multiplications are either between two secret-shared bits, or a secret-shared bit and a fixed, secret string. So, we do not need the full power of an MPC protocol for arithmetic circuit evaluation over \mathbb{F}_{2^κ} or \mathbb{F}_p (for large p), as used in previous works.

To compute the bit product $\lambda_u \cdot \lambda_v$, we can use any actively secure GMW-style MPC protocol for binary circuits. This protocol is only needed for computing *one secure AND per garbled AND gate*, since all bit products in $\tilde{g}_{a,b}^j$ can be computed as linear combinations of $\lambda_u \cdot \lambda_v$, λ_u and λ_v . We then need to multiply the resulting secret-shared bits by the string R^j , known to P_j . We give two variants for computing this product, the first one being more general and the second more concretely efficient. In more details,

1. The first solution performs the multiplication by running actively secure correlated OT between P_j and every other party, where P_j inputs R^j as the fixed OT correlation. The parties then run a consistency check by applying a universal linear hash function to the outputs and sacrificing a few OTs, ensuring the correct inputs were provided to the OT. This protocol is presented in Section 3.
2. The second method requires using a ‘TinyOT’-style protocol [FKOS15, BLN⁺15] based on information-theoretic MACs, and allows us to compute the bit/string products directly from the MACs, provided each party’s MAC key is chosen to be the same string R^j used in the garbling. This saves interaction since we do not need any additional OTs. This protocol is presented in Section 4.

After creating shares of all these products, the parties can compute shares of the whole garbled circuit. These shares must then be rerandomized, before they can be broadcast. Opening the garbled circuit in this way allows a corrupt party to introduce further errors into the garbling by changing their share, even *after learning the correct garbled circuit*, since we may have a rushing adversary. Nevertheless, we prove that the BMR online phase remains secure when this type of error is allowed, as it would only lead to an abort. This

significantly strengthens the result from [LPSY15], which only allowed corrupt parties to provide incorrect PRF values, and is an important factor that allows our preprocessing protocol to be so efficient.

1.2.1 Concurrent Work

Two recent works by Katz, Ranellucci and Wang introduced constant round, two-party [WRK17] and multi-party [KRW17] protocols based on *authenticated garbling*, with a preprocessing phase that can be instantiated based on TinyOT. At the time of writing, their two-party paper also reports on an implementation, but the multi-party version does not. Our work is conceptually quite similar, since both involve generating a garbled circuit in a distributed manner using TinyOT. The main difference seems to be that our protocol is symmetric, since all parties evaluate the same garbled circuit. With authenticated garbling, the garbled circuit is only evaluated by one party. This makes the garbled circuit slightly smaller, since there are $n - 1$ sets of keys instead of n , but the online phase requires at least one more round of interaction (if all parties learn the output). The works of Katz et al. also contain concrete and asymptotic improvements to the two-party and multi-party TinyOT protocols, which improves upon our protocol in Appendix A by a factor of $O(s/\log |C|)$ where s is a statistical parameter. These improvements can be directly plugged into our second garbling protocol. We remark that the two-party protocol in [WRK17] inspired our use of TinyOT MACs to perform the bit/string multiplications in our protocol from Section 4. The rest of our work is independent.

Another difference is that our protocol from Section 3 is more generic, since $\mathcal{F}_{\text{BitMPC}}$ can be implemented with *any* secret-sharing based bit-MPC protocol, rather than just TinyOT. This can be instantiated with [IPS08] to obtain an OT-based constant-round protocol with complexity $O(|C|\kappa n^2)$. The analogous two-party result from [WRK17] achieves the same complexity under less general assumptions such as the Φ -hiding problem, due to the need for constant rate bit-OT. The second multi-party paper [KRW17] does not have an analogous generic MPC protocol.

2 Preliminaries

We denote the security parameter by κ . We say that a function $\mu : \mathbb{N} \rightarrow \mathbb{N}$ is *negligible* if for every positive polynomial $p(\cdot)$ and all sufficiently large κ it holds that $\mu(\kappa) < \frac{1}{p(\kappa)}$. We use the abbreviation PPT to denote probabilistic polynomial-time. We further denote by $a \leftarrow A$ the uniform sampling of a from a set A , and by $[d]$ the set of elements $(1, \dots, d)$. We often view bit-strings in $\{0, 1\}^k$ as vectors in \mathbb{F}_2^k , depending on the context, and denote exclusive-or by “ \oplus ” or “ $+$ ”. If $a, b \in \mathbb{F}_2$ then $a \cdot b$ denotes multiplication (or AND), and if $c \in \mathbb{F}_2^k$ then $a \cdot c \in \mathbb{F}_2^k$ denotes the product of a with every component of c .

For vectors $\mathbf{x} = (x_1, \dots, x_n) \in \mathbb{F}_2^n$ and $\mathbf{y} \in \mathbb{F}_2^m$, the *tensor product* (or *outer product*) $\mathbf{x} \otimes \mathbf{y}$ is defined as the $n \times m$ matrix over \mathbb{F}_2 where the i -th row is $x_i \cdot \mathbf{y}$. We use the following property.

Fact 2.1 *If $\mathbf{x} \in \mathbb{F}_2^n$, $\mathbf{y} \in \mathbb{F}_2^m$ and $\mathbf{M} \in \mathbb{F}_2^{m \times n}$ then*

$$\mathbf{M} \cdot (\mathbf{x} \otimes \mathbf{y}) = (\mathbf{M} \cdot \mathbf{x}) \otimes \mathbf{y}.$$

We next specify the definition of computational indistinguishability.

Definition 2.1 *Let $X = \{X(a, \kappa)\}_{a \in \{0,1\}^*, \kappa \in \mathbb{N}}$ and $Y = \{Y(a, \kappa)\}_{a \in \{0,1\}^*, \kappa \in \mathbb{N}}$ be two distribution ensembles. We say that X and Y are computationally indistinguishable, denoted $X \stackrel{c}{\approx} Y$, if for every PPT machine \mathcal{D} and every $a \in \{0, 1\}^*$, there exists a negligible function negl such that:*

$$|\Pr[\mathcal{D}(X(a, \kappa), a, 1^\kappa) = 1] - \Pr[\mathcal{D}(Y(a, \kappa), a, 1^\kappa) = 1]| < \text{negl}(\kappa).$$

2.1 Pseudorandom Functions

The BMR garbling technique from [LPSY15] is proven secure based on a pseudorandom function (PRF) with multiple keys, defined below.

Definition 2.2 *Let $F : \{0, 1\}^n \times \{0, 1\}^n \mapsto \{0, 1\}^n$ be an efficient, length preserving, keyed function. F is a pseudorandom function under multiple keys if for all polynomial-time distinguishers \mathcal{D} , there exists a negligible function negl such that:*

$$|\Pr[\mathcal{D}^{F_{\bar{k}}(\cdot)}(1^\kappa) = 1] - \Pr[\mathcal{D}^{\bar{f}(\cdot)}(1^\kappa) = 1]| \leq \text{negl}(\kappa).$$

where $F_{\bar{k}} = F_{k_1}, \dots, F_{k_{m(n)}}$ are the pseudorandom function F keyed with polynomial number of randomly chosen keys $k_1, \dots, k_{m(n)}$ and $\bar{f} = f_1, \dots, f_{m(n)}$ are $m(n)$ random functions from $\{0, 1\}^n \mapsto \{0, 1\}^n$. The probability in both cases is taken over the randomness of \mathcal{D} as well.

When the keys are independently chosen then security with multiple keys is implied by the standard security PRF notion, by a simple hybrid argument. However, since our scheme supports free-XOR, we require assuming a stronger notion, discussed next.

2.2 Circular 2-Correlation Robust PRF

We adapt the definition of correlation robustness with circularity from [CKKZ12] given for hash functions to double-key PRFs. This definition captures the related key and circularity requirements induced by supporting the free-XOR technique. Formally, fix some function $F : \{0, 1\}^n \times \{0, 1\}^\kappa \times \{0, 1\}^\kappa \mapsto \{0, 1\}^\kappa$. We define an oracle Circ_R as follows:

- $\text{Circ}_R(k_1, k_2, g, j, b_1, b_2, b_3)$ outputs $F_{k_1 \oplus b_1 R, k_2 \oplus b_2 R}(g \| j) \oplus b_3 R$.

The outcome of oracle Circ is compared with the a random string of the same length computed by an oracle Rand :

- $\text{Rand}(k_1, k_2, g, j, b_1, b_2, b_3)$: if this input was queried before then return the answer given previously. Otherwise choose $u \leftarrow \{0, 1\}^\kappa$ and return u .

Definition 2.3 (Circular 2-correlation robust PRF) *A PRF F is circular 2-correlation robust if for any non-uniform polynomial-time distinguisher \mathcal{D} making legal queries to its oracle, there exists a negligible function negl such that:*

$$|\Pr[R \leftarrow \{0, 1\}^\kappa; \mathcal{D}^{\text{Circ}_R(\cdot)}(1^\kappa) = 1] - \Pr[\mathcal{D}^{\text{Rand}(\cdot)}(1^\kappa) = 1]| \leq \text{negl}(\kappa).$$

As in [CKKZ12], some trivial queries must be ruled out. Specifically, the distinguisher is restricted as follows: (1) it is not allowed to make any query of the form $\mathcal{O}(k_1, k_2, g, j, 0, 0, b_3)$ (since it can compute $F_{k_1, k_2}(g \| j)$ on its own) and (2) it is not allowed to query both tuples $\mathcal{O}(k_1, k_1, g, j, b_1, b_2, 0)$ and $\mathcal{O}(k_1, k_1, g, j, b_1, b_2, 1)$ for any values k_1, k_2, g, j, b_1, b_2 (since that would allow it to trivially recover the global difference). We say that any distinguisher respecting these restrictions makes legal queries.

2.3 Almost-1-Universal Linear Hashing

We use a family of almost-1-universal linear hash functions over \mathbb{F}_2 , defined by:

Definition 2.4 (Almost-1-Universal Linear Hashing) We say that a family \mathcal{H} of linear functions $\mathbb{F}_2^m \rightarrow \mathbb{F}_2^s$ is ε -almost 1-universal, if it holds that for every non-zero $\mathbf{x} \in \mathbb{F}_2^m$ and for every $\mathbf{y} \in \mathbb{F}_2^s$:

$$\Pr_{\mathbf{H} \leftarrow \mathcal{H}} [\mathbf{H}(\mathbf{x}) = \mathbf{y}] \leq \varepsilon$$

where \mathbf{H} is chosen uniformly at random from the family \mathcal{H} . We will identify functions $\mathbf{H} \in \mathcal{H}$ with their $s \times m$ transformation matrix, and write $\mathbf{H}(\mathbf{x}) = \mathbf{H} \cdot \mathbf{x}$.

This definition is slightly stronger than a family of almost-universal linear hash functions (where the above need only hold for $\mathbf{y} = 0$, as in [CDD⁺16]). However, this is still much weaker than 2-universality (or pairwise independence), which a linear family of hash functions cannot achieve, because $\mathbf{H}(0) = 0$ always. The two main properties affecting the efficiency of a family of hash functions are the *seed size*, which refers to the length of the description of a random function $\mathbf{H} \leftarrow \mathcal{H}$, and the *computational complexity* of evaluating the function. The simplest family of almost-1-universal hash functions is the set of all $s \times m$ matrices; however, this is not efficient as the seed size and complexity are both $O(m \cdot s)$. Recently, in [CDD⁺16], it was shown how to construct a family with seed size $O(s)$ and complexity $O(m)$, which is asymptotically optimal. A more practical construction is a polynomial hash based on GMAC (used also in [NST17]), described as follows (here we assume that s divides m , for simplicity):

- Sample a random seed $\alpha \leftarrow \mathbb{F}_{2^s}$
- Define \mathbf{H}_α to be the function:

$$\mathbf{H}_\alpha : \mathbb{F}_{2^s}^{m/s} \rightarrow \mathbb{F}_{2^s}, \quad \mathbf{H}_\alpha(x_1, \dots, x_{m/s}) = \alpha \cdot x_1 + \alpha^2 \cdot x_2 + \dots + \alpha^{m/s} \cdot x_{m/s}$$

Note that by viewing elements of \mathbb{F}_{2^s} as vectors in \mathbb{F}_2^s , multiplication by a fixed field element $\alpha^i \in \mathbb{F}_{2^s}$ is linear over \mathbb{F}_2 . Therefore, \mathbf{H}_α can be seen as an \mathbb{F}_2 -linear map, represented by a unique matrix in $\mathbb{F}_2^{s \times m}$.

Here, the seed is short, but the computational complexity is $O(m \cdot s)$. However, in practice when $s = 128$ the finite field multiplications can be performed very efficiently in hardware on modern CPUs. Note that this gives a 1-universal family with $\varepsilon = \frac{m}{s} \cdot 2^{-s}$. This can be improved to 2^{-s} (i.e. perfect), at the cost of a larger seed, by using m/s distinct elements α_i , instead of powers of α .

2.4 Security Model

Universal composability. We prove security of our protocols in the universal composability (UC) framework [Can01] (see also [CCL15] for a simplified version of UC). This framework is based on the real/ideal paradigm, where all the entities (including the parties and the adversary) are modeled as interactive Turing machines. The goal of a protocol is defined by an *ideal functionality*, which can be seen as a trusted party sending the desired results to the parties. To prove security of a protocol, we aim to show that any adversary attacking the real protocol can be used to construct a corresponding ideal adversary, called the *simulator*, that runs in the ideal world, interacting only with the functionality \mathcal{F} and the real adversary, such that the distributions of messages seen in the real world and ideal world executions are indistinguishable. The UC

The Functionality $\mathcal{F}_{\text{Commit}}$
<p>Commit: On input $(\text{Commit}, x, i, \tau_x)$ from P_i, store (x, i, τ_x) and output (i, τ_x) to all parties.</p>
<p>Open: On input (Open, i, τ_x) by P_i, output (x, i, τ_x) to all parties.</p> <p style="margin-left: 20px;">If instead $(\text{NoOpen}, i, \tau_x)$ is given by the adversary, and P_i is corrupt, the functionality outputs (\perp, i, τ_x) to all parties.</p>

Figure 1: Ideal commitments

framework additionally defines a powerful entity called the *environment*, which is the interactive machine trying to distinguish the two worlds. The environment has total control over the adversary, and can choose the inputs, and see the outputs, of *all* parties.

We denote by $\mathbf{REAL}_{\pi, \mathcal{A}, \mathcal{Z}}(1^\kappa, z)$ the output distribution of the environment \mathcal{Z} in the real world execution of protocol π , with n parties and an adversary \mathcal{A} , where κ is the security parameter and z is the auxiliary input to \mathcal{Z} . The output distribution of \mathcal{Z} in the ideal world is denoted by $\mathbf{IDEAL}_{\mathcal{F}, \mathcal{S}, \mathcal{Z}}(1^\kappa, z)$, where \mathcal{F} is the ideal functionality to be realized and \mathcal{S} is the simulator. Additionally, we denote the hybrid execution of a protocol π , which is given access to an ideal functionality \mathcal{G} , by $\mathbf{HYB}_{\pi, \mathcal{A}, \mathcal{Z}}^{\mathcal{G}}(1^\kappa, z)$. This is defined similarly to the real execution, and is known as the \mathcal{G} -hybrid model. Security of a protocol is then defined as follows.

Definition 2.5 *A protocol π UC-securely computes an ideal functionality \mathcal{F} in the \mathcal{G} -hybrid model if for any PPT adversary \mathcal{A} , there exists a PPT simulator \mathcal{S} such that for any PPT environment \mathcal{Z} , it holds that:*

$$\mathbf{HYB}_{\pi, \mathcal{A}, \mathcal{Z}}^{\mathcal{G}} \stackrel{c}{\approx} \mathbf{IDEAL}_{\mathcal{F}, \mathcal{S}, \mathcal{Z}}.$$

The *composition theorem* provides security guarantees when protocols are composed together. This means that if ρ is a UC-secure protocol for \mathcal{G} , then the protocol π in the \mathcal{G} -hybrid model can be replaced by the composition $\pi \circ \rho$. Informally, the composition theorem then guarantees that $\mathbf{REAL}_{\pi \circ \rho, \mathcal{A}, \mathcal{Z}}$ is indistinguishable from $\mathbf{HYB}_{\pi, \mathcal{A}, \mathcal{Z}}^{\mathcal{G}}$.

Communication model. We assume all parties are connected via authenticated communication channels, as well as secure point-to-point channels and a broadcast channel. The default method of communication in our protocols is authenticated channels, unless otherwise specified. Note that in practice, these can all be implemented with standard techniques (in particular, for broadcast a simple 2-round protocol suffices, since we allow abort [GL05]).

Adversary model. The adversary model we consider is a static, active adversary who corrupts up to $n - 1$ out of n parties. This means that the identities of the corrupted parties are fixed at the beginning of the protocol, and they may deviate arbitrarily from the protocol.

2.5 Commitment Functionality

We require a UC commitment functionality $\mathcal{F}_{\text{Commit}}$ (Figure 1). This can easily be implemented in the random oracle model by defining $\text{Commit}(x, P_i) = \text{H}(x, i, r)$, where H is a random oracle and $r \leftarrow \{0, 1\}^\kappa$.

Functionality $\mathcal{F}_{\text{Rand}}$

Upon receiving (rand, S) from all parties, where S is any efficiently sampleable set, it samples $r \leftarrow S$ and outputs r to all parties.

Figure 2: Coin-tossing functionality

Fixed Correlation OT Functionality - \mathcal{F}_{COT}

Initialize: Upon receiving (init, Δ) , where $\Delta \in \{0, 1\}^\kappa$ from P_S and (init) from P_R , store Δ . Ignore any subsequent (init) commands.

Extend: Upon receiving $(\text{extend}, x_1, \dots, x_m)$ from P_R , where $x_i \in \{0, 1\}$, and (extend) from P_S , do the following:

- Sample $t_i \in \{0, 1\}^\kappa$, for $i \in [m]$. If P_R is corrupted then wait for \mathcal{A} to input t_i .
- Compute $q_i = t_i + x_i \cdot \Delta$, for $i \in [m]$.
- If P_S is corrupted then wait for \mathcal{A} to input $q_i \in \{0, 1\}^\kappa$ and recompute $t_i = q_i + x_i \cdot \Delta$.
- Output t_i to P_R and q_i to P_S , for $i \in [m]$.

Figure 3: Fixed correlation oblivious transfer functionality

2.6 Coin-Tossing Functionality

We use a standard coin-tossing functionality, $\mathcal{F}_{\text{Rand}}$ (Figure 2), which can be implemented with UC commitments to random values.

2.7 Correlated Oblivious Transfer

In this work we use an actively secure protocol for oblivious transfer (OT) on correlated pairs of strings of the form $(a_i, a_i \oplus \Delta)$, where Δ is fixed for every OT. The TinyOT protocol [NNOB12] for secure two-party computation constructs such a protocol, and a significantly optimized version of this is given in [NST17]. The communication cost is roughly $\kappa + s$ bits per OT. The ideal functionality is shown in Figure 3.

2.8 Functionality for Secret-Sharing-Based MPC

We make use of a general, actively secure protocol for secret-sharing-based MPC for binary circuits, which is modeled by the functionality $\mathcal{F}_{\text{BitMPC}}$ in Figure 4. This functionality allows parties to provide private inputs, which are then stored and can be added or multiplied internally by $\mathcal{F}_{\text{BitMPC}}$, and revealed if desired. Note that we also need the **Multiply** command to output a random additive secret-sharing of the product to all parties; this essentially assumes that the underlying protocol is based on secret-sharing.

We use the notation $\langle x \rangle$ to represent a secret-shared value x that is stored internally by $\mathcal{F}_{\text{BitMPC}}$, and define x^i to be party P_i 's additive share of x (if it is known). We also define the $+$ and \cdot operators on two shared values $\langle x \rangle, \langle y \rangle$ to call the **Add** and **Multiply** commands of $\mathcal{F}_{\text{BitMPC}}$, respectively, and return the identifier associated with the result.

The Bit MPC Functionality - $\mathcal{F}_{\text{BitMPC}}$

The functionality runs with parties P_1, \dots, P_n and an adversary \mathcal{A} . The functionality maintains a dictionary, $\text{Val} \leftarrow \{\}$, to keep track of values in \mathbb{F}_2 .

Input: On receiving $(\text{Input}, \text{id}_1, \dots, \text{id}_\ell, x_1, \dots, x_\ell, P_j)$ from party P_j and $(\text{Input}, \text{id}_1, \dots, \text{id}_\ell, P_j)$ from all other parties, where $x_i \in \mathbb{F}_2$, store $\text{Val}[\text{id}_i] \leftarrow x_i$ for $i \in [\ell]$.

Add: On input $(\text{Add}, \overline{\text{id}}, \text{id}_1, \dots, \text{id}_\ell)$ from all parties, where $(\text{id}_1, \dots, \text{id}_\ell)$ are keys in Val , set $\text{Val}[\overline{\text{id}}] \leftarrow \sum_{i=1}^{\ell} \text{Val}[\text{id}_i]$.

Multiply: On input $(\text{multiply}, \overline{\text{id}}, \text{id}_1, \text{id}_2)$ from all parties, where $(\text{id}_1, \text{id}_2)$ are keys in Val , compute $y \leftarrow \text{Val}[\text{id}_1] \cdot \text{Val}[\text{id}_2]$. Receive shares $y^i \in \mathbb{F}_2$ from \mathcal{A} , for $i \in I$, then sample random honest parties' shares $y^j \in \mathbb{F}_2$, for $j \notin I$, such that $\sum_{i=1}^n y^i = y$. Send y^i to party P_i , for $i \in [n]$, and store the value $\text{Val}[\overline{\text{id}}] \leftarrow y$.

Open: On input (Open, id) from all parties, where id is a key in Val , send $x \leftarrow \text{Val}[\text{id}]$ to \mathcal{A} . Wait for an input from \mathcal{A} . If it inputs OK then output x to all parties, otherwise output \perp and terminate.

Figure 4: Functionality for GMW-style MPC for binary circuits

2.9 BMR Garbling

The [BMR90] garbling technique by Beaver, Micali and Rogaway involves garbling each gate separately using pseudorandom generators while ensuring consistency between the wires. This method was recently improved in a sequence of works [LPSY15, LSS16, BLO16], where the latter work further supports the free XOR property. The main task of generating the garbled circuit while supporting this property is to compute, for each AND gate g with input wires u, v and output wire w , the $4n$ values:

$$\begin{aligned} \tilde{g}_{a,b}^j &= \left(\bigoplus_{i=1}^n F_{k_{u,a}^i, k_{v,b}^i}(g \| j) \right) \oplus k_{w,0}^j \\ &\oplus (R^j \cdot ((\lambda_u \oplus a) \cdot (\lambda_v \oplus b) \oplus \lambda_w)), \quad (a, b) \in \{0, 1\}^2, j \in [n] \end{aligned} \quad (2)$$

where the wire masks $\lambda_u, \lambda_v, \lambda_w \in \{0, 1\}$ are secret-shared between all parties, while the PRF keys $k_{u,a}^j, k_{v,b}^j$ and the global difference string R^j are known only to party P_j .

3 Generic Protocol for Multi-Party Garbling

We now describe our generic method for creating the garbled circuit using any secret-sharing based MPC protocol (modeled by $\mathcal{F}_{\text{BitMPC}}$) and the correlated OT functionality \mathcal{F}_{COT} . We first describe the functionality in Section 3.1 and the protocol in Section 3.2, and then analyse its security in Sections 3.4–3.5.

3.1 The Preprocessing Functionality

The preprocessing functionality, formalized in Figure 5, captures the generation of the garbled circuit as well as an error introduced by the adversary. The adversary is allowed to submit an additive error, chosen adaptively after seeing the garbled circuit, that is added by the functionality to each entry when the garbled circuit is opened.

The Preprocessing Functionality

Let F be a circular 2-correlation robust PRF. The functionality runs with parties P_1, \dots, P_n and an adversary \mathcal{A} .

Garbling: On input (Garbling, C_f) from all parties, where C_f is a boolean circuit, denote by W its set of wires and by G its set of AND gates. The functionality is defined as follows:

- Sample a global difference $R^j \leftarrow \{0, 1\}^\kappa$, for each $j \notin I$, and receive corrupt parties' strings $R^i \in \{0, 1\}^\kappa$ from \mathcal{A} , for $i \in I$.
- Passing topologically through all the wires $w \in W$ of the circuit:
 - If w is an input wire:
 1. Sample $\lambda_w \leftarrow \{0, 1\}$. If P_j , the party who provides input on that wire in the online phase, is corrupt, instead receive λ_w from \mathcal{A} .
 2. Sample a key $k_{w,0}^j \leftarrow \{0, 1\}^\kappa$, for each $j \notin I$, and receive corrupt parties' keys $k_{w,0}^i$ from \mathcal{A} , for $i \in I$. Define $k_{w,1}^i = k_{w,0}^i \oplus R^i$ for all $i \in [n]$.
 - If w is the output of an AND gate:
 1. Sample $\lambda_w \leftarrow \{0, 1\}$.
 2. Sample a key $k_{w,0}^j \leftarrow \{0, 1\}^\kappa$, for each $j \notin I$, and receive corrupt parties' keys $k_{w,0}^i$ from \mathcal{A} , for $i \in I$. Set $k_{w,1}^i = k_{w,0}^i \oplus R^i$, for $i \in [n]$.
 - If w is the output of a XOR gate, and u and v its input wires:
 1. Compute and store $\lambda_w = \lambda_u \oplus \lambda_v$.
 2. For $i \in [n]$, set $k_{w,0}^i = k_{u,0}^i \oplus k_{v,0}^i$ and $k_{w,1}^i = k_{u,0}^i \oplus R^i$.
- For every AND gate $g \in G$, the functionality computes the $4n$ entries of the garbled version of g as:

$$\tilde{g}_{a,b}^j = \left(\bigoplus_{i=1}^n F_{k_{u,a}^i, k_{v,b}^i}(g||j) \right) \oplus k_{w,0}^j \oplus (R^j \cdot ((\lambda_u \oplus a) \cdot (\lambda_v \oplus b) \oplus \lambda_w)), \quad (a, b) \in \{0, 1\}^2, j \in [n].$$

Set $\tilde{\mathbf{g}}_{a,b} = \tilde{g}_{a,b}^1 \circ \dots \circ \tilde{g}_{a,b}^n$ $(a, b) \in \{0, 1\}^2$. The functionality stores the values $\tilde{\mathbf{g}}_{a,b}$.

- Wait for an input from \mathcal{A} . If it inputs OK then output λ_w to all parties for each circuit-output wire w , and output to each P_i all the keys $\{k_{w,0}^i\}_{w \in W}$, and R^i . Otherwise, output \perp and terminate.

Open Garbling: On receiving (OpenGarbling) from all parties, when the **Garbling** command has already run successfully, the functionality sends to \mathcal{A} the values $\tilde{\mathbf{g}}_{a,b}$ for all $g \in G$ and waits for a reply.

- If \mathcal{A} returns \perp then the functionality aborts.
- Otherwise, the functionality receives OK and an additive error $e = \{e_g^{a,b}\}_{a,b \in \{0,1\}, g \in G}$ chosen by \mathcal{A} . Afterwards, it sends to all parties the garbled circuit $\tilde{\mathbf{g}}_{a,b} \oplus e_g^{a,b}$ for all $g \in G$ and $a, b \in \{0, 1\}$.

Figure 5: The Preprocessing Functionality $\mathcal{F}_{\text{Preprocessing}}$

3.2 Protocol Overview

The garbling protocol, shown in Figure 6, proceeds in three main stages. Firstly, the parties locally sample all of their keys and shares of wire masks for the garbled circuit. Secondly, the parties compute shares of the products of the wire masks and each party's global difference string; these are then used by each party to locally obtain a share of the entire garbled circuit. Finally, the bit masks for the output wires are opened to all parties. The opening of the garbled circuit is shown in Figure 7.

Concretely, each party P_i starts by sampling a global difference string $R^i \leftarrow \{0, 1\}^\kappa$, and for each wire w which is an output wire of an AND gate, or an input wire, P_i also samples the keys $k_{w,0}^i, k_{w,1}^i = k_{w,0}^i \oplus R^i$ and an additive share of the wire mask, $\lambda_w^i \leftarrow \mathbb{F}_2$. As in [BLO16], we let P_i input the actual wire mask (instead of a share) for every input wire associated with P_i 's input.

In step 3, the parties compute additive shares of the bit products $\lambda_{uv} = \lambda_u \cdot \lambda_v \in \mathbb{F}_2$, and then, for each $j \in [n]$, shares of:

$$\lambda_u \cdot R^j, \quad \lambda_v \cdot R^j, \quad \lambda_{uvw} \cdot R^j \in \mathbb{F}_2^\kappa \quad (3)$$

where $\lambda_{uvw} := \lambda_{uv} \oplus \lambda_w$, and u, v and w are the input and output wires of AND gate g . We note that (as observed in [BLO16]) only one bit/bit product and $3n$ bit/string products are necessary, even though each gate has $4n$ entries, due to correlations between the entries, as can be seen below.

We compute the bit multiplications using the $\mathcal{F}_{\text{BitMPC}}$ functionality on the bits that are already stored by $\mathcal{F}_{\text{BitMPC}}$. To compute the bit/string multiplications in (3), we use correlated OT, followed by a consistency check to verify that the parties provided the correct shares of λ_w and correlation R^i to each \mathcal{F}_{COT} instance; see Section 3.3 for details.

Using shares of the bit/string products, the parties can locally compute an unauthenticated additive share of the entire garbled circuit (steps 3d–4). First, for each of the four values $(a, b) \in \{0, 1\}^2$, each party $P_i, i \neq j$ computes the share

$$\rho_{j,a,b}^i = \begin{cases} a \cdot (\lambda_v \cdot R^j)^i \oplus b \cdot (\lambda_u \cdot R^j)^i \oplus (\lambda_{uvw} \cdot R^j)^i & \text{if } i \neq j \\ a \cdot (\lambda_v \cdot R^j)^i \oplus b \cdot (\lambda_u \cdot R^j)^i \oplus (\lambda_{uvw} \cdot R^j)^i \oplus a \cdot b \cdot R^j & \text{if } i = j \end{cases}$$

These define additive shares of the values

$$\begin{aligned} \rho_{j,a,b} &= R^j \cdot (a \cdot \lambda_v \oplus b \cdot \lambda_u \oplus \lambda_{uvw} \oplus a \cdot b) \\ &= R^j \cdot ((\lambda_u \oplus a) \cdot (\lambda_v \oplus b) \oplus \lambda_w) \end{aligned}$$

Each party's share of the garbled circuit is then obtained by adding the appropriate PRF values and keys to the shares of each $\rho_{j,a,b}$. To conclude the **Garbling** stage, the parties reveal the masks for all output wires using $\mathcal{F}_{\text{BitMPC}}$, so that the outputs can be obtained in the online phase.

Before opening the garbled circuit, the parties must rerandomize their shares by distributing a fresh, random secret-sharing of each share to the other parties, via private channels. This is needed so that the shares do not leak any information on the PRF values, so we can prove security. This may seem unnecessary, since the inclusion of the PRF values in the shares should randomize them sufficiently. However, we cannot prove this intuition, as the same PRF values are used to compute the garbled circuit that is output by the protocol, so they cannot also be used as a one-time pad.² Note that this extra rerandomization step needs

²Furthermore, the environment sees all of the PRF keys of the honest parties, since these are outputs of the protocol, which seems to rule out any kind of computational reduction in the security proof.

The Preprocessing Protocol $\Pi_{\text{Preprocessing}}$ – Garbling Stage

Given a gate g , we denote by u (resp. v) its left (resp. right) input wire, and by w its output wire. $\langle \cdot \rangle^i$ denotes the i -th share of an authenticated bit and $(\cdot)^i$ the i -th share of a string.

Let $F : \{0, 1\}^\kappa \times \{0, 1\}^\kappa \times \{0, 1\}^\kappa \rightarrow \{0, 1\}^\kappa$ be a circular 2-correlation robust PRF.

Garbling:

1. Each party P_i samples a random key offset $R^i \leftarrow \mathbb{F}_{2^\kappa}$.
2. **Generate wire masks and keys:** Passing through the wires of the circuit topologically, proceed as follows:
 - If w is a *circuit-input* wire, and P_j is the party whose input is associated with it:
 - (a) P_j calls **Input** on $\mathcal{F}_{\text{BitMPC}}$ with a randomly sampled $\lambda_w \in \{0, 1\}$ to obtain $\langle \lambda_w \rangle$. P_j defines the share $\lambda_w^j = \lambda_w$, every other P_i sets $\lambda_w^i = 0$.
 - (b) Every P_i samples a key $k_{w,0}^i \leftarrow \{0, 1\}^\kappa$ and sets $k_{w,1}^i = k_{w,0}^i \oplus R^i$.
 - If the wire w is the output of an AND gate:
 - (a) Each P_i calls **Input** on $\mathcal{F}_{\text{BitMPC}}$ with a randomly sampled $\lambda_w^i \leftarrow \{0, 1\}$. The parties then compute the secret-shared wire mask as $\langle \lambda_w \rangle = \sum_{i \in [n]} \langle \lambda_w^i \rangle$.
 - (b) Every P_i samples a key $k_{w,0}^i \leftarrow \{0, 1\}^\kappa$ and sets $k_{w,1}^i = k_{w,0}^i \oplus R^i$.
 - If the wire w is the output of a XOR gate:
 - (a) The parties compute the mask on the output wire as $\langle \lambda_w \rangle = \langle \lambda_u \rangle + \langle \lambda_v \rangle$.
 - (b) Every P_i sets $k_{w,0}^i = k_{u,0}^i \oplus k_{v,0}^i$ and $k_{w,1}^i = k_{u,0}^i \oplus k_{v,1}^i$.
3. **Secure product computations:**
 - (a) For each AND gate $g \in G$, the parties compute $\langle \lambda_{uv} \rangle = \langle \lambda_u \rangle \cdot \langle \lambda_v \rangle$ by calling **Multiply** on $\mathcal{F}_{\text{BitMPC}}$.
 - (b) Each P_i calls **Input** on $\mathcal{F}_{\text{BitMPC}}$ with randomly sampled bits $\hat{x}_1^i, \dots, \hat{x}_s^i$. For $\ell \in [s]$, the parties compute secret-shared mask $\langle \hat{x}_\ell \rangle = \sum_{i \in [n]} \langle \hat{x}_\ell^i \rangle$.
 - (c) For every $j \in [n]$, the parties run the subprotocol $\Pi_{\text{Bit} \times \text{String}}$, where P_j inputs R^j and everyone inputs the $3|G| + s$ shared bits:

$$(\langle \lambda_u \rangle, \langle \lambda_v \rangle, \langle \lambda_{uv} \rangle + \langle \lambda_w \rangle)_{(u,v,w)} \quad \text{and} \quad (\langle \hat{x}_1 \rangle, \dots, \langle \hat{x}_s \rangle).$$

where the (u, v, w) indices are taken over the input/output wires of each AND gate $g \in G$.

- (d) For each AND gate g , party P_i obtains from $\Pi_{\text{Bit} \times \text{String}}$ an additive share of the $3n$ values (each defined as one row of the matrix \mathbf{Z}_j in this subprotocol):

$$\lambda_u \cdot R^j, \quad \lambda_v \cdot R^j, \quad \lambda_{uv} \cdot R^j, \quad \text{for } j \in [n]$$

where $\lambda_{uvw} := \lambda_{uv} + \lambda_w$. Each P_i then uses these to compute a share of

$$\rho_{j,a,b} = \lambda_{uvw} \cdot R^j \oplus a \cdot \lambda_v \cdot R^j \oplus b \cdot \lambda_u \cdot R^j \oplus a \cdot b \cdot R^j$$

4. **Garble gates:** For each AND gate $g \in G$, each $j \in [n]$, and the four combinations of $a, b \in \{0, 1\}^2$, the parties compute shares of the j -th entry of the garbled gate $\tilde{g}_{a,b}$ as follows:
 - P_j sets $(\tilde{g}_{a,b}^j)^j = \rho_{j,a,b}^j \oplus F_{k_{u,a}^j, k_{v,b}^j}(g \| j) \oplus k_{w,0}^j$.
 - For every $i \neq j$, P_i sets $(\tilde{g}_{a,b}^j)^i = \rho_{j,a,b}^i \oplus F_{k_{u,a}^i, k_{v,b}^i}(g \| j)$.
5. **Reveal masks for output wires:** For every circuit-output-wire w , the parties call **Open** on $\mathcal{F}_{\text{BitMPC}}$ to reveal λ_w to all the parties.

Figure 6: The preprocessing protocol that realizes $\mathcal{F}_{\text{Preprocessing}}$ in the $\{\mathcal{F}_{\text{COT}}, \mathcal{F}_{\text{BitMPC}}, \mathcal{F}_{\text{Rand}}, \mathcal{F}_{\text{Commit}}\}$ -hybrid model.

The Preprocessing Protocol $\Pi_{\text{Preprocessing}}$ – Open Garbling Stage

Open Garbling: Let $\tilde{C}^i = ((\tilde{g}_{a,b}^j)^i)_{j,a,b,g} \in \{0,1\}^{4n\kappa|G|}$ be P_i 's share of the whole garbled circuit.

3. Each party P_i samples random additive shares of zero, $S_j^i \leftarrow \{0,1\}^{4n\kappa|G|}$, $j \in [n]$, such that $\bigoplus_j S_j^i = 0$. P_i sends S_j^i to P_j over a private channel, for $j \neq i$.^a
4. Each P_j broadcasts $\tilde{C}^j \oplus \bigoplus_{i=1}^n S_j^i$, and XORs these together to reconstruct the garbled circuit, \tilde{C} .

^aThis step is independent of \tilde{C}^i , so can be merged with a previous round in the **Garbling** stage.

Figure 7: Open Garbling stage of the preprocessing protocol.

$O(n^3)$ communication, whereas the rest of the protocol can be done in $O(n^2)$; in Section 4.4 we show how to reduce the cost of the entire preprocessing to $O(n^2)$ using random oracles.

Finally, to reconstruct the garbled circuit, the parties sum up and broadcast the rerandomized shares and add them together to get $\tilde{g}_{a,b}^j$.

3.3 Bit/String Multiplications

Our method for this is in the subprotocol $\Pi_{\text{Bit} \times \text{String}}$ (Figure 8). It proceeds in two stages: first the **Multiply** step creates the shared products, and then the **Consistency Check** verifies that the correct inputs were used to create the products.

Recall that the task is for the parties to obtain an additive sharing of the products, for each $j \in [n]$ and $(a, b) \in \{0,1\}^2$:

$$R^j \cdot ((\lambda_u \oplus a) \cdot (\lambda_v \oplus b) \oplus \lambda_w) \quad (4)$$

where the string R^j is known only to P_j , and fixed for every gate. Denote by x one of the additively shared $\lambda_{(\cdot)}$ bits used in a single bit/string product and stored by $\mathcal{F}_{\text{BitMPC}}$. We obtain shares of $x \cdot R^j$ using actively secure correlated OT (cf. Figure 3), as follows:

1. For each $i \neq j$, parties P_i and P_j run a correlated OT, with choice bit x^i and correlation R^j . P_i obtains $T_{i,j}$ and P_j obtains $Q_{i,j}$ such that:

$$T_{i,j} = Q_{i,j} + x^i \cdot R^j.$$

2. Each P_i , for $i \neq j$, defines the share $Z^i = T_{i,j}$, and P_j defines $Z^j = \sum_{i \neq j} Q_{i,j} + x^j \cdot R^j$. Now we have:

$$\sum_{i=1}^n Z^i = \sum_{i \neq j} T_{i,j} + \sum_{i \neq j} Q_{i,j} + x^j \cdot R^j = \sum_{i \neq j} (T_{i,j} + Q_{i,j}) + x^j \cdot R^j = x \cdot R^j$$

as required.

The above method is performed $3|G|$ times and for each P_j , to produce the shared bit/string products $x \cdot R^j$, for $x \in \{\lambda_u, \lambda_v, \lambda_{uv}\}$.

Bit/string multiplication subprotocol – $\Pi_{\text{Bit} \times \text{String}}$

Inputs: Each P_j inputs the private global difference string $R^j \in \mathbb{F}_2^\kappa$, which was generated in the main protocol. All parties input $3|G|$ authenticated, additively shared bits, $\langle x_1 \rangle, \dots, \langle x_{3|G|} \rangle$, and s additional, random shared bits, $\langle \hat{x}_1 \rangle, \dots, \langle \hat{x}_s \rangle$, to be used as masking values and discarded.

I: Init: Every ordered pair of parties (P_i, P_j) calls **Initialize** on \mathcal{F}_{COT} , where P_j , the sender, inputs the global difference string R^j .

II: Multiply: For each $j \in [n]$, the parties do as follows:

1. For every $i \neq j$, parties P_i and P_j call **Extend** on the \mathcal{F}_{COT} instance where P_j is sender, and P_i inputs the choice bits $\mathbf{x}^i = (x_1^i, \dots, x_{3|G|}^i, \hat{x}_1^i, \dots, \hat{x}_s^i)$.

For each OT between (P_i, P_j) , P_j receives $q \in \{0, 1\}^\kappa$ and P_i receives $t \in \{0, 1\}^\kappa$. P_i stores their $3|G| + s$ strings from this instance into the rows of a matrix $\mathbf{T}_{i,j}$, and P_j stores the corresponding outputs in $\mathbf{Q}_{i,j}$. These satisfy:

$$\mathbf{T}_{i,j} = \mathbf{Q}_{i,j} + \mathbf{x}^i \otimes R^j \in \mathbb{F}_2^{(3|G|+s) \times \kappa}.$$

2. Each P_i , for $i \neq j$, defines the matrix $\mathbf{Z}_j^i = \mathbf{T}_{i,j}$, and P_j defines $\mathbf{Z}_j^j = \sum_{i \neq j} \mathbf{Q}_{i,j} + \mathbf{x}^j \otimes R^j$.

Now, it should hold that $\sum_{i=1}^n \mathbf{Z}_j^i = \mathbf{x} \otimes R^j$, for each $j \in [n]$.

III: Consistency Check: The parties check correctness of the above as follows:

1. Each P_i removes the last s rows from \mathbf{Z}_j^i (for $j \in [n]$) and places these ‘dummy’ masking values in a matrix $\hat{\mathbf{Z}}_j^i \in \mathbb{F}_2^{s \times \kappa}$. Similarly, redefine $\mathbf{x}^i = (x_1^i, \dots, x_{3|G|}^i)$ and let $\hat{\mathbf{x}}^i = (\hat{x}_1^i, \dots, \hat{x}_s^i)$.
2. The parties call $\mathcal{F}_{\text{Rand}}$ (Figure 2) to sample a seed for a uniformly random, ε -almost 1-universal linear hash function, $\mathbf{H} \in \mathbb{F}_2^{s \times 3|G|}$.
3. All parties compute the vector:

$$\langle \mathbf{c}_x \rangle = \mathbf{H} \cdot \langle \mathbf{x} \rangle + \langle \hat{\mathbf{x}} \rangle \in \mathbb{F}_2^s$$

and open \mathbf{c}_x using the **Open** command of $\mathcal{F}_{\text{BitMPC}}$. If $\mathcal{F}_{\text{BitMPC}}$ aborts, the parties abort.

4. Each party P_i calls **Commit** on $\mathcal{F}_{\text{Commit}}$ (Figure 1) with input the n matrices:

$$\mathbf{C}_j^i = \mathbf{H} \cdot \mathbf{Z}_j^i + \hat{\mathbf{Z}}_j^i, \quad \text{for } j \neq i, \quad \text{and} \quad \mathbf{C}_i^i = \mathbf{H} \cdot \mathbf{Z}_i^i + \hat{\mathbf{Z}}_i^i + \mathbf{c}_x \otimes R^i.$$

5. All parties open their commitments and check that, for each $j \in [n]$:

$$\sum_{i=1}^n \mathbf{C}_j^i = 0.$$

If the check fails, the parties abort.

6. Each party P_i stores the matrices $\mathbf{Z}_1^i, \dots, \mathbf{Z}_n^i$.

Figure 8: Subprotocol for bit/string multiplication and checking consistency

3.4 Consistency Check

We now show how the parties verify that the correct shares of x and correlations R^j were used in the correlated OTs, and analyse the security of this check. The parties first create $m + s$ bit/string products, where m is the number of products needed and s is a statistical security parameter, and then open random linear combinations (over \mathbb{F}_2) of all the products and check correctness of the opened results. This is possible because the products are just a linear function of the fixed string R^j . In more detail, the parties first sample a random ε -almost 1-universal hash function $\mathbf{H} \leftarrow \mathbb{F}_2^{m \times s}$, and then open

$$\mathbf{c}_x = \mathbf{H} \cdot \mathbf{x} + \hat{\mathbf{x}}$$

using $\mathcal{F}_{\text{BitMPC}}$. Here, \mathbf{x} is the vector of all m wire masks to be multiplied, whilst $\hat{\mathbf{x}} \in \mathbb{F}_2^s$ are the additional, random masking bits, used as a one-time pad to ensure that \mathbf{c}_x does not leak information on \mathbf{x} .

To verify that a single shared matrix \mathbf{Z}_j is equal to $\mathbf{x} \otimes R^j$ (as in Figure 8), each party P_i , for $i \neq j$, then commits to $\mathbf{H} \cdot \mathbf{Z}_j^i$, whilst P_j commits to $\mathbf{H} \cdot \mathbf{Z}_j^j + \mathbf{c}_x \otimes R^j$. The parties then open all commitments and check that these sum to zero, which should happen if the products were correct.

The intuition behind the check is that any errors present in the original bit/string products will remain when multiplied by \mathbf{H} , except with probability ε , by the almost-1-universal property (Definition 2.4). Furthermore, it turns out that cancelling out any non-zero errors in the check requires either guessing an honest party's global difference R^j , or guessing the secret masking bits $\hat{\mathbf{x}}$.

We formalize this, by first considering the exact deviations that are possible by a corrupt P_j in $\Pi_{\text{Bit} \times \text{String}}$. These are:

1. Provide inconsistent inputs R^j when acting as sender in the **Initialize** command of the \mathcal{F}_{COT} instances with two different honest parties.
2. Input an incorrect share x^j when acting as receiver in the **Extend** command of \mathcal{F}_{COT} .

Note that in both of these cases, we are only concerned when the other party in the \mathcal{F}_{COT} execution is honest, as if both parties are corrupt then \mathcal{F}_{COT} does not need to be simulated in the security proof.

We model these two attacks by defining $R^{j,i}$ and $x^{j,i}$ to be the *actual* inputs used by a corrupt P_j in the above two cases, and then define the errors (for $j \in I$ and $i \notin I$):

$$\begin{aligned} \Delta^{j,i} &= R^{j,i} + R^j \\ \delta_\ell^{j,i} &= x_\ell^{j,i} + x_\ell^j, \quad \ell \in [3|G|]. \end{aligned}$$

Note that $\Delta^{j,i}$ is fixed in the initialization of \mathcal{F}_{COT} , whilst $\delta_\ell^{j,i}$ may be different for every OT. Whenever P_i and P_j are both corrupt, or both honest, for convenience we define $\Delta^{j,i} = 0$ and $\delta^{j,i} = 0$.

This means that the outputs of \mathcal{F}_{COT} with (P_i, P_j) then satisfy (omitting ℓ subscripts):

$$t_{i,j} = q_{i,j} + x^i \cdot R^j + \delta^{i,j} \cdot R^j + \Delta^{j,i} \cdot x^i$$

where $\delta^{i,j} \neq 0$ if P_i cheated, and $\Delta^{j,i} \neq 0$ if P_j cheated.

Now, as in step 1 of the first stage of $\Pi_{\text{Bit} \times \text{String}}$, we can put the \mathcal{F}_{COT} outputs for each party into the rows of a matrix, and express the above as:

$$\mathbf{T}_{i,j} = \mathbf{Q}_{i,j} + \mathbf{x}^i \otimes R^j + \boldsymbol{\delta}^{i,j} \otimes R^j + \Delta^{j,i} \otimes x^i$$

where $\boldsymbol{\delta}^{j,i} = (\delta_1^{j,i}, \dots, \delta_{3|G|}^{j,i})$, and the tensor product notation is defined in Section 2.

Accounting for these errors in the outputs of the **Multiply** step in $\Pi_{\text{Bit} \times \text{String}}$, we get:

$$\mathbf{Z}_j = \sum_{i=1}^n \mathbf{Z}_j^i = \mathbf{x} \otimes R^j + R^j \cdot \underbrace{\sum_{i \in I} \delta^{i,j}}_{=\delta^j} + \sum_{i \notin I} x_i \cdot \Delta^{j,i}. \quad (5)$$

The following lemma shows if a party cheated, then to pass the check they must either guess all of the shares $\hat{\mathbf{x}}^i \in \mathbb{F}_2^s$ for some honest P_i , or guess P_i 's global difference R^i (except with negligible probability over the choice of the ε -almost 1-universal hash function, \mathbf{H}).

Lemma 3.1 *If the check in $\Pi_{\text{Bit} \times \text{String}}$ passes, then except with probability $\max(2^{-s}, \varepsilon + 2^{-\kappa})$, all of the errors $\delta^j, \Delta^{i,j}$ are zero.*

Proof: From (5), we have, for each $j \in [n]$:

$$\mathbf{Z}_j = \sum_{i=1}^n \mathbf{Z}_j^i = \mathbf{x} \otimes R^j + \delta^j \otimes R^j + \sum_{i \notin I} \mathbf{x}^i \otimes \Delta^{j,i}.$$

Notice that steps 4–5 of the check in Figure 8 perform n individual checks on the matrices $\mathbf{Z}_1, \dots, \mathbf{Z}_n$ in parallel. Fix j , and first consider the check for a single matrix \mathbf{Z}_j . From here, we omit the subscript j to simplify notation.

Let $(\mathbf{C}^*)^i$, for $i \in I$, be the values committed to by corrupt parties in step 4, and define

$$\tilde{\mathbf{C}}^i = \begin{cases} \mathbf{H} \cdot \mathbf{Z}^i + \hat{\mathbf{Z}}^i, & \text{if } i \neq j \\ \mathbf{H} \cdot \mathbf{Z}^i + \hat{\mathbf{Z}}^i + \mathbf{c}_x \otimes R^i, & \text{if } i = j \end{cases}$$

to be the value which a corrupt P_i should have committed to.

Denote the *difference* between what a corrupt P_i actually committed to, and what they should have committed to, by:

$$\mathbf{D}^i = (\mathbf{C}^*)^i + \tilde{\mathbf{C}}^i \in \mathbb{F}_2^{s \times \kappa}.$$

Also, define the sum of the differences $\mathbf{D}_I = \sum_{i \in I} \mathbf{D}^i$. To pass the consistency check, it must hold that:

$$\begin{aligned} 0 &= \sum_{i \notin I} \mathbf{C}^i + \sum_{i \in I} \tilde{\mathbf{C}}^i + \mathbf{D}_I \\ \Leftrightarrow \mathbf{D}_I &= \sum_{i \notin I} \mathbf{C}^i + \sum_{i \in I} \tilde{\mathbf{C}}^i \\ &= \mathbf{H} \left(\sum_{i=1}^n \mathbf{Z}^i \right) + \sum_{i=1}^n \hat{\mathbf{Z}}^i + \mathbf{c}_x \otimes R^j \\ &= \mathbf{H}(\mathbf{x} \otimes R^j + \delta^j \otimes R^j + \sum_{i \notin I} \mathbf{x}^i \otimes \Delta^{j,i}) + \hat{\mathbf{Z}} + \mathbf{H}(\mathbf{x}) \otimes R^j + \hat{\mathbf{x}} \otimes R^j \end{aligned} \quad (6)$$

$$= \mathbf{H}(\delta^j \otimes R^j + \sum_{i \notin I} \mathbf{x}^i \otimes \Delta^{j,i}) + \hat{\mathbf{Z}} + \hat{\mathbf{x}} \otimes R^j \quad (7)$$

where (6) holds because $\mathbf{c}_x = \mathbf{H}(\mathbf{x}) + \hat{\mathbf{x}}$, and (7) due to linearity of \mathbf{H} and Fact 2.1.

Now, taking into account the fact that $\hat{\mathbf{Z}}$ is constructed the same way as \mathbf{Z} , and considering (5), there exist some adversarially chosen errors $\hat{\delta}^j \in \mathbb{F}_2^s$ such that:

$$\hat{\mathbf{Z}} = \hat{\mathbf{x}} \otimes R^j + \hat{\delta}^j \otimes R^j + \sum_{i \notin I} \hat{\mathbf{x}}^i \otimes \Delta^{j,i}.$$

Plugging this into equation (7), the check passes if and only if:

$$\begin{aligned} \mathbf{D}_I &= \mathbf{H}(\delta^j \otimes R^j + \sum_{i \notin I} \mathbf{x}^i \otimes \Delta^{j,i}) + \hat{\delta}^j \otimes R^j + \sum_{i \notin I} \hat{\mathbf{x}}^i \otimes \Delta^{j,i} \\ &= (\mathbf{H}(\delta^j) + \hat{\delta}^j) \otimes R^j + \sum_{i \notin I} (\mathbf{H}(\mathbf{x}^i) + \hat{\mathbf{x}}^i) \otimes \Delta^{j,i}. \end{aligned} \quad (8)$$

We now show that the probability of this holding is negligible, if any errors are non-zero.

First consider the left-hand summation in (8), supposing that at least one of $\delta^j, \hat{\delta}^j$ is non-zero. Recall that δ^j and $\hat{\delta}^j$ are fixed by the adversary's inputs to \mathcal{F}_{COT} , so are independent of the random choice of the hash function \mathbf{H} . Therefore, by the ε -almost 1-universal property of the family of linear hash functions (Definition 2.4), it holds that

$$\Pr_{\mathbf{H}}[\mathbf{H}(\delta^j) + \hat{\delta}^j = 0] \leq \varepsilon.$$

So except with probability ε , \mathcal{A} will have to guess R^j to construct \mathbf{D}_I to pass the check, since R^j is independent of the right-hand summation. By a union bound, therefore, if at least one of δ^j or $\hat{\delta}^j$ is non-zero then the check passes with probability at most $\varepsilon + 2^{-\kappa}$.

Now suppose that $\delta^j = \hat{\delta}^j = 0$, so \mathcal{A} only needs to guess the right-hand summation of (8) to pass the check. If the error $\Delta^{j,i} \neq 0$ for some $i \notin I$ then the adversary must successfully guess $\mathbf{H}(\mathbf{x}^i) + \hat{\mathbf{x}}^i$ to be able to pass the check. Since $\hat{\mathbf{x}}^i$ is uniformly random in the view of the adversary, this can only occur with probability 2^{-s} .

In conclusion, the probability of passing the j -th check when any of the errors $\delta^j, \hat{\delta}^j$ or $\Delta^{j,i}$ are non-zero, is no more than $\max(2^{-s}, \varepsilon + 2^{-\kappa})$. Since the adversary must pass all n checks to prevent an abort, this also gives an upper bound for the overall success probability. ■

3.5 Security Proof

We now give some intuition behind the security of the whole protocol. In the proof, the strategy of the simulator is to run an internal copy of the protocol, using dummy, random values for the honest parties' keys and wire mask shares. All communication with the adversary is simulated by computing the correct messages according to the protocol and the dummy honest shares, until the final output stage. In the output stage, we switch to fresh, random honest parties' shares, consistent with the garbled circuit received from $\mathcal{F}_{\text{Preprocessing}}$ and the corrupt parties' shares.

Firstly, by Lemma 3.1, it holds that in the real execution, if the adversary introduced any non-zero errors then the consistency check fails with overwhelming probability. The same is true in the ideal execution; note that the errors are still well-defined in this case because the simulator can compute them by comparing all inputs received to \mathcal{F}_{COT} with the inputs the adversary should have used, based on its random tape. This implies that the probability of passing the check is the same in both worlds. Also, if the check fails then

both executions abort, and it is straightforward to see that the two views are indistinguishable because no outputs are sent to honest parties (hence, also the environment).

It remains to show that the two views are indistinguishable when the consistency check passes, and the environment sees the outputs of all honest parties, as well as the view of the adversary during the protocol. The main point of interest here is the output stage. We observe that, without the final rerandomization step, the honest parties' shares of the garbled circuit would *not be uniformly random*. Specifically, consider an honest P_i 's share, $(\tilde{g}_{a,b}^j)^i$, where P_j is corrupt. This is computed by adding some PRF value, v , to the \mathcal{F}_{COT} outputs where P_i was receiver and P_j was sender (step 2 of $\Pi_{\text{Bit} \times \text{String}}$). Since P_j knows both strings in each OT, there are only two possibilities for P_i 's output (depending on the choice bit), so this is not uniformly random. It might be tempting to argue that v is a random PRF output, so serves as a one-time pad, but this proof attempt fails because v is also used to compute the final garbled circuit. In fact, it seems difficult to rely on any computational argument, since all the PRF keys are included in the output to the environment.

To avoid this issue, we need the rerandomization step, and the additional assumption of secure point-to-point channels. Note that this is missing from the protocol of [BLO16], which does not currently have a security proof. Rerandomization ensures that the honest shares can be simulated with random values which, together with the corrupt shares, sum up to the correct garbled circuit. We proceed with the complete proof.

Theorem 3.1 *Protocol $\Pi_{\text{Preprocessing}}$ from Figure 6 UC-securely computes $\mathcal{F}_{\text{Preprocessing}}$ from Figure 5 in the presence of a static, malicious adversary corrupting up to $n - 1$ parties in the $\{\mathcal{F}_{\text{COT}}, \mathcal{F}_{\text{BitMPC}}, \mathcal{F}_{\text{Rand}}, \mathcal{F}_{\text{Commit}}\}$ -hybrid model.*

Proof: Let \mathcal{A} denote a PPT adversary corrupting a strict subset $I \subsetneq [n]$ of parties. As part of the proof, we will construct a simulator \mathcal{S} that plays the roles of the honest parties on arbitrary inputs, as well as the roles of functionalities $\{\mathcal{F}_{\text{COT}}, \mathcal{F}_{\text{BitMPC}}, \mathcal{F}_{\text{Rand}}, \mathcal{F}_{\text{Commit}}\}$ and interacts with \mathcal{A} . We assume w.l.o.g. that \mathcal{A} is a deterministic adversary, which receives as additional input a random tape that determines its internal coin tosses. Nevertheless, since \mathcal{A} is malicious, it may still ignore the random tape, and use its own (possibly biased) random values instead.

The simulator begins by initializing \mathcal{A} with the inputs from the environment, \mathcal{Z} , and a uniform string r as its random tape. During the simulation, we will use r to compute values that \mathcal{A} *should* (but might not) use during the protocol. We can now define the rest of \mathcal{S} as follows:

- Garbling:**
1. The simulator emulates $\mathcal{F}_{\text{COT}}.\text{Initialize}$ as follows:
 - For a honest party $P_i, i \notin I$, \mathcal{S} samples $R^i \in \{0, 1\}^\kappa$.
 - For a corrupted party $P_j, j \in I$, \mathcal{S} computes R^j from that party's random tape. Additionally, for each pair of parties involving that party, (P_j, P_i) where $i \notin I$, \mathcal{S} receives by \mathcal{A} values $R^{j,i} \in \{0, 1\}^\kappa$ and stores $\Delta^{j,i} = R^{j,i} + R^j$. If $\forall i \notin I, \Delta^{j,i} = d$, then \mathcal{S} modifies its stored values by setting $R^j \leftarrow R^j + d$ and $\Delta^{j,i} \leftarrow 0, \forall i \notin I$.
 2. GENERATE WIRE MASKS AND KEYS: Passing through each wire w of the circuit topologically, the simulator \mathcal{S} proceeds as follows.
 - It emulates $\mathcal{F}_{\text{BitMPC}}$ and defines the wire masks:
 - If w is a *circuit-input* wire, P_i is the party whose input is associated with it and $i \in I$, then \mathcal{S} receives λ_w by \mathcal{A} . If $i \notin I$, then \mathcal{S} chooses λ_w .
 - If w is the output of an AND gate, \mathcal{S} samples $\lambda_w \leftarrow \mathbb{F}_2$ and receives from the adversary λ_w^i for every $i \in I$. Then, \mathcal{S} samples random $\lambda_w^j, j \notin I$, such that $\lambda_w = \sum_{\ell \in [n]} \lambda_w^\ell$.
 - If w is the output of a XOR gate, \mathcal{S} , it sets $\lambda_w = \lambda_u + \lambda_v$.

- It defines the PRF keys:
 - If w is not the output of a XOR gate, \mathcal{S} computes $k_{w,0}^i \in \{0,1\}^\kappa$ for $i \in [n]$. For corrupted parties $i \in I$, \mathcal{S} reads this off P_i 's random tape, whereas for honest parties it samples a random key.
 - If w is the output of a XOR gate, for $i \in [n]$, it sets $k_{w,0}^i = k_{u,0}^i \oplus k_{v,0}^i$ and $k_{w,1}^i = k_{u,0}^i \oplus R^i$ for $i \in [n]$.
 - Finally, it sends to $\mathcal{F}_{\text{Preprocessing}}$ the global difference R^i and the keys $k_{w,0}^i$, for each $i \in I$ and each w that is an output wire of an AND gate, as well as the wire masks λ_w (for each w that is an input wire of a corrupt party).
3. **SECURE PRODUCT COMPUTATIONS:** The simulator \mathcal{S} emulates $\mathcal{F}_{\text{BitMPC}}.\text{Input}$ receiving $\hat{\mathbf{x}}^i = (\hat{x}_1^i, \dots, \hat{x}_s^i)$ for every $i \in I$, and also samples honest parties' shares $\hat{\mathbf{x}}^j$, for $j \notin I$. For each AND gate $g \in G$, it emulates $\mathcal{F}_{\text{BitMPC}}.\text{Multiply}$ by receiving shares $(\lambda_{uv})^i$ from \mathcal{A} for $i \in I$ and setting random $(\lambda_{uv})^j$ for $j \notin I$ such that $\sum_{\ell \in [n]} (\lambda_{uv})^\ell = \lambda_u \cdot \lambda_v$. For the $\Pi_{\text{Bit} \times \text{String}}$ subprotocol:
- **Multiply:** \mathcal{S} emulates $\mathcal{F}_{\text{COT}}.\text{Extend}$ between each pair of parties P_i and P_j . If both parties are honest, or if both are corrupted, the simulation is trivial. Hereafter, we focus on the cases where exactly one party of each pair is corrupted:
 - When P_i is a corrupted sender, \mathcal{S} receives a (possibly) different $q_i \in \{0,1\}^\kappa$ from \mathcal{A} for each of the $3|G| + s$ calls.
 - When P_i is a corrupted receiver, \mathcal{S} receives $(\lambda_u^i + \delta_{\lambda_u}^{i,j}, \lambda_v^i + \delta_{\lambda_v}^{i,j}, \lambda_{uv}^i + \lambda_w^i + \delta_{\lambda_{uv} + \lambda_w}^{i,j})_{(u,v,w)}$ for each AND gate, plus the values $\hat{x}_1^i + \delta_{\hat{x}_1}^{i,j}, \dots, \hat{x}_s^i + \delta_{\hat{x}_s}^{i,j}$. For each of the $3|G| + s$ previous inputs, it also receives a (possibly) different $t_i \in \{0,1\}^\kappa$ from \mathcal{A} .
 Note that the errors $\delta^{i,j}$ and the t_i, q_i values received from \mathcal{A} are stored by \mathcal{S} , whilst the λ values and shares were fixed in the previous stage.
 - **Consistency Check:**
 2. \mathcal{S} emulates $\mathcal{F}_{\text{Rand}}$ and sends a seed for a uniformly random ε -almost 1-universal linear hash function $\mathbf{H} \in \mathbb{F}_2^{s \times 3|G|}$ to \mathcal{A} .
 3. \mathcal{S} emulates $\mathcal{F}_{\text{BitMPC}}.\text{Open}$ and sends $\mathbf{c}_x = \mathbf{H} \cdot \mathbf{x} + \hat{\mathbf{x}} \in \mathbb{F}_2^s$ to \mathcal{A} , where \mathbf{x} is the vector of $3|G|$ values $(\lambda_u, \lambda_v, \lambda_{uv})_{(u,v,w)}$ from the previous stage, and $\hat{\mathbf{x}} = \sum_{i \in [n]} \hat{\mathbf{x}}^i$, received just before the **Multiply** step. If \mathcal{A} does not send back OK to \mathcal{S} , then \mathcal{S} sends \perp to $\mathcal{F}_{\text{Preprocessing}}$ and aborts.
 - 4-5. Emulating $\mathcal{F}_{\text{Commit}}$, \mathcal{S} receives \mathbf{C}_ℓ^i from \mathcal{A} for all $\ell \in [n]$ and $i \in I$. It then computes \mathbf{C}_ℓ^j for $j \notin I$, as each honest party would, and completes the emulation of $\mathcal{F}_{\text{Commit}}$ by sending these to \mathcal{A} . If $\sum_{i \in I} \mathbf{C}_\ell^i + \sum_{j \notin I} \mathbf{C}_\ell^j \neq 0$, for any $\ell \in [n]$, \mathcal{S} sends \perp to $\mathcal{F}_{\text{Preprocessing}}$ and terminates.
4. **GARBLE GATES:** For every AND gate $g \in G$, the simulator \mathcal{S} computes and stores corrupt parties' shares of the garbled circuit, \tilde{C}^i , for $i \in I$, as the adversary should do according to the protocol. Note that \mathcal{S} has all the necessary values to do so from the messages it previously received and the knowledge of \mathcal{A} 's random tape. Namely, the simulator knows the PRF keys, the global differences, and the t_i and q_i values received in the \mathcal{F}_{COT} calls.
5. **REVEAL MASKS FOR OUTPUT WIRES:** \mathcal{S} emulates $\mathcal{F}_{\text{BitMPC}}.\text{Open}$ and for every circuit-output wire w , it calls $\mathcal{F}_{\text{Preprocessing}}$ to get the wire mask λ_w and forward it to \mathcal{A} . If \mathcal{A} does not send back OK to \mathcal{S} , then \mathcal{S} sends \perp to $\mathcal{F}_{\text{Preprocessing}}$ and terminates.

Open Garbling:

6. For each $i \in I$, \mathcal{S} samples random shares $\{S_j^i\}_{j \notin I}$ and sends these to \mathcal{A} .
7. \mathcal{S} then calls $\mathcal{F}_{\text{Preprocessing}}$ to receive the garbled circuit \tilde{C} . Using the corrupted parties' shares \tilde{C}^i , $i \in I$, received previously, \mathcal{S} generates random honest parties' shares \tilde{C}^j , $j \notin I$, subject to the constraint that $\sum_{\ell \in [n]} \tilde{C}^\ell = \tilde{C}$. Once this is done, \mathcal{S} forwards the honest shares of the garbled circuit to \mathcal{A} . If \mathcal{A} does not respond with OK then \mathcal{S} sends \perp to $\mathcal{F}_{\text{Preprocessing}}$ and terminates. Otherwise, it receives from the adversary OK and shares \hat{C}^i for $i \in I$. Finally, \mathcal{S} computes the error $E = \sum_{i \in I} (\tilde{C}^i + \hat{C}^i)$ and sends this to $\mathcal{F}_{\text{Preprocessing}}$.

INDISTINGUISHABILITY: We will first show that, during the **Garbling** phase, the environment \mathcal{Z} cannot distinguish between an interaction with \mathcal{S} and $\mathcal{F}_{\text{Preprocessing}}$ and an interaction with the real adversary \mathcal{A} and $\Pi_{\text{Preprocessing}}$. We then argue that the garbled circuit, and the honest parties' shares of it, are also identically distributed in both worlds.

Garbling phase indistinguishability: Let's look at the **Garbling** command. In both worlds and for every AND gate, the honest parties's shares for the masks λ_w , and for the products λ_{uv} are uniformly random additive shares, whereas the corrupted parties shares' are chosen by \mathcal{A} . Every other step up to the execution of the $\Pi_{\text{Bit} \times \text{String}}$ subprotocol provides no output to the parties, and hence \mathcal{Z} has exactly the same view in both worlds up to that point.

In the **Multiply** step of $\Pi_{\text{Bit} \times \text{String}}$, \mathcal{S} only receives values from \mathcal{A} , so no further information is added to his view here. Note that since the corrupted parties' inputs to \mathcal{F}_{COT} are received by \mathcal{S} , all the errors $\Delta^{i,j}, \delta^j = \sum_{i \in I} \delta^{i,j}$ are well-defined in the simulation.

Next, consider the **Consistency Check** step. If any of the errors are non-zero, then from Lemma 3.1, we know that in both worlds the check fails with overwhelming probability. In this case, no outputs are sent to the honest parties, and (recalling that there are no inputs from honest parties) indistinguishability is trivial since the simulator just behaved as honest parties would until this point.

We now assume that all of the errors $\Delta^{i,j}, \delta^j = \sum_{i \in I} \delta^{i,j}$ are zero, and so the check passes. The values \mathbf{H} and $c_x = \mathbf{H}\mathbf{x} + \hat{\mathbf{x}}$ seen by \mathcal{A} are uniformly random in both worlds, since the masking values $\hat{\mathbf{x}}$ are uniformly random and never seen by the environment. The distribution of the committed and opened values, \mathbf{C}_j^i , is more subtle, however. First, consider the case when there is exactly one honest party. In this case, in both worlds the values \mathbf{C}_j^i , for honest P_i , are a deterministic function of the adversary's behaviour, since they should satisfy $\sum_{i=1}^n \mathbf{C}_j^i = 0$. Therefore, these values are identically distributed in both worlds.

Now, suppose there is more than one honest party. The values \mathbf{C}_j^i are computed based on the \mathbf{Z}_j^i values, which are the sum of outputs from \mathcal{F}_{COT} with every other party. This means for every honest P_i , \mathbf{C}_j^i is uniformly random, since it includes an \mathcal{F}_{COT} output with one other honest party. On the other hand, the values \mathbf{C}_j^i , where $j \in I$ and $i \notin I$, only come from a single \mathcal{F}_{COT} instance between P_i and P_j , and P_i 's output from \mathcal{F}_{COT} in this case is not random in the view of \mathcal{A} . It actually should satisfy:

$$\mathbf{C}_j^i = \mathbf{H} \cdot \mathbf{Z}_j^i + \hat{\mathbf{Z}}_j^i = \mathbf{H} \cdot \mathbf{Q}_{i,j} + \hat{\mathbf{Q}}_{i,j} + (\mathbf{H} \cdot \mathbf{x}^i + \hat{\mathbf{x}}^i) \otimes R^j$$

where $\mathbf{Q}_{i,j}, \hat{\mathbf{Q}}_{i,j}$ are the \mathcal{F}_{COT} outputs of corrupt P_j , and R^j is also known to P_j . This means for each row of \mathbf{C}_j^i , in the view of \mathcal{A} there are only two possibilities, depending on one bit from $(\mathbf{H} \cdot \mathbf{x}^i + \hat{\mathbf{x}}^i)$. Since the shares $\hat{\mathbf{x}}^i$ are uniformly random and never seen by the environment, $\mathbf{H} \cdot \mathbf{x}^i + \hat{\mathbf{x}}^i$ is also uniformly random in both worlds, subject to the constraint that these sum to c_x (which was opened previously). We conclude that the \mathbf{C}_j^i values are identically distributed.

After $\Pi_{\text{Bit} \times \text{String}}$, \mathcal{Z} remains unable to distinguish in the garbling phase. First, the **Garble Gates** step of $\Pi_{\text{Preprocessing}}$ requires no communication. Finally, regarding **Reveal masks for output wires**, the revealed wire masks are random bits in both worlds.

Open Garbling phase indistinguishability: In the real world, the first set of shares in the **Open Garbling** stage are uniformly random in the view of \mathcal{Z} , since \mathcal{Z} sees at most $n - 1$ of each set of n random shares. Similarly, the rerandomized shares sent in the final step are uniformly random, subject to summing up to the garbled circuit \tilde{C} , since \mathcal{Z} never sees the resharing sent between honest parties. Therefore, the simulation of this stage is perfect, as \mathcal{S} uses the correct garbled circuit output by $\mathcal{F}_{\text{Preprocessing}}$, and the errors are defined according to the correct shares that should have been sent by \mathcal{A} . ■

4 More Efficient Garbling with Multi-Party TinyOT

We now describe a less general, but concretely more efficient, variant of the protocol in the previous section. We replace the generic $\mathcal{F}_{\text{BitMPC}}$ functionality with a more specialized one based on ‘TinyOT’-style information-theoretic MACs. This is asymptotically worse, but more practical, than using [IPS08] for $\mathcal{F}_{\text{BitMPC}}$. It also allows us to completely remove the bit/string multiplications and consistency checks in $\Pi_{\text{Bit} \times \text{String}}$, since we show that these can be obtained directly from the TinyOT MACs. In addition, we show how to optimize the communication cost of the rerandomization step, in the random oracle model. This means the only cost in the protocol, apart from opening and evaluating the garbled circuit, is the single bit multiplication per AND gate in the underlying TinyOT-based protocol.

In Appendix A we present a complete description of a suitable TinyOT-based protocol. This is done by combining the multiplication triple generation protocol (over \mathbb{F}_2) from [FKOS15] with a consistency check to enforce correct shared random bits, which is similar to the more general check from the previous section.

4.1 Secret-Shared MAC Representation

For $x \in \{0, 1\}$ held by P_i , define the following two-party MAC representation, as used in 2-party TinyOT [NNOB12]:

$$[x]_{i,j} = (x, M_j^i, K_i^j), \quad M_j^i = K_i^j + x \cdot R^j$$

where P_i holds x and a MAC M_j^i , and P_j holds a local MAC key K_i^j , as well as the fixed, global MAC key R^j .

Similarly, we define the n -party representation of an additively shared value $x = x^1 + \dots + x^n$:

$$[x] = (x^i, \{M_j^i, K_j^i\}_{j \neq i})_{i \in [n]}, \quad M_j^i = K_j^i + x^i \cdot R^j$$

where each party P_i holds the $n - 1$ MACs M_j^i on x^i , as well as the keys K_j^i on each x^j , for $j \neq i$, and a global key R^i . Note that this is equivalent to every pair (P_i, P_j) holding a representation $[x^i]_{i,j}$.

The key observation for this section, is that a sharing $[x]$ can be used to directly compute shares of all the products $x \cdot R^j$, as in the following claim.

Claim 4.1 *Given a representation $[x]$, the parties can locally compute additive shares of $x \cdot R^j$, for each $j \in [n]$.*

Proof: Write $[x] = (x^i, \{M_j^i, K_j^i\}_{j \neq i})_{i \in [n]}$. Each party P_i defines the n shares:

$$Z_i^j = x^i \cdot R^j + \sum_{j \neq i} K_j^i \quad \text{and} \quad Z_j^i = M_j^i, \quad \text{for each } j \neq i$$

We then have, for each $j \in [n]$:

$$\sum_{i=1}^n Z_j^i = Z_j^j + \sum_{i \neq j} Z_j^i = (x^j \cdot R^j + \sum_{i \neq j} K_i^j) + \sum_{i \neq j} M_j^i = x^j \cdot R^j + \sum_{i \neq j} (M_j^i + K_i^j) = x^j \cdot R^j + \sum_{i \neq j} (x^i \cdot R^j) = x \cdot R^j.$$

■

We define addition of two shared values $[x], [y]$, to be straightforward addition of the components. We define addition of $[x]$ with a public constant $c \in \mathbb{F}_2$ by:

- P_1 stores: $(x^1 + c, \{M_j^1, K_j^1\}_{j \neq 1})$
- P_i stores: $(x^i, (M_1^i, K_1^i + c \cdot R^i), \{M_j^i, K_j^i\}_{j \in [n] \setminus \{1, i\}}))$, for $i \neq 1$

This results in a correct sharing of $[x + c]$.

We can create a sharing of the product of two shared values using a random multiplication triple $([x], [y], [z])$ such that $z = x \cdot y$ with Beaver's technique [Bea92], shown in Figure 18.

4.2 MAC-Based MPC Functionality

The functionality $\mathcal{F}_{\text{n-TinyOT}}$, which we use in place of $\mathcal{F}_{\text{BitMPC}}$ for the optimized preprocessing, is shown in Figure 9. It produces authenticated sharings of random bits and multiplication triples. For both of these, $\mathcal{F}_{\text{n-TinyOT}}$ first receives corrupted parties' shares, MAC values and keys from the adversary, and then randomly samples consistent sharings and MACs for the honest parties.

Another important aspect of the functionality is the **Key Queries** command, which allows the adversary to try to guess the MAC key R^i of any party, and will be informed if the guess is correct. This is needed to allow the security proof to go through; we explain this in more detail in Appendix A. In that section we also present a complete description of a variant on the multi-party TinyOT protocol, which can be used to implement this functionality.

4.3 Garbling with $\mathcal{F}_{\text{n-TinyOT}}$

Following from the observation in Claim 4.1, if each party P_j chooses the global difference string in $\Pi_{\text{Preprocessing}}$ to be the same R^j as in the MAC representation, then given $[\lambda]$, additive shares of the products $\lambda \cdot R^j$ can be obtained at no extra cost. Moreover, the shares are guaranteed to be correct, and the honest party's shares will be random (subject to the constraint that they sum to the correct value), since they come directly from the $\mathcal{F}_{\text{n-TinyOT}}$ functionality. This means there is no need to perform the consistency check, which greatly simplifies the protocol.

The rest of the protocol is mostly the same as $\Pi_{\text{Preprocessing}}$ in Figure 6, using $\mathcal{F}_{\text{n-TinyOT}}$ with $[\cdot]$ -sharings instead of $\mathcal{F}_{\text{BitMPC}}$ with $\langle \cdot \rangle$ -sharings. One other small difference is that because $\mathcal{F}_{\text{n-TinyOT}}$ does not have a private input command, we instead sample $[\lambda_w]$ shares for input wires using random bits, and later use a private output protocol to open the relevant input wire masks to P_i . This change is not strictly

Functionality $\mathcal{F}_{n\text{-TinyOT}}$

Initialize: On receiving (init) from all parties, the functionality receives $R^i \in \{0, 1\}^\kappa$, for $i \in I$, from the adversary, and then samples $R^i \leftarrow \{0, 1\}^\kappa$, for $i \notin I$, and sends R^i to party P_i .

Prep: On receiving (Prep, m, M) from all parties, generate m random bits as follows:

1. Receive corrupted parties' shares $b_\ell^i \in \mathbb{F}_2$ from \mathcal{A} , for $i \in I$.
2. Sample honest parties' shares, $b_\ell^i \leftarrow \mathbb{F}_2$, for $i \notin I$ and $\ell \in [m]$.
3. Run n -Bracket($b_\ell^1, \dots, b_\ell^n$), for every $\ell \in [m]$, so each party obtains the shares b_ℓ^i , as well as $n - 1$ MACs on b_ℓ^i and a key on each b_ℓ^j , for $j \neq i$.

And M multiplication triples as follows:

1. Sample $a_\ell, b_\ell \leftarrow \mathbb{F}_2$ and compute $c_\ell = a_\ell \cdot b_\ell$, for $\ell \in [M]$.
2. For each $x \in \{a_\ell, b_\ell, c_\ell\}_{\ell \in [M]}$, authenticate x as follows:
 - (a) Receive corrupted parties' shares $x^i \in \mathbb{F}_2$, for $i \in I$, from \mathcal{A} .
 - (b) Sample honest parties' shares $x^i \leftarrow \mathbb{F}_2$, for $i \notin I$ subject to $\sum_{i=1}^n x^i = x$.
 - (c) Run n -Bracket(x^1, \dots, x^n), so the parties obtain $[x]$.

Key queries: On receiving (i, R') from \mathcal{A} , where $i \in [n]$, output 1 to \mathcal{A} if $R^i = R'$. Otherwise, output 0 to \mathcal{A} .

Figure 9: Functionality for secure multi-party computation based on TinyOT

Macro n -Bracket

This subroutine of $\mathcal{F}_{n\text{-TinyOT}}$ uses the global MAC keys R^1, \dots, R^n stored by the functionality.

On input (x^1, \dots, x^n) , authenticate the share $x^i \in \{0, 1\}$, for each $i \in [n]$, as follows:

If P_i is corrupt: receive a MAC $M_j^i \in \mathbb{F}_2^\kappa$ from \mathcal{A} and compute the key $K_i^j = M_j^i + x^i \cdot R^j$, for each $j \neq i$.

Otherwise:

1. Sample honest parties' keys $K_i^j \leftarrow \mathbb{F}_2^\kappa$, for $j \in [n] \setminus (I \cup \{i\})$.
2. Receive keys $K_i^j \in \mathbb{F}_2^\kappa$, for each $j \in I$, from \mathcal{A} .
3. Compute the MACs $M_j^i = K_i^j + x^i \cdot R^j$, for $j \in I$.

Finally, output $(x^i, \{M_j^i, K_j^i\}_{j \neq i})$ to party P_i , for $i \in [n]$.

Figure 10: Macro used by $\mathcal{F}_{n\text{-TinyOT}}$ to authenticate bits

necessary, but simplifies the protocol for implementing $\mathcal{F}_{n\text{-TinyOT}}$ — if $\mathcal{F}_{n\text{-TinyOT}}$ also had an **Input** command for sharing private inputs based on n -Bracket, it would be much more complex to implement with the correct distribution of shares and MACs.

In more detail, the **Garbling** phase proceeds as follows.

1. Each party obtains a random key offset R^i by calling the **Initialize** command of $\mathcal{F}_{n\text{-TinyOT}}$.
2. For every wire w which is an input wire, or the output wire of an AND gate, the parties obtain a shared mask $[\lambda_w]$ using the **Bit** command of $\mathcal{F}_{n\text{-TinyOT}}$.
3. All the wire keys $k_{w,0}^i, k_{w,1}^i = k_{w,0}^i \oplus R^i$ are defined by P_i the same way as in $\Pi_{\text{Preprocessing}}$.
4. For XOR gates, the output wire mask is computed as $[\lambda_w] = [\lambda_u] + [\lambda_v]$.
5. For each AND gate, the parties compute $[\lambda_{uv}] = [\lambda_u \cdot \lambda_v]$ using the subprotocol Π_{Mult} in Figure 18.
6. The parties then obtain shares of the garbled circuit as follows:
 - For each AND gate $g \in G$ with wires (u, v, w) , the parties use Claim 4.1 with the shared values $[\lambda_u], [\lambda_v], [\lambda_{uv} + \lambda_w]$, to define, for each $j \in [n]$, shares of the bit/string products:
$$\lambda_u \cdot R^j, \quad \lambda_v \cdot R^j, \quad (\lambda_{uv} + \lambda_w) \cdot R^j$$
 - These are then used to define shares of $\rho_{j,a,b}$ and the garbled circuit, as in the original protocol.
7. For every circuit-output-wire w , the parties run Π_{Open} to reveal λ_w to all the parties.
8. For every *circuit input wire* w corresponding to party P_i 's input, the parties run Π_{Open}^i (Figure 15) to open λ_w to P_i .

The only interaction introduced in the new protocol is in the multiply and opening protocols, which were abstracted away by $\mathcal{F}_{\text{BitMPC}}$ in the previous protocol. Simulating and proving security of these techniques is straightforward, due to the correctness and randomness of the multiplication triples and MACs produced by $\mathcal{F}_{n\text{-TinyOT}}$. One important detail is the **Key Queries** command of the $\mathcal{F}_{n\text{-TinyOT}}$ functionality, which allows the adversary to try to guess an honest party's global MAC key share, R^i , and learn if the guess is correct. To allow the proof to go through, we modify $\mathcal{F}_{\text{Preprocessing}}$ to also have a **Key Queries** command, so that the simulator can use this to respond to any key queries from the adversary. We denote this modified functionality by $\mathcal{F}_{\text{Preprocessing}}^{\text{KQ}}$.

The following theorem can be proven, similarly to the proof of Theorem 3.1 where we modify the preprocessing functionality to support key queries, and adjust the simulation as described above.

Theorem 4.1 *The modified protocol described above UC-securely computes $\mathcal{F}_{\text{Preprocessing}}^{\text{KQ}}$ from Figure 5 in the presence of a static, malicious adversary corrupting up to $n - 1$ parties in the $\mathcal{F}_{n\text{-TinyOT}}$ -hybrid model.*

Finally, in Section 5.1 we discuss how to extend the proof of the online phase, showing that allowing key queries in the preprocessing functionality does not affect security.

4.4 Optimizing the Rerandomization Step

Asymptotically, the most expensive part of the preprocessing stage is generating the random shares of zero in the rerandomization step, because this requires $O(|C|\kappa n^3)$ communication in total. We can reduce this to $O(|C|\kappa n^2)$, in the random oracle model, by replacing **Open Garbling** with the following:

- Let $H : \{0, 1\}^\kappa \rightarrow \{0, 1\}^{4n\kappa|G|}$ be a random oracle.
- Each party P_i samples random seeds $s_j^i \leftarrow \{0, 1\}^\kappa$, $j \neq i$. P_i sends s_j^i to P_j over a private channel, for $j \neq i$.
- P_i computes the shares $S_i^i = \bigoplus_{i \neq j} H(s_j^i)$, and $S_i^j = H(s_j^i)$, for $j \neq i$.
- Each P_i , for $i = 2, \dots, n$, sends $\tilde{C}^i \oplus \bigoplus_{j=1}^n S_i^j$ to P_1 .
- P_1 reconstructs the garbled circuit, \tilde{C} , and broadcasts this.

Since every party no longer needs to broadcast an entire garbled circuit share, this reduces the overall cost of the preprocessing stage to $O(|C|\kappa n^2)$.

5 The Online Phase

Our final protocol, presented in Figure 11, implements the online phase where the parties reveal the garbled circuit's shares and evaluate it. Our protocol is presented in the $\mathcal{F}_{\text{Preprocessing}}$ -hybrid model. Upon reconstructing the garbled circuit and obtaining all input keys, the process of evaluation is similar to that of [Yao86], except here all parties run the evaluation algorithm, which involves each party computing n^2 PRF values per gate. During evaluation, the parties only see the randomly masked wire values and cannot determine the actual wire values. Upon completion, the parties compute the actual output using the output wire masks revealed from $\mathcal{F}_{\text{Preprocessing}}$. We conclude with the following theorem.

Theorem 5.1 *Let f be an n -party functionality $\{0, 1\}^{n\kappa} \mapsto \{0, 1\}^\kappa$ and assume that F is a PRF. Then Protocol Π_{MPC} from Figure 11, UC-securely computes f in the presence of a static malicious adversary corrupting up to $n - 1$ parties in the $\mathcal{F}_{\text{Preprocessing}}$ -hybrid.*

Proof overview. Our proof follows by first demonstrating that the adversary's view is computationally indistinguishable in both real and simulated executions. To be concrete, we consider an event for which the adversary successfully causes the bit transferred through some wire to be flipped and prove that this event can only occur with negligible probability (our proof is different to the proof in [LPSY15] as in our case the adversary may choose its additive error as a function of the garbled circuit). Then, conditioned on the event flip not occurring, we prove that the two executions are computationally indistinguishable via a reduction to the correlation robust PRF, inducing a garbled circuit that is indistinguishable. The complete proof is found below.

Proof: Let \mathcal{A} be a PPT adversary corrupting a subset of parties $I \subset [n]$. We prove that there exists a PPT simulator \mathcal{S} with access to an ideal functionality \mathcal{F} that implements f , that simulates the adversary's view. Denoting the set of honest parties by \bar{I} , our simulator \mathcal{S} is defined below.

The MPC Protocol - Π_{MPC}

On input a circuit C_f representing the function f and $\rho = (\rho_1, \dots, \rho_n)$ where ρ_i is party's P_i input, the parties execute the following commands in sequence.

Preprocessing: This sub-task is performed as follows.

- Call **Garbling** on $\mathcal{F}_{\text{Preprocessing}}$ with input C_f .
- Each party P_i obtains the λ_w wire masks for every output wire and every wire associated with their input, and all the keys $\{k_{w,0}^i\}_{w \in W}$ and R^i .

Online Computation: This sub-task is performed as follows.

- For all input wires w with input from P_i , party P_i computes $\Lambda_w = \rho_w \oplus \lambda_w$, where ρ_w is P_i 's input to C_f , and λ_w was obtained in the preprocessing stage. Then, P_i broadcasts the public value Λ_w to all parties.
- For all input wires w , each party P_i broadcasts the key k_w^i associated to Λ_w .
- The parties call **Open Garbling** on $\mathcal{F}_{\text{Preprocessing}}$ to reconstruct $\tilde{g}_{a,b}^j$ for every gate g and values a, b .
- Passing through the circuit topologically, the parties can now locally compute the following operations for each gate g . Let the gates input wires be labelled u and v , and the output wire be labelled w . Let a and b be the respective public values on the input wires.
 1. If g is a XOR gate, set the public value on the output wire to be $c = a + b$. In addition, for every $j \in [n]$, each party computes $k_{w,c}^j = k_{u,a}^j \oplus k_{v,b}^j$.
 2. If g is an AND gate, then each party computes, for all $j \in [n]$:

$$k_{w,c}^j = \tilde{g}_{a,b}^j \oplus \left(\bigoplus_{i=1}^n F_{k_{u,a}^i, k_{v,b}^i}(g||j) \right)$$

3. If $k_{w,c}^i \notin \{k_{w,0}^i, k_{w,1}^i = k_{w,0}^i \oplus R^i\}$, then P_i outputs **abort**. Otherwise, it proceeds. If P_i aborts it notifies all other parties with that information. If P_i is notified that another party has aborted it aborts as well.
 4. If $k_{w,c}^i = k_{w,0}^i$ then P_i sets $c = 0$; if $k_{w,c}^i = k_{w,1}^i$ then P_i sets $c = 1$.
 5. The output of the gate is defined to be $(k_{w,c}^1, \dots, k_{w,c}^n)$ and the public value c .
- Assuming no party aborts, everyone will obtain a public value c_w for every circuit-output wire w . The party can then recover the actual output value from $\rho_w = c_w \oplus \lambda_w$, where λ_w was obtained in the preprocessing stage.

Figure 11: The MPC Protocol - Π_{MPC}

The description of the simulation.

1. **INITIALIZATION.** Upon receiving the adversary's input $(1^\kappa, I, \vec{x}_I)$, \mathcal{S} incorporates \mathcal{A} and internally emulates an execution of the honest parties running Π_{MPC} with the adversary \mathcal{A} :
2. **PROCESSING.** \mathcal{S} emulates the preprocessing phase of functionality $\mathcal{F}_{\text{Preprocessing}}$, obtaining the adversary input (init, C_f) where C_f is a Boolean circuit that computes f with a set of wires W and a set G of AND gates.
3. **GARBLING.** Let W' denote the set of input wires that are associated with the adversary's input. Then upon receiving the input $(\text{Garbling}, C_f)$ from the adversary the simulator emulates the garbling phase as follows.

- Upon receiving the global differences $\{R^i\}_{i \in I}$ from the adversary the simulator records this set.
- For every input wire $w \in W'$ that is associated to the adversary's input, the simulator obtains from the adversary a random masking value $\lambda_w \in \{0, 1\}$ and an input key $k_{w,0}^i \in \{0, 1\}^\kappa$.
- For every wire $w \in W$ that is the output of an AND gate and $i \in I$, the simulator chooses a random $\lambda_w \in \{0, 1\}$ and records it. Moreover, the simulator obtains from the adversary a key $k_{w,0}^i$ and records the pair $(k_{w,0}^i, k_{w,1}^i = k_{w,0}^i \oplus R^i)$.
- Upon receiving an OK command from the adversary, the simulator forwards it a random masking value $\lambda_w \in \{0, 1\}$, for every output wire $w \in W$.

4. **ONLINE COMPUTATION.** In the online computation the simulator honestly generates the public values $\{\Lambda_w\}_{w \in W''}$ and the input keys $\{k_{w,\Lambda_w}^i\}_{i \in \bar{I}, w \in W''}$ that are associated with the honest parties' input wire set W'' , and broadcasts these to the adversary.

It then obtains the adversary's public values $\{\Lambda_w\}_{w \in W'}$ as well as its input keys $\{\hat{k}_w^i\}_{i \in I, w \in W'}$ (which may be different to the keys received in the garbling phase), and defines the adversary's input as follows.

- **INPUT EXTRACTION.** For each input wire $w \in W'$, the simulator computes $\rho_w = \Lambda_w \oplus \lambda_w$ and fixes the adversary's input $\{\vec{x}_I\}$ to be the concatenation of these bits. \mathcal{S} sends this input to the trusted party computing f , receiving the output $\mathbf{y} = (y_1, \dots, y_m)$. Note that \mathcal{A} may still provide inconsistent input keys with ρ which we view as providing incorrect PRF values for these wires.

5. **SIMULATED GARBLED CIRCUIT GENERATION.** Upon receiving the adversary's (`OpenGarbling`) message on $\mathcal{F}_{\text{Preprocessing}}$ the simulator completes the generation of the garbled circuit as follows.

- It first generates the honest parties' keys $\{k_{w,\Lambda_w}^i\}_{i \in \bar{I}, w \in W}$ associated with every internal wire $w \in W$ that is an output of an AND gate. Note that for the honest parties the simulator generates a single key per wire.
- Next, the simulator chooses a random $\Lambda_w \leftarrow \{0, 1\}$ for the public value on every internal wire $w \in W$ that is an output of an AND gate, except for the circuit output wires. For the t -th output wire, \mathcal{S} defines $\Lambda_w = \lambda_w \oplus y_t$ (recall that the masking values for the output wires are already fixed at this point, so the public values must be consistent with the output $\mathbf{y} = y_1, \dots, y_m$).
- For every XOR gate with input wires u and v and output wire w , \mathcal{S} sets $k_{w,0}^i = k_{u,0}^i \oplus k_{v,0}^i$ and $k_{w,1}^i = k_{w,0}^i \oplus R^i$ for all $i \in [n]$, and $\Lambda_w = \Lambda_u \oplus \Lambda_v$.

- **ACTIVE PATH GENERATION.** In the next step the simulator computes an active path of the garbled circuit which corresponds to the sequence of keys that will be observed by the adversary. More formally, for every AND gate g that is not an output gate, \mathcal{S} honestly generates the entry in row (Λ_u, Λ_v) , where Λ_u (resp. Λ_v) is the public value associated to the left (resp. right) input wire to g . Namely, the simulator computes

$$\tilde{g}_{\Lambda_u, \Lambda_v}^j = \left(\bigoplus_{i=1}^n F_{k_{\Lambda_u, \Lambda_u}^i, k_{\Lambda_v, \Lambda_v}^i} (g \| j) \right) \oplus k_{w, \Lambda_w}^j$$

fixing $\tilde{\mathbf{g}}_{\Lambda_u, \Lambda_v} = \tilde{g}_{\Lambda_u, \Lambda_v}^1 \circ \dots \circ \tilde{g}_{\Lambda_u, \Lambda_v}^n$. The remaining three rows are sampled uniformly at random from $\{0, 1\}^{n\kappa}$. Importantly, \mathcal{S} never uses the inactive keys $k_{u, \bar{\Lambda}_u}^i, k_{v, \bar{\Lambda}_v}^i$ and $k_{w, \bar{\Lambda}_w}^i$ in order to generate the garbled circuit.

6. The simulator hands the adversary the complete garbled circuit. In case the adversary aborts, the simulator sends *NO-GO* to the trusted party and aborts. Otherwise, the simulator obtains an additive error $e = \{e_g^{a,b}\}_{a,b \in \{0,1\}, g \in G}$ and computes the modified garbled circuit as $\tilde{\mathbf{g}}_{\Lambda_u, \Lambda_v} + e_g^{\Lambda_u, \Lambda_v}$.

Next, the simulator evaluates the modified circuit using the input wire keys $\{\hat{k}_{w, \Lambda_w}^i\}_{w \in W', i \in I}$ and $\{k_{w, \Lambda_w}^j\}_{w \in W'', j \in \bar{I}}$ and checks whether the honest parties would have aborted. Namely, for each gate, whether the evaluation reveals the honest parties' keys associated with Λ_w for w the output wire of some AND gate. If there exists a gate for which the evaluation does not yield the key associated with Λ_w then the simulator outputs fail and aborts.

This concludes the description of the simulation. Note that the difference between the simulated and the real executions is regarding the way the garbled circuit is generated. More concretely, the simulated garbled circuit is only generated *after* the simulator extracts the adversary's input. Moreover, the simulated garbled gates include a single row that is properly produced, whereas the remaining three rows are picked at random. Let $\mathbf{HYB}_{\Pi_{\text{MPC}}, \mathcal{A}, \mathcal{Z}}^{\mathcal{F}\text{Preprocessing}}(1^\kappa, z)$ denote the output distribution of the adversary \mathcal{A} and honest parties in a real execution using Π_{MPC} with adversary \mathcal{A} . Moreover, let $\mathbf{IDEAL}_{\mathcal{F}, \mathcal{S}, \mathcal{Z}}(1^\kappa, z)$ denote the output distribution of \mathcal{S} and the honest parties in an ideal execution.

We next define Flip to be the event that there exists an AND gate g and an honest party P_j , who, when evaluating the modified garbled circuit, (1) Does not abort; and (2) Obtains the incorrect key $k_{w, \bar{\Lambda}_w}^j$ for the output wire w of g . Note that this event implies that the adversary causes P_j to compute an incorrect value, as the bit value being transferred within the output wire w is now flipped with respect to P_j .

To prove that this event occurs with negligible probability, we consider an execution $\widetilde{\mathbf{IDEAL}}$ where a simulator $\tilde{\mathcal{S}}$ produces a view that is identical to the view produced by \mathcal{S} in \mathbf{IDEAL} . Namely, the adversary's view is simulated exactly as in \mathbf{IDEAL} by a simulator $\tilde{\mathcal{S}}$ with the exception that $\tilde{\mathcal{S}}$ further picks the global differences $\{R^i\}_{i \in \bar{I}}$ and $\{k_{w, \bar{\Lambda}_w}^j\}_{j \in \bar{I}, w \in W}$ (which are never defined by \mathcal{S}). Moreover, the event for which the simulator outputs fail and aborts is modified as follows. Namely, the simulator aborts if there exists a gate for which the evaluation does not yield the key associated with Λ_w or with $\bar{\Lambda}_w$. Note that this event is well-defined since all the wire keys are chosen in this game. Then the difference between \mathbf{IDEAL} and $\widetilde{\mathbf{IDEAL}}$ is the event that \mathcal{S} aborts whereas $\tilde{\mathcal{S}}$ does not abort. Note that this event occurs when the adversary successfully flipped a wire value. Specifically, this will yield a valid evaluation in $\widetilde{\mathbf{IDEAL}}$ but not in \mathbf{IDEAL} . We next show that this event occurs with negligible probability.

Fix the additive error $e = \{e_g^{a,b}\}_{a,b \in \{0,1\}, g \in G}$ that is added to the simulated garbled circuit, and let $\tilde{\mathbf{g}}_{a,b} + e_g^{a,b}$ for all $g \in G$ and $a, b \in \{0, 1\}$ denote the garbled circuit with the additive error. We prove

that Flip only occurs with negligible probability in $\widetilde{\text{IDEAL}}$ which implies that the statement also holds in IDEAL . Intuitively, this is due to the fact that the adversary can only succeed in this attack by guessing correctly the global difference R^i .

Lemma 5.1 *The probability that Flip occurs in $\widetilde{\text{IDEAL}}$ is no more than $n \cdot 2^{-\kappa}$.*

Proof: Recall first that the simulated garbling in IDEAL involves only generating a single key k_w^j per wire and per honest party, which either corresponds to $k_{w,0}^j$ or $k_{w,1}^j$. Consequently, the simulator does not even need to choose a global difference R^i in order to complete the garbling. Furthermore, the simulator in $\widetilde{\text{IDEAL}}$ does generate these extra values, but never uses them; this means that the simulated garbled circuit given to \mathcal{A} is completely independent of the honest parties' global differences.

Now, suppose Flip occurs with respect to party P_j , and let g be the first flipped AND gate (in some topological order), with input wires u, v and output wire w . Then, because P_j did not abort, the keys on wires u and v obtained by P_j must contain $k_{u,\Lambda_u}^j, k_{v,\Lambda_v}^j$. Note that it is possible that the corrupt parties' keys for these wires may be incorrect, so we denote these by \hat{k}_u^i, \hat{k}_v^i , for $i \in I$. Since gate g was flipped, the j -th entry of the active row of the garbled gate is

$$\hat{g}_{\Lambda_u, \Lambda_v}^j = \bigoplus_{i \in \bar{I}}^n \left(F_{k_{u,\Lambda_u}^i, k_{v,\Lambda_v}^i} (g \| j) \right) \oplus \bigoplus_{i \in I}^n \left(F_{\hat{k}_u^i, \hat{k}_v^i} (g \| j) \right) \oplus k_{w, \bar{\Lambda}_w}^j.$$

To cause this to happen, the adversary needs to introduce an error into this entry of the original garbled gate \tilde{g} , given by:

$$\begin{aligned} \Delta_g &:= \hat{g}_{\Lambda_u, \Lambda_v}^j \oplus \tilde{g}_{\Lambda_u, \Lambda_v}^j \\ &= \bigoplus_{i \in I}^n \left(F_{\hat{k}_u^i, \hat{k}_v^i} (g \| j) \oplus F_{k_{u,\Lambda_u}^i, k_{v,\Lambda_v}^i} (g \| j) \right) \oplus R^j \end{aligned}$$

This boils down to correctly guessing R^j for the honest party P_j , which is bounded by $2^{-\kappa}$ as R^j is picked truly at random and independently of all other items in the execution. Taking a union bound over the global differences of all honest parties completes the proof. \square

In the next step we prove that the ideal and real executions are indistinguishable, conditioned on the event Flip not occurring.

Lemma 5.2 *Conditioned on the event $\overline{\text{Flip}}$, the following two distributions are computationally indistinguishable:*

- $\{\text{HYB}_{\Pi_{\text{MPC}}, \mathcal{A}, \mathcal{Z}}^{\mathcal{F}_{\text{Preprocessing}}}(1^\kappa, z)\}_{\kappa \in \mathbb{N}, z \in \{0,1\}^*}$
- $\{\text{IDEAL}_{\mathcal{F}, \mathcal{S}, \mathcal{Z}}(1^\kappa, z)\}_{\kappa \in \mathbb{N}, z \in \{0,1\}^*}$

Proof: We begin by defining a slightly modified real execution $\widetilde{\text{HYB}}$, where the creation of the garbled circuit is moved from the preprocessing stage to the online computation stage, after the parties have broadcast their masked inputs. Note that the garbled circuit is still computed according to $\mathcal{F}_{\text{Preprocessing}}$, and the rest of the protocol is identical to HYB , which induces the same view for the adversary. This hybrid execution is needed in order to construct a distinguisher for the correlation robustness assumption. Let

$\widetilde{\mathbf{HYB}}_{\Pi_{\text{MPC}}, \mathcal{A}}^{\mathcal{F}_{\text{Preprocessing}}}(1^\kappa, z)$ denote the output distribution of the adversary \mathcal{A} and honest parties in this game. It is simple to verify that in the $\mathcal{F}_{\text{Preprocessing}}$ -hybrid model, the adversary's views in $\widetilde{\mathbf{HYB}}$ and \mathbf{HYB} are identical.

Our proof of the lemma follows by a reduction to the correlation robustness of the PRF F (cf. Definition 2.3). Assume by contradiction the existence of an environment \mathcal{Z} , an adversary \mathcal{A} and a non-negligible function $p(\cdot)$ such that

$$\left| \Pr[\mathcal{Z}(\widetilde{\mathbf{HYB}}_{\Pi_{\text{MPC}}, \mathcal{A}, \mathcal{Z}}^{\mathcal{F}_{\text{Preprocessing}}}(1^\kappa, z)) = 1] - \Pr[\mathcal{Z}(\mathbf{IDEAL}_{\mathcal{F}, \mathcal{S}, \mathcal{Z}}(1^\kappa, z)) = 1] \right| \geq \frac{1}{p(\kappa)}$$

for infinitely many κ 's. We construct a distinguisher \mathcal{D}' with access to an oracle \mathcal{O} (that implements either Circ or Rand) that breaks the security of the correlation robustness assumption. Namely, we show that

$$\left| \Pr[R \leftarrow \{0, 1\}^n; \mathcal{A}^{\text{Circ}_{R(\cdot)}}(1^\kappa) = 1] - \Pr[\mathcal{A}^{\text{Rand}(\cdot)}(1^\kappa) = 1] \right| \geq \frac{1}{p(\kappa)}.$$

Distinguisher \mathcal{D}' receives the environment's input z and internally invokes \mathcal{Z} and simulator \mathcal{S} , playing the role of functionality f . In more details,

- \mathcal{D}' internally invokes \mathcal{Z} that fixes the honest parties' inputs ρ .
- \mathcal{D}' emulates the communication with the adversary (controlled by \mathcal{Z}) in the initialization, preprocessing and garbling steps as in the simulation with \mathcal{S} .
- For each wire u , let $\ell_u \in \{0, 1\}$ be the actual value on wire u . Note that these values, as well as the output of the computation y , can be determined since \mathcal{D}' knows the actual input of all parties to the circuit (where the adversary's input is extracted as in the simulation with \mathcal{S}).
- It next constructs the garbled circuit as follows. For each wire w in the circuit that is an output wire of an AND gate and $i \in \bar{I}$, it samples a key k_w^i and a public value Λ_w . Using the internal values ℓ_w , we can also compute the masks $\lambda_w = \ell_w \oplus \Lambda_w$.
- For each wire that is the output of an XOR gate with input wires u and v and output wire w , the distinguisher sets $k_w^i = k_u^i \oplus k_v^i$ for all $i \in [n]$, and $\Lambda_w = \Lambda_u \oplus \Lambda_v$.
- The distinguisher picks an honest party, say P_{i_0} , and samples global differences R^i for $i \in \bar{I} \setminus \{i_0\}$. For every $i \in \bar{I} \setminus \{i_0\}$ and $w \in W$, \mathcal{D}' now has both keys $k_{w, \Lambda_w}^i = k_w^i$ and $k_{w, \bar{\Lambda}_w}^i = k_w^i \oplus R^i$.
- Finally, for each wire that is the output of an AND gate g with input wires u and v and output wire w , the distinguisher computes four ciphertexts c_{00}, c_{01}, c_{10} and c_{11} as the garbled gate, that are generated as follows,

- First, the j -th entry in the (Λ_u, Λ_v) -th row is computed as

$$\left(\bigoplus_{i=1}^n F_{k_{u, \Lambda_u}^i, k_{v, \Lambda_v}^i}^i(g \| j) \right) \oplus k_{w, \Lambda_w}^j.$$

- Next, for for all $(a, b) \in \{0, 1\}^2$ such that $(a, b) \neq (\Lambda_u, \Lambda_v)$ the distinguisher sets $\ell_{a,b} = 0$ if $g(a \oplus \lambda_u, b \oplus \lambda_v) = \ell_w$, and sets $\ell_{a,b} = 1$ otherwise. It then queries $h_{a,b}^j = \mathcal{O}(k_{u,\Lambda_u}^{i_0}, k_{v,\Lambda_v}^{i_0}, g, j, a \oplus \lambda_u, b \oplus \lambda_v, \ell_{a,b})$, and sets the j -th entry of row (a, b) in the garbled gate to be:

$$\left(\bigoplus_{i \neq i_0} F_{k_{u,a}^i, k_{v,b}^i}(g||j) \right) \oplus h_{a,b}^j \oplus k_{w,\Lambda_w}^j$$

- For the output wires the distinguisher sets the public values as in the simulation.
- \mathcal{D}' hands the adversary the complete description of the garbled circuit and concludes the execution as in the simulation with \mathcal{S} .
- \mathcal{D}' outputs whatever \mathcal{Z} does.

Note first that \mathcal{D}' only makes legal queries to its oracle. Furthermore, if $\mathcal{O} = \text{Circ}$ then the view of \mathcal{A} is identically distributed to its view in the real execution of the protocol on the given inputs, whereas if $\mathcal{O} = \text{Rand}$ then \mathcal{A} 's view is distributed identically to the output of the simulator described previously since the oracle's response is truly random in this case. This completes the proof. \square

Finally, we demonstrate that the probability Flip occurs in **HYB** is negligible as well due to indistinguishability of executions. This concludes the proof as it demonstrates that with overwhelming probability the adversary is getting caught whenever cheating in the computation of the PRF values.

Lemma 5.3 *The probability that Flip occurs in **HYB** is bounded by $2^{-\kappa} + \text{negl}(\kappa)$ for some negligible function $\text{negl}(\cdot)$.*

Proof: Intuitively speaking, we prove that if Flip occurs in the real execution with a non-negligible probability, then we can leverage this distinguishing gap in order to break the correlation robustness assumption. Namely, if this event occurs then it is possible to extract R^i and all pairs of inputs keys associated with every wire with respect to an honest party. Given all keys it is possible to recompute the garbled circuit and verify whether it was generated honestly or as in the simulation. More formally, assume by contradiction that

$$\Pr[\text{Flip occurs in **HYB**}] \geq \frac{1}{q(\kappa)}$$

for some non-negligible function $q(\cdot)$ and infinitely many κ 's. We construct a distinguisher \mathcal{D} that breaks the security of the underlying correlation robust PRF with non-negligible probability as follows.

1. Distinguisher \mathcal{D} is identically defined as the distinguisher in the proof of Lemma 5.2, externally communicating with an oracle \mathcal{Q} that either realizes the function Circ or Rand, while internally invoking \mathcal{A} . The only difference is that \mathcal{D} chooses i_0 at random. This is due to the fact that the event Flip holds with respect to (at least) one honest party, whose identity is unknown.
2. Upon receiving the modified garbled circuit from \mathcal{A} , \mathcal{D} evaluates the circuit on the parties' inputs and compares every active key \tilde{k}_w^i that is revealed during the execution with the actual active key k_w^i that was created by \mathcal{D} in the garbling phase. For every gate g for which there exists a difference $\Delta_g^i = \tilde{k}_w^i \oplus k_w^i$ for all $i \in \bar{I}$, \mathcal{D} sets $R_g^i = \Delta_g^i$.

3. For every gate g for which \mathcal{D} recorded a global difference $R_g^{i_0}$ for party i_0 , it defines the inactive key for the output wire $w \in W$ of this gate by $k_{w, \bar{\Lambda}_w}^{i_0} = k_{w, \Lambda_w}^{i_0} \oplus R_g^{i_0}$. Next, for some gate g' for which wire w is an input wire (say associated with left input wire to g' w.l.o.g., \mathcal{D} queries its oracle on $(k_{w, \bar{\Lambda}_w}^{i_0}, k_v^{i_0}, g, j, \bar{a} \oplus \lambda_w, b \oplus \lambda_v, \ell_{a,b})$ where $k_v^{i_0}$ is the active key associated with the other input wire of P_{i_0} . \mathcal{D} compares this outcome with the values it obtained from its oracle for the query $(k_{w, \Lambda_w}^{i_0}, k_v^{i_0}, g, j, a \oplus \lambda_w, b \oplus \lambda_v, \ell_{a,b})$. If equality holds, then \mathcal{D} outputs Circ.
4. Upon concluding the execution so that \mathcal{D} did not output Circ, it returns Rand.

Clearly, whenever Flip occurs with respect to i_0 than \mathcal{D} can identify this event by extracting some inactive key and querying its oracle in this key. Therefore \mathcal{D} outputs Circ with probability $\frac{1}{q(\kappa) \cdot n}$. On the other hand, due to the claim made in Lemma 5.2, Flip rarely occurs in **IDEAL** and thus \mathcal{D} outputs Rand on the event of Flip only with negligible probability. This implies a non-negligible gap with respect to the event occurring in the two executions and concludes the proof. \square \blacksquare

5.1 The Online Phase with $\mathcal{F}_{\text{Preprocessing}}^{\text{KQ}}$

In this section we now prove the following theorem, for the online protocol based on $\mathcal{F}_{\text{Preprocessing}}$ with key queries, denoted by $\mathcal{F}_{\text{Preprocessing}}^{\text{KQ}}$ and formally defined in Section 4.3.

Theorem 5.2 *Let f be an n -party functionality $\{0, 1\}^{n\kappa} \mapsto \{0, 1\}^\kappa$ and assume that F is a PRF. Then Protocol Π_{MPC} from Figure 11, UC-securely computes f in the presence of a static malicious adversary corrupting up to $n - 1$ parties in the $\mathcal{F}_{\text{Preprocessing}}^{\text{KQ}}$ -hybrid model.*

In what follows, we discuss how to adapt the proof of Theorem 5.1 to support key queries.

Proof Sketch: We first modify the simulator specified in that proof. Namely, upon receiving the adversary's queries (i, R') , the simulator outputs 0. Intuitively, we claim that with overwhelming probability the adversary only sees zero responses to its key queries as it can only guess a global key with negligible probability. In the following, we formalize this intuition and discuss how to modify the proof of Theorem 5.1 by re-proving Lemma 5.1. Namely, we need to take into account the fact that the probability that the event Flip occurs also depends on the leakage obtained by the key queries made to the functionality.

We define a new hybrid game **H** where the simulator $\mathcal{S}_{\mathbf{H}}$ is defined identically to simulator \mathcal{S} with the exception that $\mathcal{S}_{\mathbf{H}}$ knows the honest parties' inputs and further generates the inactive keys by picking global differences for the honest parties. Furthermore, for every key query (i, R') made by \mathcal{A} , $\mathcal{S}_{\mathbf{H}}$ verifies first whether $R' = R^i$ and aborts in case equality holds. Else, it replies with 0. Nevertheless, $\mathcal{S}_{\mathbf{H}}$ garbles the circuit the same way \mathcal{S} does. Let Guess denote the event in **H** for which the adversary makes a key query R^i (meaning, it guesses the correct R^i value). We prove the following.

Lemma 5.4 *The probability that Flip occurs in **H** is no more than $(q + 1)/2^\kappa$, where q is the number of key queries.*

Proof: We analyze the probability that the event Flip occurs.

$$\begin{aligned} \Pr(\text{Flip}) &= \Pr(\text{Flip}|\text{Guess}) \cdot \Pr(\text{Guess}) + \Pr(\text{Flip}|\overline{\text{Guess}}) \cdot \Pr(\overline{\text{Guess}}) \\ &\leq \Pr(\text{Guess}) + \Pr(\text{Flip}|\overline{\text{Guess}}) \leq q/2^\kappa + 2^{-\kappa}. \end{aligned}$$

\square

This implies that the distributions induced within **IDEAL** and **H** are statistically close since the only difference is whenever event **Guess** occurs. We next claim that the proof of Lemma 5.2 holds with respect to **H** and **HYB**.

Lemma 5.5 *Conditioned on the event $\overline{\text{Flip}}$, the following two distributions are computationally indistinguishable:*

- $\{\mathbf{HYB}_{\Pi_{\text{MPC}}, \mathcal{A}}^{\mathcal{F}\text{Preprocessing}}(1^\kappa, z)\}_{\kappa \in \mathbb{N}, z \in \{0,1\}^*}$
- $\{\mathbf{H}_{\Pi_{\text{MPC}}, \mathcal{S}_H}^{\mathcal{F}\text{Preprocessing}}(1^\kappa, z)\}_{\kappa \in \mathbb{N}, z \in \{0,1\}^*}$

Proof: This proof will have to incorporate the key queries as well. Namely, distinguisher \mathcal{D}' first picks the identity of party i_0 at random. Then, whenever a key query (i_0, R^{i_0}) is made by \mathcal{A} , \mathcal{D}' uses it to calculate the inactive keys of party P_{i_0} and checks whether this yields the garbling it obtained from its oracle. In case it does, \mathcal{D} outputs **Circ**. Otherwise, it outputs **Rand**. Otherwise, if at the end of the execution no queries have resulted in a correct garbling, output **Rand**. \square

Finally, we reprove Lemma 5.3 by demonstrating that if the success probability of **Flip** is non-negligibly higher in **HYB**, then we can distinguish the two executions **HYB** and **H**.

Lemma 5.6 *The probability that **Flip** occurs in **HYB** is bounded by $2^{-\kappa} + \text{negl}(\kappa)$ for some negligible function $\text{negl}(\cdot)$.*

Proof: This proof follows similarly to the proof of Lemma 5.3 in the sense that the reduction additionally needs to reply the adversary's key queries. Namely, for each query (i, R^i) such that $i \neq i_0$, \mathcal{D} can answer this query as it picked the global difference for that party. Moreover, for each query (i_0, R^{i_0}) , \mathcal{D} uses this query to fix a set of inactive keys for party i_0 and verifies whether this guess is correct by recomputing the garbled circuit and comparing it with the original garbled circuit. If equality holds then \mathcal{D} responds with 1 to this query. The rest of the proof follows identically. \square ■

6 Performance

In this section we present implementation results for our protocol from Section 4 for up to 9 parties. We also analyse the concrete communication complexity of the protocol and compare this with previous, state-of-the-art protocols in a similar setting. We remark that to the best of our knowledge, no implementations of constant round, actively secure MPC supporting $n - 1$ out of n corruptions have previously been published.³

We have made a couple of tweaks to our protocol to simplify the implementation. We moved the **Open Garbling** stage to the preprocessing phase, instead of the online phase. This optimizes the online phase so that the amount of communication is independent of the size of the circuit. This change means that our standard model security proof would no longer apply, but we could prove it secure using a random oracle instead of the circular-correlation robust PRF, similarly to [BHR12, LR15]. Secondly, when not working in a modular fashion with a separate preprocessing functionality, the share rerandomization step in the output stage (step 3) is not necessary to prove security of the entire protocol, so we omit this.

³At the time of writing, the concurrent work of Katz et al. [KRW17] does not describe an implementation, although some preliminary results were presented at the Eurocrypt 2017 rump session.

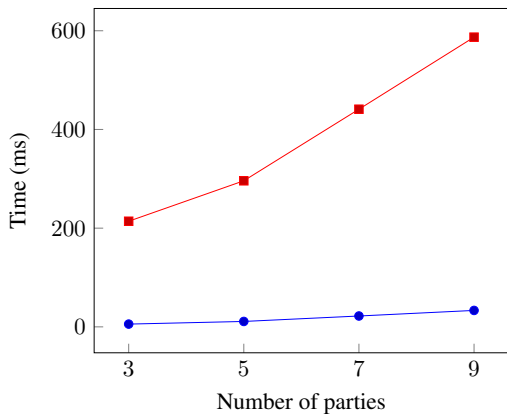

Figure 12: AES performance (6800 AND gates).

Figure 13: SHA-256 performance (90825 AND gates).

6.1 Implementation

We implemented our variant of the multi-party TinyOT protocol (Section A) using the `libOTe` library [Rin] for the fixed-correlation OTs, and tested it for between 3 and 9 parties. We benchmarked the protocol over a 1Gbps LAN on 5 servers with 2.3GHz Intel Xeon CPUs with 20 cores. For the experiments with more than 5 parties, we had to run more than one party per machine; this should not make much difference in a LAN, as the number of threads being used was still fewer than the number of cores. As benchmarks, we measured the time for securely computing the circuits for AES (6800 AND gates) and SHA-256 (90825 AND gates).

For the TinyOT bit and triple generation, every pair of parties needs two correlated OT instances running between them (one in each direction). We ran each OT instance in a separate thread with `libOTe`, so that each party uses $2(n - 1)$ OT threads. This gave a small improvement ($\approx 6\%$) compared with running $n - 1$ threads. We also considered a multiple execution setting, where many (possibly different) secure computations are evaluated. Provided the total number of AND gates in the circuits being evaluated is at least 2^{20} , this allows us to generate the TinyOT triples for all executions at once using a bucket size of $B = 3$, compared with $B = 5$ for one execution of AES or $B = 4$ for one execution of SHA-256. Since the protocol in Section A scales with B^2 , this has a big impact on performance. The results for 9 parties, for the different choices of B , are shown in Table 2.

Figures 12–13 show how the performance of AES and SHA-256 scales with different numbers of parties, in the amortized setting. Although the asymptotic complexity is quadratic, the runtimes grow relatively slowly as the number of parties increases. This is because in the preprocessing phase, the amount of data sent *per party* is actually linear. However, the super-linear trend is probably due to the limitations of the total network capacity, and the computational costs.

Comparison with other works. We calculated the cost of computing the SPDZ-BMR protocol [LPSY15] using [KOS16] to derive estimates for creating the SPDZ triples (the main cost). Using MASCOT over \mathbb{F}_{2^κ} with free-XOR, SPDZ-BMR requires $3n + 1$ multiplications per garbled AND gate. This gives an estimated cost of at least 14 seconds to evaluate AES, which is over 20x slower than our protocol.

Compared with protocols based solely on secret-sharing, such as SPDZ and TinyOT, the advantage of our protocol is the low round complexity. We have not yet managed to benchmark our protocol in a WAN setting, but since our total round complexity is less than 20, it should perform reasonably fast. With secret-sharing, using e.g. TinyOT, evaluating the AES circuit requires at least 40 rounds in just the online phase (it can be done with 10 rounds [DNNR16], but this uses a special representation of the AES function, rather than a general circuit), whilst computing the SHA-256 circuit requires *4000 rounds*. In a network with 100ms delay between parties, the AES online time alone would be at least 4 seconds, whilst SHA-256 would take over *10 minutes* to securely compute in that setting. If our protocol is run in this setting, we should be able to compute both AES and SHA-256 in just a few seconds (assuming that latency rather than bandwidth is the bottleneck).

6.2 Communication Complexity Analysis

We now focus on analysing the concrete communication complexity of the optimized variant of our protocol and compare it with the state of the art in constant-round two-party and multi-party computation protocols. We have not implemented our protocol, but since the underlying computational primitives are very simple, the communication cost will be the overall bottleneck. As a benchmark, we estimate the cost of securely computing the AES circuit (6800 AND gates, 25124 XOR gates), where we assume that one party provides a 128-bit plaintext or ciphertext and the rest of them have an XOR sharing of a 128-bit AES key. This implies we have $128 \cdot n$ input wires and an additional layer of XOR gates in the circuit to add the key shares together. We consider a single set of 128 output wires, containing the final encrypted or decrypted message.

6.2.1 Complexity of Our TinyOT-Based Protocol

We now measure the exact communication cost of our optimized protocol based on TinyOT (in the random oracle model), in terms of number of bits sent over the network per party (multiply this by n for the overall complexity). We exclude one-time costs such as checking MACs, which can be done in a batch at the end, and initializing the base OTs. Consider a circuit with G AND gates, I input wires (in total) and O output wires. The costs of the different stages are as follows, with computational security parameter $\kappa = 128$ and statistical security parameter $s = 40$.

TinyOT Preprocessing. One triple and one random bit per AND gate, plus one random bit per input wire. From the analysis in Appendix A this gives:

$$(504B^2 + 168)(n - 1)G + 168(n - 1)I.$$

Garbling. Two bit openings for each AND gate (for the bit multiplication), one bit opening for every output wire and one private opening for every input wire, gives

$$2(n - 1)G + (n - 1)O + (n - 1)I.$$

	1024	2.0 MB	872 kB	4.22 kB

Table 3: Communication estimates for secure AES evaluation with our protocol and previous works in the two-party setting. Cost is the maximum amount of data sent by any one party, per execution.

Open Garbling. Using random oracles (Section 4.4), the rerandomization step costs $\kappa(n - 1)$ bits per party. Opening the garbled circuit can be done efficiently by each party sending their share to P_1 , who broadcasts the result; this costs $4n\kappa G$ bits per party, giving a total of

$$4n\kappa G + \kappa(n - 1).$$

Online. If party P_i has I_i input bits then the cost for P_i is $I_i + I \cdot (n - 1) \cdot \kappa$ bits.

Note that for a single execution of AES we have $G = 6800$, $I = 128n$ and $O = 128$, which means for multi-party TinyOT we can choose $B = 4$, following the combinatorial analysis of [FLNW17].

6.2.2 Two Parties.

In Table 3 we compare the cost of our protocol in the two-party case, with state-of-the-art secure two-party computation protocols. We instantiate our TinyOT-based preprocessing method with the optimized, two-party TinyOT protocol from [WRK17], lowering the previous costs further. For consistency with the other two-party protocols, we divide the protocol costs into three phases: function-independent preprocessing, which only depends on the size of the circuit; function-dependent preprocessing, which depends on the exact structure of the circuit; and the online phase, which depends on the parties’ inputs. As with the implementation, we move the garbled circuit opening to the function-dependent preprocessing, to simplify the online phase.

Protocol	Security	Function-indep. prep.		Function-dep. prep.	
		$n = 3$	$n = 10$	$n = 3$	$n = 10$
SPDZ-BMR	active	25.77 GB	328.94 GB	61.57 MB	846.73 MB
SPDZ-BMR	covert, pr. $\frac{1}{5}$	7.91 GB	100.98 GB	61.57 MB	846.73 MB
MASCOT- BMR-FX	active	3.83 GB	54.37 GB	12.19 MB	178.25 MB
Ours	active	14.01 MB	63.22 MB	1.31 MB	4.37 MB

Table 4: Comparison of the cost of our protocol with previous constant-round MPC protocols in a range of security models, for secure AES evaluation. Costs are the amount of data sent over the network per party.

The online phase of the modified protocol is just two rounds of interaction, and has the lowest online cost of *any* actively secure two-party protocol.⁴ The main cost of the function-dependent preprocessing is opening the garbled circuit, which requires each party to send 8κ bits per AND gate. This is slightly larger than the best Yao-based protocols, due to the need for a set of keys for every party in BMR.

In the batch setting, where many executions of the *same circuit* are needed, protocols such as [RR16] clearly still perform the best. However, if many circuits are required, but they may be different, or not known in advance, then our multi-party protocol is highly competitive with two-party protocols.

6.2.3 Comparison with Multi-Party Protocols

In Table 4 we compare our work with previous constant-round protocols suitable for any number of parties, again for evaluating the AES circuit. We do not present the communication complexity of the online phase as we expect it to be very similar in all of the protocols. We denote by MASCOT-BMR-FX an optimized variant of [LPSY15], modified to use free-XOR as in our protocol, with multiplications done using the OT-based MASCOT protocol [KOS16].

As in the previous section, we move the cost of opening the garbled circuit to the preprocessing phase for all of the presented protocols (again relying on random oracles). By applying this technique the online phase of our work is just two rounds, and has exactly the same complexity as the current most efficient *semi-honest* constant-round MPC protocol for any number of parties [BLO16], except we achieve active security. We see that with respect to other actively secure protocols, we improve the communication cost of the preprocessing by around 2–4 orders of magnitude. Moreover, our protocol scales much better with n , since the complexity is $O(n^2)$ instead of $O(n^3)$.

⁴If counting the *total* amount of data sent, in both directions, our online cost would be larger than [WRK17], which is highly asymmetric. In practice, however, the latency depends on the largest amount of communication from any one party, which is why we measure in this way.

A Protocol for GMW-Style MPC for Binary Circuits

Here we describe the full protocol for realizing the $\mathcal{F}_{n\text{-TinyOT}}$ functionality. It essentially consists of the bit triple generation protocol from [FKOS15], with some minor modifications, and a method for producing random shared bits with a consistency check that is similar to the bit/string check from Section 3.3.

We first recall the two-party and n -party MAC representations from Section 4:

$$\begin{aligned}
 [x^i]_{i,j} &= (x^i, M_j^i, K_i^j) \\
 [x] &= (x^i, \{M_j^i, K_j^i\}_{j \neq i})_{i \in [n]}, \quad M_j^i = K_i^j + x^i \cdot R^j
 \end{aligned}$$

where in the two-party sharing $[x^i]_{i,j}$, P_i holds the share x^i and MAC M_j^i , whilst P_j holds the local key K_i^j and a fixed, global key R^j . In the n -party sharing, each party P_i holds $n - 1$ MACs on x^i , as well as a key

Subprotocol Π_{Open}

To open a shared value $[x]$ to all parties:

1. Each party P_i broadcasts its share x^i , and sends the MAC M_j^i to P_j , for $j \neq i$.
2. All parties compute $x = x^1 + \dots + x^n$.
3. Each P_i has received MACs M_i^j , for $j \neq i$, and checks that

$$M_i^j = K_j^i + x^j \cdot R^i.$$

If any check fails, broadcast \perp and abort.

Figure 14: Subprotocol for opening and checking MACs on n -party authenticated secret shares

Subprotocol Π_{Open}^j

To open a shared value $[x]$ to only P_j :

1. Each party P_i , for $i \neq j$, privately sends its share x^i and MAC M_j^i to P_j .
2. P_j computes $x = x^1 + \dots + x^n$, and checks that, for each $i \neq j$

$$M_j^i = K_i^j + x^i \cdot R^j.$$

If any check fails, broadcast \perp and abort.

Figure 15: Subprotocol for private opening to one party

on x^j , for each $j \neq i$, and a global key R^i . Note that if P_i holds x^i and P_j holds the key R^j , a sharing $[x^i]_{i,j}$ can easily be created using one call to the correlated OT functionality (Figure 3), in which the correlation R^j is fixed by P_j in the initialization stage.

As required in the modified preprocessing protocol from Section 4, we need a method for opening $[x]$ -shared values, both to all parties, and privately to a single party. These are straightforward, shown in Figure 14–15.

The main protocol, shown in Figure 16, consists of two main parts, for creating shared random bits, and for multiplication (AND) triples. Creating shared bits is straightforward, by using \mathcal{F}_{COT} to MAC random bits, then opening a random linear combination of the MACs to ensure consistency.

To create shares of a random multiplication triple (x, y, z) , each party first locally samples shares x^i, y^i , and then uses \mathcal{F}_{COT} to authenticate these shares. The MAC on a share x^i is used to obtain a sharing of the product of x^i with a random bit $(u_\ell^{i,j} + v_\ell^{i,j})$ known to P_j (using a hash function), and then P_j converts this to a share of $x^i \cdot y^j$ by sending a correction bit in step 4a. This opens up an avenue for cheating, as P_j may send an incorrect correction value to some P_i . This could result in the triple being correct, or, if $x^i = 0$ the triple would still be correct but P_j would learn the bit x^i . These issues are addressed by the bucket-based cut-and-choose procedure in Figure 17, which first checks correctness by sacrificing triples, and then removes any potential leakage on the x values by combining several triples together. Note that the complex bucketing procedure is necessary for these steps, as opposed to simple pairwise checks, because with triples over \mathbb{F}_2 , one pairwise check (or leakage combiner) can only guarantee correctness (or remove leakage) if *at least one* of the two triples is correct (or leakage-free). So, the cut-and-choose and bucketing procedure are done so that each bucket contains at least one good triple, with overwhelming probability.

Protocol $\Pi_{n\text{-TinyOT}}$

Let $H : \{0, 1\}^\kappa \rightarrow \{0, 1\}$ be a single-bit output hash function, modeled as a random oracle.

Initialize:

1. Each party P_i samples $R^i \leftarrow \{0, 1\}^\kappa$.
2. Every ordered pair (P_i, P_j) calls \mathcal{F}_{COT} , where P_i sends (init, R^i) and P_j sends (init) .

Prep: To create m random shared bits $[b_1], \dots, [b_m]$ do:

1. Each party P_i samples $m + \kappa$ random bits $b_1^i, \dots, b_m^i, r_1^i, \dots, r_\kappa^i \leftarrow \{0, 1\}$.
2. Every ordered pair (P_i, P_j) calls \mathcal{F}_{COT} , where P_i is receiver and inputs $(\text{extend}, b_1^i, \dots, b_m^i, r_1^i, \dots, r_\kappa^i)$.
3. Use the previous outputs to define sharings $[b_1], \dots, [b_m], [r_1], \dots, [r_\kappa]$.
4. Check consistency of the \mathcal{F}_{COT} inputs as follows:
 - (a) Call $\mathcal{F}_{\text{Rand}}$ to obtain random field elements $\chi_1, \dots, \chi_m \in \mathbb{F}_{2^\kappa}$
 - (b) The parties locally compute (with arithmetic over \mathbb{F}_{2^κ})

$$[C] = \sum_{\ell=1}^m \chi_\ell \cdot [b_\ell] + \sum_{h=1}^{\kappa} X^{h-1} \cdot [r_h]$$

- (c) Each P_i now has a share $C^i \in \mathbb{F}_{2^\kappa}$, and the MACs and keys $(M_j^i, K_j^i)_{j \neq i}$ from $[C]$.
- (d) Each P_i rerandomizes C^i by privately distributing fresh shares, and sums up the shares they receive to obtain a new share \bar{C}^i .
- (e) Broadcast \bar{C}^i and reconstruct $c = \bar{C}^1 + \dots + \bar{C}^n$.
- (f) Each party P_i defines and commits to the $n + 1$ values:

$$C^i, \quad Z_j^i = M_j^i \quad (\text{for } j \neq i), \quad Z_i^i = \sum_{j \neq i} K_j^i + (C + C^i) \cdot R^i.$$

- (g) All parties open their commitments and check that, for each $j \in [n]$, $\sum_{i=1}^n Z_j^i = 0$. Additionally, each P_i checks that $Z_i^i = K_j^i + C^j \cdot R^i$. If any check fails, abort.

To create M AND triples, first create $m' = B^2 M + c$ triples as follows:

1. Each party P_i samples $x_\ell^i, y_\ell^i \leftarrow \mathbb{F}_2$ for $\ell \in [m']$
2. Every ordered pair (P_i, P_j) calls \mathcal{F}_{COT} , where P_i is receiver and inputs $(\text{extend}, x_1^i, \dots, x_{m'}^i)$.
3. P_i and P_j obtain their respective value of $[x_\ell^i]_{i,j} = (M_\ell^{i,j}, K_\ell^{j,i})$, such that $M_\ell^{i,j} = K_\ell^{j,i} + x_\ell^i \cdot R^j \in \mathbb{F}_2^\kappa$.
4. For each $\ell \in [m']$ and each pair of parties (P_i, P_j) :
 - (a) P_j computes $u_\ell^{j,i} = H(K_\ell^{j,i})$, $v_\ell^{j,i} = H(K_\ell^{j,i} + R^j)$, and sends $d = u_\ell^{j,i} + v_\ell^{j,i} + y_\ell^j$ to P_i
 - (b) P_i computes $w_\ell^{i,j} = H(M_\ell^{i,j}) + x_\ell^i \cdot d = u_\ell^{j,i} + x_\ell^i \cdot y_\ell^j$
5. Each party P_i defines shares

$$z_\ell^i = \sum_{j \neq i} (u_\ell^{i,j} + w_\ell^{i,j}) + x_\ell^i \cdot y_\ell^i$$

6. Every ordered pair (P_i, P_j) calls \mathcal{F}_{COT} , where P_i is receiver and inputs $(\text{extend}, \{y_\ell^i, z_\ell^i\}_{\ell \in [m']})$.
7. Use the above, and the previously obtained MACs on x_ℓ^i , to create sharings $[x_\ell], [y_\ell], [z_\ell]$.

Finally, run $\Pi_{\text{TripleBucketing}}$ on $([x_\ell], [y_\ell], [z_\ell])_{\ell \in [m']}$, to output M correct and secure triples.

Figure 16: Protocol for TinyOT-style secure multi-party computation of binary circuits

Subprotocol $\Pi_{\text{TripleBucketing}}$

The protocol takes as input $m' = B^2m + c$ triples, which may be incorrect and/or have leakage on the x component, and produces m triples which are guaranteed to be correct and leakage-free.

B determines the bucket size, whilst c determines the amount of cut-and-choose to be performed.

Input: Start with the shared triples $\{[x_i], [y_i], [z_i]\}_{i \in [m']}$.

I: Cut-and-choose: Using $\mathcal{F}_{\text{Rand}}$, the parties select at random c triples, which are opened with Π_{Open} and checked for correctness. If any triple is incorrect, abort.

II: Check correctness: The parties now have B^2m unopened triples.

1. Use $\mathcal{F}_{\text{Rand}}$ to sample a random permutation on $\{1, \dots, B^2m\}$, and randomly assign the triples into mB buckets of size B , accordingly.
2. For each bucket, check correctness of the first triple in the bucket, say $[T] = ([x], [y], [z])$, by performing a pairwise sacrifice between $[T]$ and every other triple in the bucket. Concretely, to check correctness of $[T]$ by sacrificing $[T'] = ([x'], [y'], [z'])$:
 - (a) Open $d = x + x'$ and $e = y + y'$ using Π_{Open} .
 - (b) Compute $[f] = [z] + [z'] + d \cdot [y] + e \cdot [x] + d \cdot e$.
 - (c) Open $[f]$ using Π_{Open} and check that $f = 0$.

III: Remove leakage: Taking the first triple in each bucket from the previous step, the parties are left with Bm triples. They remove any potential leakage on the $[x]$ bits of these as follows:

1. Place the triples into m buckets of size B .
2. For each bucket, combine all B triples into a single triple. Specifically, combine the first triple $([x], [y], [z])$ with $[T'] = ([x'], [y'], [z'])$, for every other triple T' in the bucket:
 - (a) Open $d = y + y'$ using Π_{Open} .
 - (b) Compute $[z''] = d \cdot [x'] + [z] + [z']$ and $[x''] = [x] + [x']$.
 - (c) Output the triple $[x''], [y], [z'']$.

If all the checks and MAC checks passed, output the first triple from each of the m buckets in the final stage.

Figure 17: Checking correctness and removing leakage from triples with cut-and-choose

Subprotocol Π_{Mult}

Given a multiplication triple $[a], [b], [c]$ and two shared values $[x], [y]$, the parties compute a sharing of $x \cdot y$ as follows:

1. Each party broadcasts $d^i = a^i + x^i$ and $e^i = b^i + y^i$.
2. Compute $d = \sum_i d^i$, $e = \sum_i e^i$, and run Π_{Open} to check the MACs on $[d]$ and $[e]$.
3. Output

$$\begin{aligned} [z] &= [c] + d \cdot [b] + e \cdot [a] + d \cdot e \\ &= [x \cdot y]. \end{aligned}$$

Figure 18: Subprotocol for multiplying secret shared values using a triple

A.1 Why the Need for Key Queries?

For completeness, we briefly explain why these are needed in $\mathcal{F}_{n\text{-TinyOT}}$, when using this protocol. After the protocol execution the environment learns the honest parties' outputs, which include MAC keys K_i and R . On the other hand, during the protocol the adversary sees values of the form (simplifying things slightly):

$$U = H(K_i) + H(K_i + R)$$

where H is modeled as a random oracle. In the security proof, U is simulated as a uniformly random value U , since the simulator, \mathcal{S} , does not know K_i or $K_i + R$. This means that if the environment later queries both K_i and $(K_i + R)$ to the random oracle then they could distinguish, as \mathcal{S} would not be able to detect this, so the response would be inconsistent with the simulated U . However, with a **Key Query** command in the functionality, the simulator can detect this (based on the technique from [NNOB12]):

- For each query Q , \mathcal{S} looks up all previous queries Q_i , and sends $(Q + Q_i)$ to the **Key Query** of the functionality.
- If **Key Query** is successful then \mathcal{S} knows that $Q + Q_i = R$, so can program the response $H(Q)$ such that $H(Q) + H(Q_i) = U$, as required.

A.2 Security

In this section we formalize the security of the implementation of the **Prep** command of $\mathcal{F}_{n\text{-TinyOT}}$ in our $\Pi_{n\text{-TinyOT}}$ protocol. More concretely, we focus on the consistency check in the production of m random bits. This guarantees that the MAC keys are consistent, after which the triple generation protocol can be proven secure similarly to [FKOS15]. The exact deviations that are possible by a corrupt P_j in the bit generation are:

1. Provide inconsistent inputs R^j when acting as sender in the **Initialize** command of the \mathcal{F}_{COT} instances with two different honest parties.
2. Input inconsistent shares $b_\ell^j, \ell \in [m]$ or $r_h^j, h \in [\kappa]$ when acting as receiver in the **Extend** command of \mathcal{F}_{COT} with two different honest parties.

Note that in both of these cases, we are only concerned when the other party in the \mathcal{F}_{COT} execution is honest, as if both parties are corrupt then \mathcal{F}_{COT} does not need to be simulated in the security proof. We should also remark that preventing the first attack in the production of the random bits extends to preventing it everywhere else in the protocol, as the R^j values are fixed in the **Initialize** phase.

These two attacks are modelled by defining $R^{j,i}, b_\ell^{j,i}$ and $r_h^{j,i}$ to be the *actual* inputs used by a corrupt P_j in the above two cases. Without loss of generality, we pick a honest party P_{i_0} and fix $b_\ell^j = b_\ell^{j,i_0}, r_h^j = r_h^{j,i_0}, R^j = R^{j,i_0}$ to be the inputs by P_j that should be consistent with every other honest party. Let I be the set of corrupted parties. For each $j \in I$, we can resume the previous statements by defining the values:

$$\begin{aligned} \Delta^{j,i_0} &= 0, & \Delta^{j,i} &= R^{j,i} + R^j, & i &\notin (I \cup i_0) \\ \delta_\ell^{j,i_0} &= 0, & \delta_\ell^{j,i} &= b_\ell^{j,i} + b_\ell^j, & \ell \in [m], i &\notin (I \cup i_0) \\ \hat{\delta}_h^{j,i_0} &= 0, & \hat{\delta}_h^{j,i} &= r_h^{j,i} + r_h^j, & h \in [\kappa], i &\notin (I \cup i_0). \end{aligned}$$

Note that $\Delta^{j,i}$ is fixed in the initialization of \mathcal{F}_{COT} , whilst $\delta_\ell^{j,i}$ may be different for every OT. Whenever P_i and P_j are both corrupt, or both honest, for convenience we define $\Delta^{j,i} = 0$ and $\delta_\ell^{j,i} = 0$. The above means that the outputs of \mathcal{F}_{COT} with (P_i, P_j) then satisfy:

$$M_i^j(b_\ell^{j,i}) = K_j^i(b_\ell^{j,i}) + b_\ell^{j,i} \cdot R^{i,j}$$

or, equivalently:

$$M_i^j(b_\ell^j + \delta_\ell^{j,i}) = K_j^i(b_\ell^j + \delta_\ell^{j,i}) + (b_\ell^j + \delta_\ell^{j,i}) \cdot (R^i + \Delta^{i,j})$$

where $\delta_\ell^{j,i} \neq 0$ if P_j (the receiver) cheated, and $\Delta^{i,j} \neq 0$ if P_i (the sender) cheated. Remember from Section 4.1 that $M_i^j(b_\ell^j + \delta_\ell^{j,i})$ represents the receiver's MAC on the value $b_\ell^j + \delta_\ell^{j,i}$ and $K_j^i(b_\ell^j + \delta_\ell^{j,i})$ and represents the sender's MAC key on that same value.

We start by assuming that the corrupted party in the couple (P_i, P_j) running \mathcal{F}_{COT} is the sender P_j , trying to have inconsistent correlations $R^{j,i}$ with different honest parties $P_i, i \notin I$. We prove the inconsistency impossible in the next claim:

Claim A.1 *If the **Prep** step of $\Pi_{\text{n-TinyOT}}$ succeeds then all the global keys R^j are consistent and well-defined, i.e. $\Delta^{j,i} = 0$ for every $i, j \in [n]$.*

Proof: We enumerate the possible deviations by the Adversary affecting the check $\sum_{i=1}^n Z_j^i = 0$ in Step 4g with which we want to catch inconsistent $R^{j,i}$ values to different honest parties. These possible disruptions are two:

In Step 4e, the parties broadcast \bar{C}^i values, every corrupted $P_\ell, \ell \in I$ can send instead some adversarial value \hat{C}^ℓ such that $\sum_{j=1}^n \hat{C}^j = C + e$, where e is some additive error of the Adversary's choice. Finally, a similar active deviation is to commit to \hat{Z}_j^ℓ values, $\ell \in I$, in such a way that $\sum_{\ell \in I} \hat{Z}_j^\ell = \sum_{\ell \in I} Z_j^\ell + E^j$.

A malicious P_j trying to cheat has to pass the aforementioned mentioned check, which becomes:

$$\begin{aligned} 0 &= \sum_{i=1}^n \hat{Z}_j^i = E^j + Z_j^j + \sum_{i \neq j} Z_j^i = E^j + \left(\sum_{i \neq j} K_i^j(C^i) + (C + e + C^j) \cdot R^j \right) + \sum_{i \neq j} M_j^i(C^i) = \\ &E^j + (C + e + C^j) \cdot R^j + \sum_{i \neq j} (K_i^j(C^i) + M_j^i(C^i)) = E^j + (C + e + C^j) \cdot R^j + \sum_{i \neq j} C^i \cdot R^{j,i} = \\ &E^j + (C + e + C^j + \sum_{i \neq j} C^i) \cdot R^j + \sum_{i \neq j} C^i \cdot \Delta^{j,i} = E^j + e \cdot R^j + \sum_{i \neq j} C^i \cdot \Delta^{j,i} \end{aligned}$$

As having inconsistent keys requires that there exists $i_0, i_1 \notin I$ such that $\Delta^{j,i_0} \neq \Delta^{j,i_1} \neq 0$, the attack would require the adversary to set $E^j + e \cdot R^j = C^{i_0} \cdot \Delta^{j,i_0} + C^{i_1} \cdot \Delta^{j,i_1}$. But this is negligible in κ , as the only information the adversary has about $C^{i_0}, C^{i_1} \in \mathbb{F}_{2^\kappa}$ at the time of committing to the values $\hat{Z}_j^\ell, \ell \in I$ is that they are two uniform additive shares of C , due to the rerandomization in Step 4d. ■

Finally, we prove that a corrupted receiver P_j cannot input inconsistent values $b_\ell^{j,i}$ to different honest parties.

Claim A.2 *If the **Prep** step of $\Pi_{\text{n-TinyOT}}$ succeeds, every ordered pair (P_i, P_j) holds a secret sharing of $b_\ell^j \cdot R^i$ for every $\ell \in [m]$. In other words, $\delta_\ell^{j,i} = 0$ for every i, j, ℓ .*

Proof: For every ordered pair (P_i, P_j) we can define P_j 's MAC on $[C^j]_{j,i}$ as

$$M_i^j(C^j) = \sum_{\ell=1}^m \chi_\ell \cdot M_i^j(b_\ell^{j,i}) + \sum_{h=1}^{\kappa} X^{h-1} \cdot M_i^j(r_h^{j,i})$$

and P_i 's key on the same value as:

$$K_j^i(C^j) = \sum_{\ell=1}^m \chi_\ell \cdot K_j^i(b_\ell^{j,i}) + \sum_{h=1}^{\kappa} X^{h-1} \cdot K_j^i(r_h^{j,i})$$

In Step 4f of **Bits**, an adversarial P_j can also commit to incorrect MACs $\hat{Z}_i^j(c^j) = M_i^j(c^j) + E_i^j$ and $\hat{C}^j = C^j + e^j$. Nevertheless, in order to succeed an attack, the check $\hat{Z}_i^j = K_j^i(C^j) + \hat{C}^j \cdot R^i$ from Step 4g would have to hold. This check implies the following:

$$\begin{aligned} M_i^j(C^j) + E_i^j &= K_j^i(C^j) + (C^j + e^j) \cdot R^i \\ \Leftrightarrow E_i^j + (C^j + e^j) \cdot R^i &= M_i^j(C^j) + K_j^i(C^j) = \left(\sum_{\ell=1}^m \chi_\ell \cdot b_\ell^{j,i} + \sum_{h=1}^{\kappa} X^{h-1} \cdot r_h^{j,i} \right) \cdot R^i \\ \Leftrightarrow E_i^j &= \left(C^j + e^j + \sum_{\ell=1}^m \chi_\ell \cdot (b_\ell^j + \delta_\ell^{j,i}) + \sum_{h=1}^{\kappa} X^{h-1} \cdot (r_h^j + \hat{\delta}_h^{j,i}) \right) \cdot R^i \\ &= (e^j + \sum_{\ell=1}^m \chi_\ell \cdot \delta_\ell^{j,i} + \sum_{h=1}^{\kappa} X^{h-1} \cdot \hat{\delta}_h^{j,i}) \cdot R^i \end{aligned}$$

A malicious P_j has then just two options to cheat P_i , both with only probability $2^{-\kappa}$ to succeed:

1. Setting $E_i^j = (e^j + \sum_{\ell=1}^m \chi_\ell \cdot \delta_\ell^{j,i} + \sum_{h=1}^{\kappa} X^{h-1} \cdot \hat{\delta}_h^{j,i}) \cdot R^i \neq 0$, which requires guessing the string $R^i \in \mathbb{F}_{2^\kappa}$ kept secret by the honest party P_i .
2. Setting $E_i^j = 0$ and $e_j = \sum_{\ell=1}^m \chi_\ell \cdot \delta_\ell^{j,i} + \sum_{h=1}^{\kappa} X^{h-1} \cdot \hat{\delta}_h^{j,i}$ for every $i \notin I$. As $\delta_\ell^{j,i_0} = \hat{\delta}_h^{j,i_0} = 0$, this implies that $e_j = 0$. Thus, for every $i \notin (I \cup i_0)$ it needs to hold that

$$0 = \sum_{\ell=1}^m \chi_\ell \cdot \delta_\ell^{j,i} + \sum_{h=1}^{\kappa} X^{h-1} \cdot \hat{\delta}_h^{j,i} = \sum_{h=1}^{\kappa} X^{h-1} \cdot (\hat{\delta}_h^{j,i} + \sum_{\ell=1}^m \delta_\ell^{j,i} \cdot \chi_{\ell,h}),$$

where the $\chi_{\ell,h}$ values are defined in such a way that $\chi_\ell = \sum_{h=1}^{\kappa} X^{h-1} \cdot \chi_{\ell,h}$. This would need that, for every $h \in [\kappa]$:

$$\hat{\delta}_h^{j,i} = \sum_{\ell=1}^m \delta_\ell^{j,i} \cdot \chi_{\ell,h} \in \mathbb{F}_2,$$

which can only happen with probability $1/2$ for each of them, as $\chi_{\ell,h} \in \mathbb{F}_2$ are uniformly random sampled field elements after the deviations $\hat{\delta}_h^{j,i}, \delta_\ell^{j,i}$ have been defined.

■

A.3 Parameters

Based on the analysis from previous works [FKOS15, FLNW17, WRK17], if roughly 1 million triples are created at once then the buckets in the cut-and-choose stages can be of size $B = 3$, to guarantee security except with probability 2^{-40} . The additional cut-and-choose parameter c can be as low as 3, so is insignificant as we initially need $m' = B^2m + c$ triples to produce m final triples.

A.4 Communication Complexity

Here we analyse the communication complexity of $\Pi_{n\text{-TinyOT}}$. The cost of creating one shared random bit is the same as one invocation of the `extend` command in \mathcal{F}_{COT} between all pairs of parties, giving $n(n-1)(\kappa+s)$ bits (we ignore the consistency check, since this cost amortizes away when creating many bits).

The cost of one triple (not counting the bucketing stage), is 3 calls to \mathcal{F}_{COT} between every pair of parties for authenticating shares of (x, y, z) , plus sending one correction bit between every pair of parties, giving $n(n-1)(3(\kappa+s)+1)$ bits. This is then multiplied by approximately B^2 to account for the bucketing. When creating a batch of at least a million triples (with $s = 40$), we can set $B = 3$, so the overall cost per party is around $(n-1)27 \cdot (\kappa+s)$ bits.

We remark that when checking a large number of MACs using Π_{Open} or Π_{Open}^i , the checks can be batched together, by first computing a random linear combination of all MACs, and checking the MAC on this, as in e.g. [DKL⁺13, KOS16]. This means that the cost of checking many MACs is roughly the cost of checking one, which is why we did not factor the MAC checks into the cost of the bucketing stage.

A.5 Round Complexity

Initializing the correlated OTs can be done with any 2-round OT protocol. Extending the correlated OTs using [NST17] and [ALSZ15] takes 3 rounds. Note that when authenticating random bits, the s additional bits in the consistency check can be created in parallel with the original m bits, giving an overall cost of 5 rounds for random bits.

The triple generation consists of one set of correlated OTs (2 + 3 rounds), plus 1 round, plus another round of correlated OTs (3 rounds). Then there are 2 rounds for $\mathcal{F}_{\text{Rand}}$ in the bucketing (which can all be done in parallel), one round for the openings in step 2a and one round for step 2c. The openings in step 2a can be merged with the previous round. This gives a total of 13 rounds.

A.6 Realizing General Secure Computation

The previous protocol can easily be used to implement a general secure computation functionality such as $\mathcal{F}_{\text{BitMPC}}$. The main feature missing is the ability for parties to provide inputs, since we only need to create random bits and triples for our application to garbled circuits. However, this is easy to do with a standard technique: if P_i wishes to secret-share an input x , the parties do as follows:

- Create a shared random bit $[b]$.
- Open b to P_i using Π_{Open}^i .
- P_i broadcasts $d = x - b$.
- All parties compute $[x] = [b] + d$.
