***Abstract*—Designing a secure permissionless distributed ledger that performs on par with centralized payment processors such as Visa is challenging. Most existing distributed ledgers are unable to "scale-out" – growing total processing capacity with number of participants – and those that do compromise security or decentralization. This work presents OmniLedger, the first scale-out distributed ledger that can preserve long-term security under permissionless operation. OmniLedger ensures strong correctness and security by using a bias-resistant public randomness protocol to choose large statistically representative shards to process transactions, and by introducing an efficient cross-shard commit protocol to handle transactions affecting multiple shards atomically. In addition, OmniLedger optimizes performance via scalable intra-shard parallel transaction processing, ledger pruning via collectively-signed state blocks, and optional low-latency "trust-but-verify" validation of low-value transactions. Evaluation of our working experimental prototype shows that OmniLedger's throughput scales linearly in the number of validators available, supporting Visa-level workloads and beyond, while confirming typical transactions in under two seconds.**

I. Introduction

The scalability of distributed ledgers (DLs), both in total transaction volume and the number of independent participants involved in processing them, is a major challenge to their mainstream adoption, especially when weighted against security and decentralization challenges. Many approaches exibit different security and performance trade-offs [10], [11], [21], [32], [40]. Replacing Nakamoto consensus [36] with PBFT [13], for example, can increase throughput while decreasing transaction commit latency [1], [32]. These approaches still require all *validators* or consensus group members to validate and process all transactions redundantly, however, so the system's total transaction processing capacity does not increase with added participants, and in fact gradually decreases due to increased coordination overheads.

The proven and obvious approach to building "*scale-out*" databases, whose total capacity scales horizontally with number of participants, is by *sharding* [14], or partitioning state into multiple shards handled in parallel by different subsets of participating validators. Sharding could benefit DLs [15] by reducing the transaction processing load on each validator and increasing the system's total processing capacity proportionally with the number of participants. Existing proposals for sharded DLs, however, forfeit permissionless decentralization [16], introduce new security assumptions, and/or trade performance for security [34], as illustrated in Figure 1 and explored in detail later in Sections II and IX.

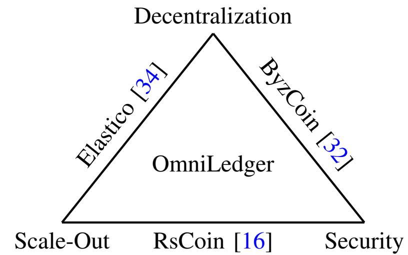

Fig. 1: A comparison of current DL system in terms of the trade-offs they offer.

This paper introduces OmniLedger, the first distributed ledger architecture that provides "scale-out" transaction processing capacity competitive with centralized payment processing systems such as Visa, without compromising security or support for permissionless decentralization. To achieve this goal, OmniLedger faces three key correctness and security challenges. First, OmniLedger must choose statistically representative groups of validators periodically via permissionless Sybil-attack-resistant foundations such as proof-of-work [36], [38], [32] or proof-of-stake [31], [25]. Second, OmniLedger must periodically form shards, or subsets of validators to record state and process transactions, that are both sufficiently large and strongly bias-resistant to ensure a negligible probability that any shard is ever compromised across the (long-term) system lifetime. Finally, OmniLedger must correctly and atomically handle *cross-shard transactions*, or transactions that affect ledger state held by two or more distinct shards.

To choose representative validators via proof-of-work, OmniLedger builds on ByzCoin [32] and Hybrid Consensus [38], using a sliding window of recent proof-of-work block miners as its validator set. To support the more power-efficient alternative of apportioning consensus group membership based on directly-invested stake (*e.g.*, coins) rather than work, OmniLedger builds on Ouroboros [31] and Algorand [25], running a public randomness or cryptographic sortition protocol within a prior validator group to pick a subsequent validator group from the current stakeholder distribution defined in the ledger. To ensure that this sampling of representative validators is both scalable and strongly bias-resistant, OmniLedger uses

RandHound [44], a protocol that serves this purpose under standard t-of-n threshold assumptions.

Appropriate use of RandHound also provides the basis by which OmniLedger addresses the second key security challenge, of securely assigning validators to shards, and periodically rotating those assignments as the set of validators evolves. Through the analysis detailed in Section VI, OmniLedger chooses random shards large enough to ensure a negligible chance that any shard is ever compromised, even across years of system operation.

Finally, to ensure that all transactions either commit or abort atomically even when they affect ledger state distributed across multiple shards (*e.g.*, several cryptocurrency accounts), OmniLedger introduces Atomix, a two-phase client-driven "lock/unlock" protocol ensuring that clients can either fully commit a transaction across all shards, or obtain "rejection proofs" needed to abort and unlock state affected by partially-completed transactions.

Besides addressing the above key security and correctness challenges, OmniLedger also introduces several performance and scalability refinements we found to be instrumental in achieving its usability goals. OmniLedger's consensus protocol, *Omnicon*, enhances the PBFT-based consensus in ByzCoin [32] to preserve performance under Byzantine denial-of-service (DoS) attacks, by adopting a more robust group commuication pattern. To help new or long-offline miners catch up to the current ledger state quickly without having to download the entire transaction history, OmniLedger adapts classic distributed checkpointing principles [20] to produce consistent, collectively-signed *state blocks* periodically.

Finally, to minimize transaction latency in common cases such as low-value payments, OmniLedger supports optional *trust-but-verify* operation, in which transactions are first processed by a small tier of fast validators. A second tier of necessarily-slower validators, where each tier is large enough to ensure long-term security, subsequently verifies the correctness of the first tier's processing. This two-level approach ensures that any misbehavior within the first tier will be detected within minutes, and can be strongly disincentivized through recourse such as loss of deposits. Clients can wait only for the first tier to process low-value transactions, while waiting for both tiers to process high-value transactions for maximum security.

To evaluate OmniLedger, we implemented a prototype in Go on commodity servers (12-core VMs on Deterlab). Our experimental results show that OmniLedger scales linearly in the number of validators yielding a throughput of 6,000 transactions per second with a 10-second consensus latency (for 1800 widely-distributed hosts, of which 12.5% are malicious). Furthermore, deploying OmniLedger with two-level, trust-but-verify validation provides a throughput of 2,250 tps with a 4-second first-tier latency under a 25% adversary. Finally, a Bitcoin validator with a month-long stale view of the state incurs 40% of the bandwidth, thanks to checkpoint state blocks.

Contributions: In summary, this paper makes the following contributions:

- We introduce the first DL architecture that provides horizontal scaling without compromising either long-term security or permissionless decentralization.
- We introduce Atomix, a Atomic Commit protocol, to commit transactions atomically across shards.
- We introduce Omnicon, a BFT consensus protocol that increases performance and robustness to DoS attacks.
- We introduce state blocks, that are deployed along OmniLedger to minimize storage and update overhead.
- We introduce two-tier trust-but-verify processing to minimize the latency of low-value transactions.
- We informally analyze the security, and implement and evaluate a prototype of OmniLedger.

II. Background

A. Scalable Byzantine Consensus in ByzCoin

OmniLedger builds on the Byzantine consensus scheme in ByzCoin [32], because it scales efficiently to thousands of consensus group members. ByzCoin uses collective signing or CoSi [45], a scalable cryptographic primitive that implements multisignatures [42], to make a traditional consensus algorithm such as PBFT [13] more scalable. ByzCoin distributes blocks using multicast trees for performance, but falls back to a less-scalable star topology for fault tolerance. Although ByzCoin's consensus is scalable, its total processing capacity does not increase with participation: *i.e.*, it does not support horizontal scale-out as in OmniLedger.

B. Transaction Processing and the UTXO model

Distributed ledgers derive current system state from a *blockchain*, or a sequence of totally-ordered blocks containing transactions. OmniLedger adopts the *unspent transaction output* (UTXO) model, to represent ledger state, due to its simplicity and parallelizability. In this model, the outputs of a transaction creates new UTXOs (and assign them credits), and inputs completely "spend" existing UTXOs. During bootstrapping, new (full) nodes crawl the entire distributed ledger and build a database of valid UTXOs needed to decide subsequently whether a new block can be accepted. The UTXO model was introduced by Bitcoin [36] but has been widely adopted by other distributed ledger systems.

C. Secure Distributed Randomness Generation

RandHound [44] is a scalable, secure multi-party computation (MPC) protocol that provides unbiasable, decentralized randomness in a Byzantine setting. RandHound assumes the existence of an externally accountable client that wants to obtain provable randomness from a large group of semi-trustworthy servers. To produce randomness, RandHound splits the group of servers into smaller ones and creates a publicly verifiable commit-then-reveal protocol [43] that leverages the pigeonhole principle to prove that the final random number includes the contribution of at least one honest participant, thus perfectly randomizing RandHound's output.

Cryptographic sortition [25] is used to select a subset of validators according to some per-validator weight function. To enable validators to prove that they belong to the selected subset, they need a public/private key pair, (pk_i, sk_i). Sortition is implemented using a verifiable random function (VRF) [35], that takes an input x and returns a random hash (ℓ-bit long string) and a proof π based on sk_i. The proof π enables anyone who knows pk_i to check that the hash indeed corresponds to x.

D. Sybil-Resistant Identities

Unlike permissioned blockchains [16], where the validators are known, permissionless blockchains need to deal with the potential of Sybil attacks [19] to remain secure. Bitcoin [36] suggested the use of Proof-of-Work (PoW), where validators (aka miners) create a valid block by performing an expensive computation (iterating through a nonce and trying to brute-force a hash of a block header such that it has a certain number of leading zeros). Bitcoin-NG [21] uses this PoW technique to enable a Sybil-resistant generation of identities. There are certain issues associated with PoW, such as the waste of electricity [17] and the fact that it causes recentralization [29] to mining pools. Other approaches for establishing Sybil-resistant identities such as Proof-of-Stake (PoS) [31], [25], Proof-of-Burn (PoB) [46] or Proof-of-Personhood [8] overcome PoW's problems and are compatible with ByzCoins identity (key-block) blockchain, and in turn with OmniLedger

E. Prior Sharded Ledgers: Elastico

OmniLedger builds closely on Elastico [34], which previously explored sharding in permissionless ledgers. Elastico bootstraps every round from PoW, then uses PoW's least-significant bits to distribute the miners to be authoritative on different shards. After this setup, every shard runs PBFT [13] to reach consensus, and a leader shard verifies all the signatures and creates a global block.

OmniLedger addresses several challenges that Elastico leaves unsolved. First, Elastico's relatively small shards (*e.g.*, 100 validators per shard in experiments) yields a high failure probability of 2.76%[1] per shard per block under a 25% Byzantine adversary, which cannot safely be relaxed in a PoW system [23]. For 16 shards, the failure probability is 97% over only 6 epochs. Second, Elastico's shard selection may not be strongly bias-resistant, since miners can selectively discard PoWs to bias results [7]. Third, Elastico does not ensure transaction atomicity across shards, potentially leaving funds in one shard locked forever if another shard rejects the transaction. Third, the validators constantly switch shards, which forces each validator to store the global state, a choice that can hinder performance but provides stronger guarantees against adaptive adversaries. Finally, the latency of transaction commitment is comparable to Bitcoin ($\approx$ 10 minutes), far from OmniLedger's usability goals.

III. System Overview

This section presents our system, network and threat models, OmniLedger's design goals, and a strawman design that we convert step-by-step into OmniLedger. It is possible that the intermediate strawman designs might deviate from our assumptions, hence we clarify them as needed.

A. System Model

We assume that there are n *validators* who process transactions and ensure the consistency of the system's state. Each validator i has a public / private key pair $(\mathsf{pk}_i, \mathsf{sk}_i)$ and we often identify i by pk_i. Validators are evenly distributed across m *shards*. We assume that the configuration parameters of a shard j are summarized in a *shard policy file*. We denote by an *epoch* e the fixed time (*e.g.*, a day) between global reconfiguration events where a new assignment of validators to shards is computed. The time during an epoch is counted in *rounds* r that do not have to be consistent between different shards. During each round, each shard processes transactions collected from clients. We assume that validators can establish identities through any Sybil-attack resistant mechanism and commit them to the identity blockchain. Validators have to register in epoch $e-1$ to participate in epoch e.

B. Network Model

For the underlying network we make the same assumption as prior work [34], [36], [31]. Specifically, we assume that (a) the network graph of honest validators is well connected and that (b) the communication channels between honest validators are synchronous, *i.e.*, that if an honest validator broadcasts a message, then all honest validators will receive the message within a known maximum delay Δ. This is a standard assumption proven by Pass et al. [39]. However, as this Δ is in the scale of minutes, we cannot use it within epochs as we target latencies of seconds. Hence, all protocols that are run inside one epoch follow the partially synchronous model [13] of having optimistic, exponentially increasing time-outs, whereas Δ is used for slow moving operations like the identity establishment and the shard assignment.

C. Threat Model

We denote the number of Byzantine validators by f and assume, unless noted otherwise, that $n = 4f$, *i.e.*, at most 25% of the validators can be malicious at any given moment similar to prior DL's [32], [34], [21]. These malicious nodes can behave arbitrarily, *e.g.*, they might refuse to participate or collude to attack the system. The remaining validators are honest and faithfully follow the protocol. We further assume that the adversary is *mildly adaptive* [34], [31] on the order of epochs, *i.e.*, he may try to corrupt validators, but it takes some time for such corruption attempts to actually take effect.

We further assume that the adversary is computationally bounded, that cryptographic primitives are secure, and that the computational Diffie-Hellman problem is hard for commonly used elliptic curves.

[1] Cumulative binomial distribution ($P = 0.25$, $N = 100$, $X \geq 34$)

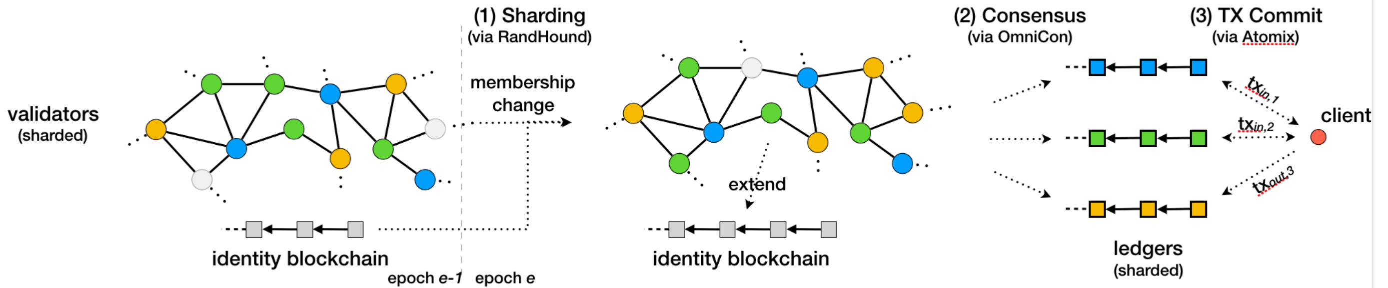

Fig. 2: OmniLedger architecture overview: At the beginning of an epoch e, validators (1) use RandHound to randomly remove old validators from shards and assign new validators who registered to the identity blockchain in epoch $e-1$. Afterwards, validators ensure (2) consistency of the shards' ledgers via Omnicon while clients ensure (3) consistency of their cross-shard transactions via Atomix (here the client spends inputs from shards 1 and 2 and outputs to shard 3).

D. System Goals

OmniLedger has the following primary goals with respect to decentralization, security and scalability.

1) **Full decentralization.** OmniLedger's architecture does not rely on any trusted third parties and does not have any single points of failure.
2) **Shard robustness.** Each shard correctly and continuously processes transactions assigned to it.
3) **Secure transactions.** Transactions are committed atomically or eventually aborted, both within and across shards.
4) **Scale-out.** The expected throughput of OmniLedger increases linearly in the number of participating validators.
5) **Low storage overhead.** OmniLedger reduces the necessary transaction history for validators to a periodically generated summary of a shard's state. Therefore, validators need not to store the full transaction history.
6) **Low latency.** OmniLedger provides low latency for transaction confirmations.

E. Design Roadmap

This section introduces SimpleLedger, a strawman distributed ledger system that we use to outline OmniLedger's design. Below we describe one epoch of SimpleLedger and show how it transitions from epoch $e-1$ to epoch e.

We start with the secure validator assignment to shards. Permitting the validators to choose the shards they want to validate is insecure, as the adversary could focus all his validators in one shard. As a result, we need a source of randomness to ensure that the validators of one shard will be a sample of the overall system and w.h.p. will have about the same fraction of malicious nodes. SimpleLedger operates a trusted randomness beacon that broadcasts a single random value rnd_e to all participants in each epoch e. Validators, who wish to participate in SimpleLedger starting from epoch e, have to first register to a global identity blockchain. They create their identities through a Sybil-attack resistant mechanism in epoch $e-1$ and broadcast these identities, together with the respective proofs, on the gossip network at most Δ before epoch $e-1$ ends.

Epoch e begins with a leader, who was elected using randomness rnd_{e-1}, who requests from the already registered and active validators a (BFT) collective signature on a block with all identities that have been provably established thus far. If at least $\frac{2}{3}$ of these validators endorse the block, it becomes valid and the leader appends it to the identity blockchain. Afterwards, all registered validators take rnd_e to determine their assignment to one of the SimpleLedger's shards and bootstrap their internal states from the shards' distributed ledgers. Once finished, the validators are ready to start processing transactions using ByzCoin.

Note that the random assignment during sharding ensures that the ratio between attacker-controlled and honest validators in any given shard closely matches the ratio across all validators with high probability.

SimpleLedger already provides a similar functionality to OmniLedger, but it has several significant security restrictions. First, the randomness beacon is a trusted third party. Second, the system stops processing transactions during the global reconfiguration at the beginning of each epoch until enough validators have bootstrapped their internal states and third, there is no support for cross-shard transactions. SimpleLedger's design also falls short performance wise. First, due to ByzCoin's failure handling mechanism, its performance deteriorates when participating nodes start failing. Second, validators face high storage and bootstrapping overheads and finally, SimpleLedger (*i.e.*, ByzCoin) cannot provide concurrently real-time transaction latencies and high transaction throughput.

To address the security challenges, we introduce OmniLedger's security design in Section IV as follows:

1) In Section IV-A, we remove the trusted randomness beacon and show how validators can autonomously perform a secure sharding using a combination of RandHound and VRF-based leader election via cryptographic sortition.
2) In Section IV-B, we show how to securely handle the validator assignment to shards between epochs while maintaining the ability to continuously process transactions.
3) In Section IV-C, we present *Atomix*, a novel two-step atomic commit protocol for atomically processing cross-shard transactions in a Byzantine setting.

To deal with the performance challenges, we introduce OmniLedger's performance and usability design in Section V as follows:

4) In Section V-A, we introduce *Omnicon*, a variant of ByzCoin, that utilizes more robust communication patterns to efficiently process transactions within shards, even if some of the validators fail, and that resolves dependencies on the transaction level to achieve better block commitment parallelization.
5) In Section V-C, we introduce *state blocks* that summarize the shards' states in an epoch and enable ledger pruning to reduce storage and bootstrapping costs for validators.
6) In Section V-D, we show how to enable optimistic real-time transaction confirmations without sacrificing security or throughput by utilizing an intra-shard architecture with *trust-but-verify transaction validation*.

A high-level overview of the (security) architecture of OmniLedger is illustrated in Figure 2.

IV. OmniLedger: Security Design

We present the core security architecture of OmniLedger.

A. Sharding Via Bias-Resistant Distributed Randomness

To generate a seed for sharding securely without requiring a trusted randomness beacon [16] or binding the protocol to PoW [34], we rely on a distributed randomness generation protocol that is collectively executed by the validators.

We require that the distributed randomness generation protocol provides unbiasability, unpredictability, third-party verifiability, and scalability. Multiple proposals exist [7], [28], [44]. The first approach relies on Bitcoin while the other two share many parts of the design; we focus on RandHound [44] due to better documentation and open-source implementation.

Because RandHound relies on a leader to orchestrate the protocol run, we need an appropriate mechanism to select one of the validators for this role. If we use a deterministic approach to perform leader election, however, then an adversary might be able to enforce up to f out of n failures in the worst case by refusing to run the protocol, resulting in up to $\frac{1}{4}n$ failures given our threat model. Hence, the selection mechanism itself must be unpredictable and unbiasable, leading to a chicken-and-egg problem since we use RandHound to generate randomness with these properties in the first place. To overcome this predicament, we use cryptographic sortition [25] for leader election.

At the beginning of an epoch e, each validator i computes a ticket $\mathsf{ticket}_{i,e,v} = \mathsf{VRF}_{\mathsf{sk}_i}(\text{“leader”} \parallel \mathsf{config}_e \parallel v)$ where config_e is the configuration containing all properly registered validators of epoch e (as stored in the identity blockchain) and v is a view counter. Validators then gossip these tickets with each other for a time Δ, after which they lock in the lowest-value valid ticket they have seen thus far and accept the corresponding node as the leader of the RandHound protocol run. If the elected node fails to start RandHound within another Δ, validators consider the current run as failed and ignore this validator for the rest of the epoch, even if he returns later on. In this case, the validators increase the view number to $v+1$ and re-run the lottery. Finally, once the validators have successfully completed a run of RandHound and the leader has broadcasted rnd_e together with its correctness proof, each of the n properly registered validators can first verify and then use rnd_e to compute a permutation π_e of $1, \ldots, n$ and subdivide the result into m approximately equally-sized buckets, thereby determining its assignment of nodes to shards.

Security Arguments: We make the following observations to informally argue the security of the above approach. Each participant can produce only a single valid ticket per view v in a given epoch e, because the VRF-based leader election only starts after the valid identities have been fixed in the identity blockchain. Moreover, as the output of a VRF is unpredictable as long as the private key sk_i is kept secret, the tickets of non-colluding nodes, hence the outcome of the lottery are also unpredictable. The synchrony bound Δ guarantees that the ticket of an honest leader is seen by all other honest validators. If the adversary wins the lottery, then he can either decide to comply and run the RandHound protocol or decide to fail it which would exclude that particular node from participating for the rest of the epoch.

After a successful run of RandHound, the adversary learns the randomness, hence the sharding assignment first. The benefit to the adversary is minimal, however. The adversary again can either decide to cooperate and publish the random value or he can withhold it in the hope of winning the lottery again and obtaining a sharding assignment that fits his agenda better. However, the probability that an adversary wins the lottery a times in a row is upper bounded by the exponentially decreasing term $(f/n)^a$. Thus, after only a few re-runs of the lottery, an honest node wins with high probability and coordinates the sharding. Finally, we remark that an adversary cannot collect random values from multiple runs and then choose the one he likes best since validators accept only the latest random value that matches their view number v.

Finally in Appendix B, we show how OmniLedger can be extended to probabilistically detect that the expected Δ does not hold and can still remain secure with a fall-back protocol.

B. Maintaining Operability During Epoch Transitions

Recall that SimpleLedger changes the assignments of all n validators to shards in each epoch e, which results in an idle phase during which the system cannot process transactions until enough validators have finished bootstrapping.

To maintain operability during transition phases, OmniLedger swaps in the new validators gradually in each shard per epoch. This enables the remaining operators to continue providing service (in the honest scenario) to OmniLedger's clients while the recently joined validators are bootstrapping. In order to achieve this continues operation we need to swap-out at most $\frac{1}{3}$ of the shard's size ($\approx \frac{n}{m}$), however the bigger the batch, (a) the higher the risk the number of remaining honest validators will not be sufficient to reach consensus and (b) the more stress to the network the downloading of the bootstrap information will cause.

To minimize the chances of a temporary loss of liveness, the shard assignment of validators in OmniLedger works as follows. First, we fix a parameter $k < \frac{1}{3}\frac{n}{m}$ specifying the swap-out batch size, *i.e.*, the number of validators that will be swapped out at a given time. For OmniLedger we decided to work in batches of $k = \log \frac{n}{m}$. Then for each shard j, we derive a seed $H(j \parallel \mathsf{rnd}_e)$ to compute a permutation $\pi_{j,e}$ of the shard's validators and specify the permutation of the batches of size k. Additionally, we compute another seed $H(0 \parallel \mathsf{rnd}_e)$ to permute and scatter the new validators who joined in epoch e and to define the order in which they will do so (again, in batches of size k). After defining the random permutation, each batch waits Δ before starting the bootstrap process in order to spread the load on the network. Once a validator is ready, he request the shard's leader to let him swapped in.

Security Arguments: We ensure the safety of the BTF consensus in each shard during the transition phase as there are always at least $\frac{2}{3}\frac{n}{m}$ validators willing to participate in the consensus within each shard, *i.e.*, no quorum of malicious nodes ever exists. Moreover, since we use the epoch's randomness rnd_e to pick the permutation of the batches, we keep the shards' configurations a moving target for an adaptive adversary. Finally, as long as there are $\frac{2}{3}\frac{n}{m}$ honest and up-to-date validators, liveness is guaranteed whereas if this quorum is breached during transition (the new batch of honest validators has not yet updated) the liveness is lost only temporarily, until the new validators update.

C. Cross-Shard Transactions

Support for processing cross-shard transactions is an attractive and likely necessary feature, as they enable interoperability for any value transfer system such that transactions are not tied to a specific company, ledger or currency. Furthermore, we can expect the majority of transactions to be cross-shard in the traditional model where UTXOs are randomly assigned to shards for processing [16], [34], see Appendix C for details.

A simple but inadequate strawman approach to cross-shard transaction, is to concurrently send a transaction to several shards for processing because some shards might commit the transaction while others might abort. In such a case, the UTXOs at the shard who accepted the transactions are lost as there is no straightforward way to roll back a half-committed transaction, without adding exploitable race conditions.

To address this issue, we propose a novel *Byzantine Shard Atomic Commit (Atomix)* protocol for *atomically* processing transactions across shards such that each transaction is either committed or eventually aborted. The goals are to ensure consistency of transactions between shards and to prevent double spending and preventing unspent funds from being locked forever. In distributed computing, this problem is known as atomic commit [47] and atomic commit protocols [27], [30] are deployed on honest but unreliable processors. Deploying such protocols in OmniLedger is unnecessarily complex, however, as the shards are collectively honest, do not crash infinitely and run ByzCoin (that provides BFT consensus). Atomix improves the strawman approach with a lock-then-unlock process. We intentionally keep the shards' logic simple and make any direct shard-to-shard communication unnecessary by tasking the client with the responsibility of driving the unlock process while allowing any other party (*e.g.*, validators or even other clients) to fill in for the client if a specific transaction stalls after being submitted for processing.

Atomix leverages the UTXO state model, see Section II-B for an overview, which enables the following simple and efficient three-step protocol, also depicted in Figure 3.

1) **Initialize.** A client creates a *cross-shard transaction* (cross-TX for short) whose inputs spend UTXOs of some *input shards* (ISs) and whose outputs create new UTXOs in some *output shards* (OSs). The client gossips the cross-TX and it eventually reaches all ISs.
2) **Lock.** *All* input shards associated with a given cross-TX proceed as follows. First, each IS leader validates the transaction within his shard to decide whether the inputs can be spent. Then, if the transaction is valid, the leader marks within the state that the inputs are spent, logs the full transaction in the shard's ledger and finally gossips a *proof-of-acceptance*, a signed Merkle proof against the block header where the transaction is included. If the transaction is not accepted, however, the leader creates an analogous *proof-of-rejection*, where a special bit indicates an acceptance or rejection. Finally, the client can use each IS ledger to verify his proofs and that the transaction was indeed locked. After all ISs have processed the lock request, the client holds enough proofs to either commit the transaction or abort it and reclaim any locked funds, but not both.
3) **Unlock.** Depending on the outcome of the lock phase, the client is able to either commit or abort his transaction.
   a) **Unlock to Commit.** If *all* IS leaders issued proofs-of-acceptance, then the respective transaction can be committed. The client (or any other entity such as an IS leader after a time-out) creates and gossips an *unlock-to-commit transaction* that consists of the lock transaction and a proof-of-acceptance for each input UTXO. In turn, each involved OS validates the transaction and includes it in the next block of its ledger in order to update the state and enable the expenditure of the new funds.
   b) **Unlock to Abort.** If, however, *at least* one IS issued a proof-of-rejection, then the transaction cannot be committed and has to abort. In order to reclaim the funds locked in the previous phase, the client (or any other entity) must request the involved ISs to unlock that particular transaction by gossiping an *unlock-to-abort transaction* that includes (at least) one proof-of-rejection for one of the input UTXOs. Upon receiving a request to unlock, the ISs' leaders follow a similar procedure as before and mark the original UTXOs as spendable again.

We remark that, although the focus of OmniLedger is on the UTXO model, Atomix can be extended with a locking mechanism for systems where objects are long-lived and hold state (*e.g.*, smart contracts [48]), see Appendix D for details.

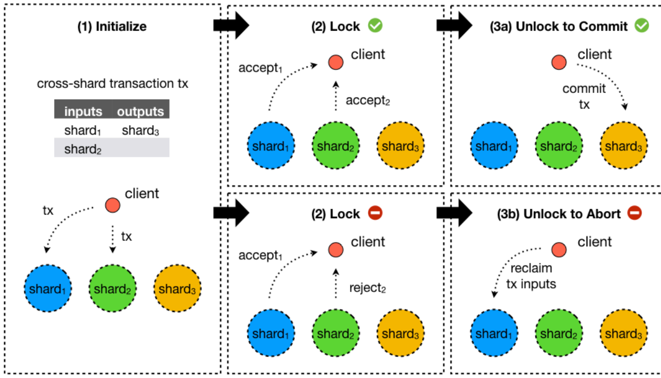

Fig. 3: Atomix protocol in OmniLedger.

Security Arguments: We now informally argue the previously claimed security properties of Atomix based on the following observations. Under our assumptions, shards are honest, do not fail, eventually receive all messages and can reach BFT-consensus. Consequently, (1) all shards always faithfully process valid transaction; (2) if all input shards issue a proof-of-acceptance, then every output shard unlocks to commit; (3) if at least one input shard issues a proof-of-rejection, then all input shards unlocks to abort; and (4) if at least one input shard issues a proof-of-rejection, then no output shard unlocks to commit.

In Atomix, each cross-TX eventually commits or aborts. Based on (1), each input shard returns exactly one response: either a proof-of-acceptance or a proof-of-rejection. Consequently, if a client has the required number of proofs (one per each input UTXO), then the client either only holds proofs-of-acceptance (allowing the transaction to be committed as (2) holds) or not (forcing the transaction to abort as (3) and (4) hold), but not both simultaneously.

In Atomix, no cross-TX can be spent twice. As shown above, cross-shard transactions are atomic and are assigned to specific shards who are solely responsible for them. Based on (1), the assigned shards do not process a transaction twice and no other shard attempts to unlock to commit.

In Atomix, if a transaction cannot be committed, then the locked funds can be reclaimed. If a transaction cannot be committed, then there must exist at least one proof-of-rejection issued by an input shard, therefore (3) must hold. Once all input shards unlock to abort, the funds become available again.

We remark that funds are not automatically reclaimed and a client or other entity must initiate the unlock to abort process. Although this approach poses the risk that if a client crashes indefinitely his funds remain locked, it enables a simplified protocol where the shards implement a minimal logic and no direct shard-to-shard communication is needed. We argue that a client who crashes indefinitely is equivalent to a client who lost his private key, which prevents him from spending the corresponding UTXOs. Furthermore, any entity in the system, for example a validator in exchange for a fee, can fill in for the client to create an unlock transaction, as all necessary information is gossiped.

To ensure better robustness, we can also assign the shard of the smallest-valued input UTXO to be a coordinator responsible for driving the process of creating unlock transactions. Because a shard's leader might be malicious, $f+1$ validators of the shard need to send the unlock transaction to guarantee that all transactions are eventually unlocked.

Size of Unlock Transactions: In Atomix, the unlock transactions are bigger than regular transactions as appropriate proofs for input UTXOs need to be included. OmniLedger relies on Omnicon (a novel BFT-consensus described in Section V-A) for processing transactions within each shard. When the shard's validators reach an agreement on a block that contains committed transactions, they produce a collective signature whose size is independent of the number of validators. This important feature enables us to keep Atomix proofs (and consequently the unlock transactions) short, even though the validity of each transaction is checked against the signed block headers of all input UTXOs. If Omnicon did not use collective signatures, the size of unlock transactions would be impractical. For example, for a shard of 100 validators a collective signature would only be 77 bytes, whereas a regular signature would be 9KB, almost two order's of magnitude bigger than the size of a simple transaction (500 bytes).

V. OmniLedger: Design Refinements for Performance

We introduce the performance sub-protocols of OmniLedger. First,we introduce a scalable BFT-consensus called *Omnicon* that is more robust and more parallelizable than ByzCoin. Then we introduce state-blocks that enable fast bootstrap and decrease storage-costs. Finally, we introduce an optional trust-but-verify validation step to provide real-time latency for low-risk transactions

A. Fault Tolerance under Byzantine Faults

The original ByzCoin design offers good scalability, partially due to the usage of a tree communication pattern. Maintaining such communication trees over long time periods can be difficult, as they are quite susceptible to faults. In the event of a failure, ByzCoin falls back on a more robust all-to-all communication pattern, similarly to PBFT. Consequently, the consensus's performance deteriorates significantly, which the adversary can exploit to hinder the system's performance.

To achieve better fault tolerance in OmniLedger, without resorting to a PBFT-like all-to-all communication pattern, we adopt for Omnicon that trades-off some of ByzCoin's high scalability by changing the message propagation mechanism within the consensus group and by reducing the depth of the communication tree. During the setup of OmniLedger in an epoch, the generated randomness is not only used to assign validators to shards but also to assign them evenly to groups within a shard. The number of groups g, from which the maximum group size can be derived by taking the shard size into account, is specified in the shard policy file. At the beginning of a Omnicon roundtrip, the protocol leader randomly selects one of the validators in each group to be the

group leader who is responsible for managing communication between the protocol leader and the respective group members. If a group leader does not reply before a predefined timeout, the protocol leader randomly chooses another group member to replace the failed leader. As soon as he receives more than $\frac{2}{3}$ of the validators' acceptances, the protocol leader proceeds to the next phase of the protocol. If the protocol leader fails, all validators initiate a PBFT-like view-change procedure.

B. Parallelizing Block Commitments

We now show how Omnicon parallelized block commitments in the UTXO model that OmniLedger utilizes by carefully analyzing and handling dependencies between the blocks' transactions.

We observe that transactions which do not conflict with each other can be committed in different blocks and consequently can be safely processed in parallel. To identify conflicting transactions, we need to analyze the dependencies that are possible between transactions. Let tx_A and tx_B denote two transactions. Then, there are two cases that need to be carefully handled: (1) both tx_A and tx_B try to spend the same UTXO and (2) an UTXO created at the output of tx_A is spent at the input of tx_B (or vice versa). To address (1) and maintain consistency, only one of the two tx can be committed. To address (2), tx_A has to be committed to the ledger before tx_B, *i.e.*, tx_B has to be in a block that depends (transitively) on the block containing tx_A. All transactions that do not exhibit those two properties can be processed safely in parallel. In particular we remark that transactions that credit the same address do not produce a conflict, as they generate different UTXOs

To capture the concurrent processing of blocks, we adopt a *block-based directed acyclic graph* or *blockDAG* [33] as a data structure, where every block can have multiple parents. The Omnicon protocol leader enforces that each pending block includes only non-conflicting transactions and captures UTXO dependencies by adding the hashes of former blocks (*i.e.*, backpointers) upon which the transactions inside the pending block depend. To decrease the number of such hashes, we remark that UTXO dependencies are transitive, enabling us to relax the requirement that blocks have to capture all UTXO dependencies directly. Instead, a given block can simply add backpointers to a set of blocks that transitively capture all necessary dependencies.

C. Shard Ledger Pruning

Next, we tackle the issues of the ever-growing ledger and the resulting costly bootstrapping of new validators; this is a particularly urgent concern for the next-generation high-throughput DL systems. For example, whereas Bitcoin's blockchain grows at a rate of 144 MB per day and has a total size of about 133 GB, next-generation systems with Visa-level throughput (*e.g.*, 4000 tx/sec and 500 B/tx) can easily produce over 150 GB per day.

To reduce the storage and bootstrapping costs for validators (whose shard assignment might change periodically), we introduce *state blocks* that are similar to stable checkpoints in PBFT [13] and summarize the entire state of a shard's ledger. To create a state block $\mathsf{sb}_{j,e}$ for shard j in epoch e, the shard's validators execute the following steps: At the end of e, the shard's leader stores the UTXOs in an ordered Merkle tree, and puts the Merkle tree's root hash in the header of $\mathsf{sb}_{j,e}$. Afterwards, the validators run consensus on the header of $\mathsf{sb}_{j,e}$ (note that each validator can construct the same ordered Merkle tree for verification) and, if successful, the leader stores the approved header in the shard's ledger making $\mathsf{sb}_{j,e}$ the genesis block of epoch $e+1$. Finally, the body of $\mathsf{sb}_{j,e-1}$ (UTXOs) can be discarded safely. However, we keep the regular blocks of epoch e until after the end of epoch $e+1$ for the purpose of creating transaction proofs.

As OmniLedger's state is split across multiple shards and as we store only the state block headers in a shard's ledger, a client cannot prove the existence of a past transaction to another party by presenting an inclusion proof to the block where the transaction was committed. We work around this by moving the responsibility of storing transactions' proofs-of-existence to the clients of OmniLedger. During epoch $e+1$ clients can ask the validators of the shard to create proofs-of-existence for transactions validated in epoch e. Such a proof for a given transaction tx contains the Merkle tree inclusion proof to the regular block B that committed tx in epoch e and a sequence of block headers from the state block $\mathsf{sb}_{j,e}$ at the end of the epoch to block B. To reduce the size of these proofs, state blocks may include several multi-hop backpointers to headers of intermediate (regular) blocks similarly to skipchains [37].

Finally, if we naively implement the creation of state blocks, it stalls the epoch's start, hence transaction processing until $\mathsf{sb}_{j,e}$ has been appended to the ledger. To avoid this downtime, the consistent validators of the shard in epoch $e+1$ include an empty state-block at the beginning of the epoch as a place-holder and once $\mathsf{sb}_{j,e}$ is ready they commit it as a regular block, pointing back to the place-holder and $\mathsf{sb}_{j,e-1}$.

D. Optional Trust-but-Verify Validation

There exists an inherent trade-off between the number of shards (and consequently the size of a shard), throughput and latency, as illustrated in Figure 4. A higher number of smaller shards results in a better performance but provides less resiliency against a more powerful attacker (25%). Because the design of OmniLedger favors security over scalability, we pessimistically assume an adversary who controls 25% of the validators and, accordingly, choose large shards at the cost of higher latency but guarantee the finality of transactions. This assumption, however, might not appropriately reflect the priorities of clients with frequent, latency-sensitive but low-value transactions (*e.g.*, checking out at a grocery store, buying gas or paying for coffee) who would like to have transactions processed as quickly as possible.

In response to the clients' needs, we augment the intra-shard architecture (see Figure 4) by following a "trust but verify" model, where *optimistic validators* process transactions quickly providing a provisional but unlikely-to-change

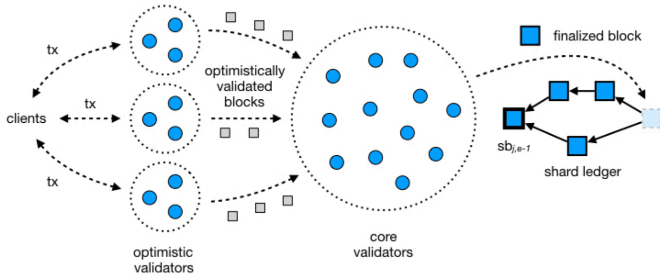

Fig. 4: Trust-but-Verify Validation Architecture

commitment and *core validators* subsequently verify the transactions again to provide finality and ensure verifiability. Optimistic validators follow the usual procedures for processing transactions and deciding which transactions are committed in which order; but they form much smaller groups, even as small as one validator per group. Consequently, they produce smaller blocks with real-time latencies but are potentially less secure as the adversary needs to control a (proportionally) smaller number of validators to subvert their operation. As a result, some bad transactions might be committed but ultimately core validators verify all provisional commitments, detecting any inconsistencies and their culprits, which makes it possible to punish rogue validators and to compensate the defrauded customers for the damages. The trust-but-verify approach strikes a balance for processing small transactions in real-time, as validators are unlikely to misbehave and only small amounts of money are at stake.

At the beginning of an epoch e, all validators assign themselves to shards using the per-epoch randomness, and then bootstrap their states from the respective shard's last state block. Then, OmniLedger assigns each validator randomly to one of multiple optimistic processing groups or a single core processing group. The shard policy file specifies the number of optimistic and core validators, as well as the number of optimistic groups.

Transactions are first processed by an optimistic group that produces optimistically validated blocks. These blocks serve as input for re-validation by core validators who run concurrently and combine inputs from multiple optimistic processing groups, thus maximizing the throughput of the system (see Figure 4). If transactions validate successfully, then they are included in a finalized block, added to the shard's ledger and finally included in the state block. However, when core validators detect an inconsistency, then the respective optimistically validated transaction is excluded and the validators who signed the invalid block are identified and held accountable, for example, withholding any rewards or excluding them from the system. We remark that the exact details of such punishments depend on the employed incentive scheme which are out of scope of this paper. Given a minimal incentive to misbehave and the quantifiable confidence in the security of optimistic validation (Figure 6), clients can choose to take advantage of real-time processing with an optimistic assurance of finality or to wait to have their transaction finalized, depending on what fits their needs best.

VI. Security Analysis

Our contributions are mainly pragmatic rather than theoretical and in this section we provide an informal security analysis that supplements and uses the arguments provided in Sections IV and V.

A. Randomness Creation

RandHound assumes an honest leader who is responsible for coordinating the protocol run and making the produced randomness available to others. In OmniLedger, however, we cannot always guarantee that an honest leader will be selected. Although a dishonest leader cannot affect the unbiasability of the random output, he can choose to withhold the randomness if it is not to his liking, forcing the protocol to restart. We economically disincentivize such behavior and bound the bias by the randomized leader election process.

The leader-election process is unpredictable as the adversary is bound by the usual cryptographic hardness assumptions and is unaware of (a) the private keys of the honest validators and (b) the input string x to the VRF function. In addition, OmniLedger's membership is unpredictable at the moment of private key selection and private keys are bound to identities. As a result, the adversary has at most $m = 1/4$ chance per round to control the elected leader as he controls at most 25% of all nodes. Each time an adversary-controlled leader is elected and runs RandHound, the adversary can choose to accept the random output, and consequently the sharding assignment produced by it, or to forfeit it and try again in hopes of a more favorable yet still random assignment. Consequently, the probability that an adversary controls n consecutive leaders is upper-bounded by $P[X \geq n] = \frac{1}{4^n} < 10^{-\lambda}$. For $\lambda = 6$, the adversary will control at most 10 consecutive RandHound runs. This is an upper bound as we do not include the exclusion of the previous leader from the consecutive elections.

B. Shard Size Security

We previously made the assumption that each shard is collectively honest. This assumption holds as long as each shard has less than $c = \lfloor \frac{n}{3} \rfloor$ malicious validators, because Omnicon requires $n = 3f + 1$ to provide BFT consensus.

The security of OmniLedger's validator assignment mechanism is modeled as a random sampling problem with two possible outcomes (honest or malicious). Assuming an infinite pool of potential validators, we can use the binomial distribution (Eq. 1). We can assume random sampling due to RandHound's unpredictability property that guarantees that each selection is completely random, thus leading to the adversarial power of at most $m = 0.25$.

$$P\left[X \leq \lfloor \frac{n}{3} \rfloor\right] = \sum_{k=0}^{n} \binom{n}{k} m^k (1-m)^{n-k} \tag{1}$$

To calculate the failure rate of one shard, *i.e.*, the probability that a shard is controlled by an adversary, we use the

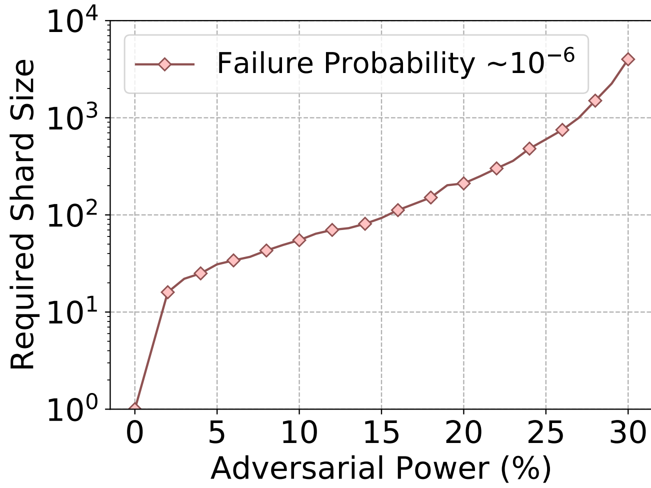

Fig. 5: Shard sizes given the percentage of malicious hosts for a fixed failure probability.

cumulative distributions over the shard size n, where X is the random variable that represents the number of times we pick a malicious node. Figure 5 (right) illustrates the proposed shard size based on the power of the adversary.

In a similar fashion we calculate the confidence a client can have that an optimistic validation group is honest in Figure 6 (left).

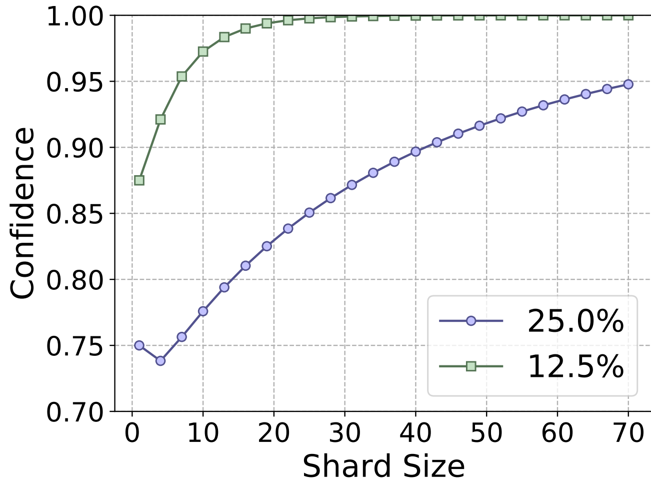

Fig. 6: Confidence in a security of an optimistic validation group given 12.5% and 25% adversary by group size.

C. Epoch Security

Although the security of single shard can be modeled as a random selection process, the failure probability calculated in the previous section does not express the failure probability of the entire system within one epoch. We are interested in an epoch-level security as validators are reassigned at the beginning of a new epoch. The total failure rate of a correctly bootstrapped epoch is the union bound of the failure rates of the individual shards.

We argue that given an adequately large shard size, the failure probability of an epoch is negligible. We can calculate an upper bound on the total failure probability by allowing the adversary to run RandHound multiple times and to choose the random output he prefers. This is a stronger assumption than what RandHound permits, as the adversary cannot choose to roll back to a previously selected random output if he chose to re-run RandHound.
An upper bound of X_E (epoch failure event) is calculated as:

$$P\left[X_E\right] \leq \sum_{k=0}^{l} \frac{1}{4^k} \cdot n \cdot P\left[X_S\right] \tag{2}$$

where l is the number of consecutive views the adversary controls, n is the number of shards and $P\left[X_S\right]$ is the failure probability of one shard as calculated in Section VI-B. For $l \to \infty$, we get $P\left[X_E\right] \leq \frac{4}{3} \cdot n \cdot P\left[X_S\right]$. More concretely, the failure probability given a 12.5%-adversary and 16 shards is $4 \cdot 10^{-5}$ or one failure in 68.5 years if one epoch corresponds to one day.

D. Group Communication

We now show that OmniLedger's group communication pattern has a high probability of convergence under faults. We assume that there are N nodes, that are split in $\sqrt{N}$ groups of $\sqrt{N}$ nodes each.

1) Setting the Time-Outs: In order to ensure that the shard leader will have enough time to find honest group leaders, we need to setup the view-change time-outs accordingly. OmniLedger achieves this by having two time-outs. The first timeout T_1 is used by the shard leader to retry the request to non-responsive group members. The second timeout T_2 is used by the group members to identify a potential failure of a shard leader and to initiate a view-change [13]. We have a fixed ratio of $T_1 = 0.1T_2$ to ensure that the shard leader has enough time to retry his requests. However, if the T_2 is triggered, then in the new view T_2 doubles (as is typical [13]) in order to contemplate for increase in the network's asynchrony, hence T_1 should double to respect the ratio.

2) Reaching Consensus: We calculate the probability for a group size $N = 600$ where $\sqrt{N} = 25$: Given a population of 600 nodes and a sampling size of 25, we use the hypergeometric distribution for our calculation which yields a probability of 99.93% that a given group will have less than $25 - 10 = 15$ malicious nodes. A union bound over 25 groups yields a probability of 98.25% that no group will have more than 15 malicious nodes. In the worst case, where there are exactly $\frac{1}{3}$ malicious nodes in total, we need all of the honest validators to reply. For a group that contains exactly 15 malicious nodes, the shard's leader will find an honest group leader (for Omnicon) after 10 tries with a probability of $1 - ((15/24)^{10})$ = 98.6%. As a result, the total probability of failure is $1 - 0.986 * 0.9825 = 0.031$.

We remark that this failure does not constitute a compromise of security of OmniLedger. Rather, it represents the probability of a failure for the shard leader who is in charge of coordinating the shard's operation. If a shard leader indeed fails, then a new shard leader will be elected, who has 97% probability of successfully reaching consensus.

VII. Implementation

We implemented OmniLedger and its subprotocols for sharding, consensus, and processing of cross-shard transactions in Go [26]. For sharding, we combined RandHound's code, which is available on GitHub, with our implementation of a VRF-based leader election mechanism using a VRF construction similar to the one of Frankling and Zhang [22]. Similarly, to implement Omnicon we extended ByzCoin's code, which is publicly available on GitHub as well, by the parallel block commitment mechanism as introduced in Section V-B. Finally, we also implemented the Atomix protocol, see Section IV-C, on top of the shards, as well as a client that dispatches and verifies cross-shard transactions and its proofs. We will make all implementations publicly available on GitHub.

VIII. Evaluation

This section experimentally evaluates our prototype implementation of OmniLedger. The primary questions we want to evaluate concern the overall performance of OmniLedger and whether it truly scales out (Section VIII-B), the cost of epoch transitions (Section VIII-C), the client-perceived latency when committing cross-shard transactions (Section VIII-D), and the performance differences between Omnicon and ByzCoin with respect to throughput and latency (Section VIII-E).

A. Experimental Setup

We ran all our experiments on DeterLab [18] using 60 physical machines, each equipped with an Intel E5-2420 v2 CPU, 24 GB of RAM, and a 10 Gbps network link. To simulate a realistic, globally distributed deployment, we restricted the bandwidth of all connections between nodes to 20 Mbps and impose a latency of 100 ms on all communication links. The basis for our experiments is a data set consisting of the first $10,000$ blocks of the Bitcoin blockchain.

B. OmniLedger Performance

In this experiment, we evaluate the performance of OmniLedger in terms of throughput and latency in different situations: we distinguish the cases where we have a fixed shard size and varying adversarial power (in particular 1%, 5%, 12.5%, and 25%) or the other way round. We also distinguish between configurations with regular or trust-but-verify validations where we use 1 MB blocks in the former case and 500 KB for optimistically validated blocks and 16 MB for final blocks in the latter case. In order to provide enough data for the final blocks, for each shard there are 32 concurrent optimistic validaton groups concurrently running which feeding to one final shard, enabling low latency for low-risk transactions (Table I) and high throughput of the total system.

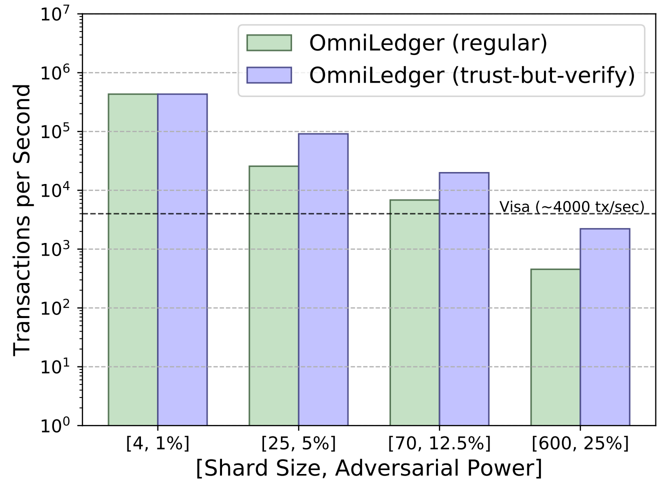

Fig. 7: OmniLedger throughput for 1800 hosts, varying shard sizes s, and adversarial power f/n.

TABLE I: OmniLedger transaction confirmation latency in seconds for different configurations with respect to the shard size s, adversarial power f/n, and validation types.

$[s, f/n]$	$[4, 1\%]$	$[25, 5\%]$	$[70, 12.5\%]$	$[600, 25\%]$
Regular val.	1.38	5.99	8.04	14.52
1st lvl. val.	1.38	1.38	1.38	4.48
2nd lvl. val.	1.38	55.89	41.84	62.96

Figure 7 shows OmniLedger's throughput for 1800 hosts in different configurations and, for comparison, includes the average throughput of Visa at ≈ 4000 tx/sec. Additionally, Table I shows the confirmation latency in the above configuration.

We observe that OmniLedger's throughput with trust-but-verify validation is almost an order of magnitude higher than with regular validation, at the cost of a higher latency for high-risk transactions that require both validation steps to complete. For low-risk transactions, OmniLedger provides an optimistic confirmation in a few seconds after the first validation step, with less than 10% probability that the confirmation was vulnerable to a double spending attacks due to higher-than-average number of malicious validators. For high-risk transactions, the latency is still less than one minute and the finality of transactions is guaranteed.

Table II shows the scale-out throughput of OmniLedger with a 12.5% adversary, a shard size of 70, and a number of shards m between 1 and 16. As we can see, the throughput increases almost linearly in the number of shards.

In Figure 7, with a 12.5% adversary and a total number of 1800 hosts, we distributed the latter across 25 shards for which we measured a throughput of $13,000$ tps corresponding to 3 times the level of Visa. Finally, if we want to maintain OmniLedger's security against a 25% adversary and still achieve the same average throughput of Visa, *i.e.*, 4000 tps, then we estimate that we need to increase the number of hosts to about 4200 (which is less than the number of Bitcoin

TABLE II: OmniLedger scale-out throughput in transactions per second (tps) for a adversarial power of $f/n = 12.5\%$ shard size of $s = 70$, and a varying number of shards m.

m	1	2	4	8	16
tps	439	869	1674	3240	5850

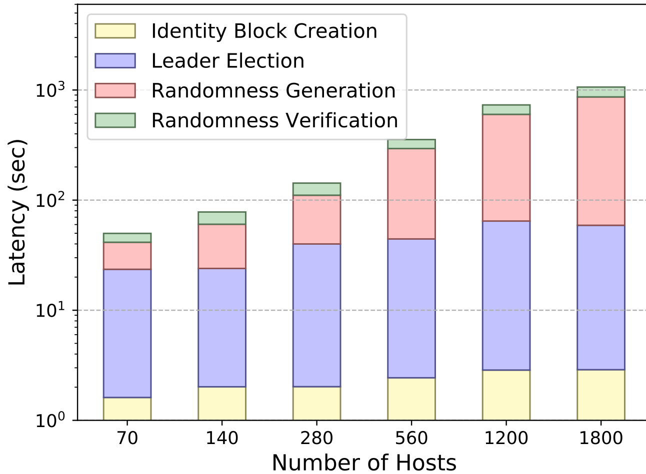

Fig. 8: Epoch transition latency.

full nodes [4]) and split them into 7 shards. Unfortunately, our experimental platform could not handle such a high load, therefore, we mention here only an estimated value.

C. Epoch Transition Costs

In this experiment, we evaluate the costs for transitioning from an epoch $e-1$ to epoch e. Recall, that at the end of epoch $e - 1$ the new membership configuration is first collectively signed, then used for the VRF-based leader-election. Once the leader is elected, he runs RandHound with a group-size of 16 hosts (which is secure for a 25% adversary [44]) and broadcasts it to all validators, who then verify the result and connect to their peers. We assume that validators already know the state of the shard they will be validating. It is important to mention that this process is not on the critical path, but occurs concurrently with the previous epoch. Once the new groups have been setup, the new shard leaders enforce a view-change.

As we can see in Figure 8, the cost of bootstrapping is mainly due to RandHound that takes up more than 70% of the total run time. To estimate the worst-case scenario, we can come back to our security analysis in Section VI-A and see that even in the case with 1800 hosts, an honest leader is elected after 10 RandHound runs with high probability, which takes approximately 3 hours. Given an epoch duration of one day, this worst case overhead is acceptable.

D. Client-Perceived End-to-End Latency with Atomix

In this experiment we evaluate, for different shard configurations, the client-perceived, end-to-end latency for cross-shard transactions when using Atomix.

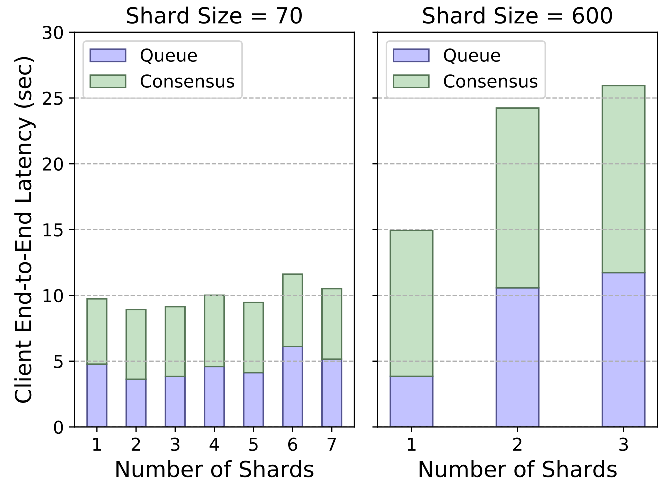

Fig. 9: Client-perceived, end-to-end latency for cross-shard transactions via Atomix.

TABLE III: Omnicon latency in seconds for different concurrency levels and data sizes.

	Concurrency			
Data Size	1	2	4	8
1 MB	15.4	13.5	12.6	11.4
8 MB	32.2	27.7	26.0	23.2
32 MB	61.6	58.0	50.1	50.9

As shown in Figure 9, the client-perceived latency is almost double the value of the consensus latency as there are already other blocks waiting to be processed in the common case. As a consequence, the inclusion of the transaction in a block is delayed. This latency increases slightly further when multiple shards validate a transaction. The overall end-to-end latency would be even higher if a client had to wait for output shards to run consensus which, however, is not needed, see Section IV-C.

If the client wants to directly spend the new funds he can batch together the proof-of-acceptance and the expenditure transaction in order to respect the input-after-output constraint.

Overall, the client-perceived, end-to-end latency for cross-shard transactions is not significantly affected when increasing the number of shards.

E. Omnicon Performance

In this experiment, we measure the performance improvements of Omnicon over the original ByzCoin. To have a fair comparison, each data-series corresponds to the total size of data concurrently in the network, meaning that if the concurrency level is 2 then there are 2 blocks of 4 MB concurrently, adding to a total of 8 MB, whereas a concurrency level of 4 means 4 blocks of 2 MB each.

In Figures 10 and Table III, we can see that there is a 20% performance increase when moving from one big block to 4 smaller concurrently running blocks, with a *concurrent* 35% decrease in the per block consensus latency. This can

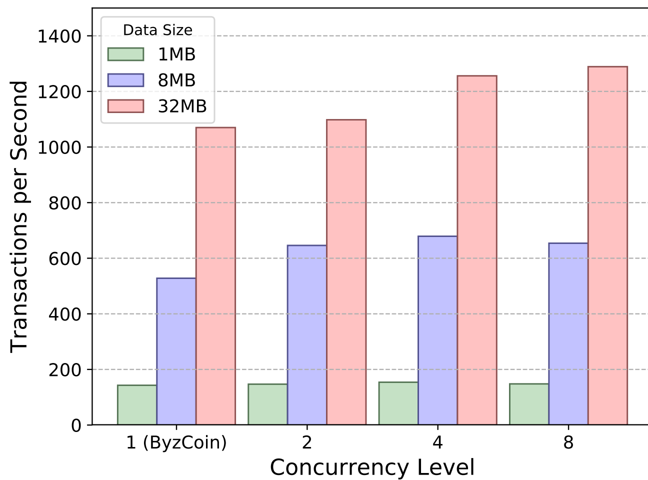

Fig. 10: Omnicon throughput in transactions per second for different levels of concurrency.

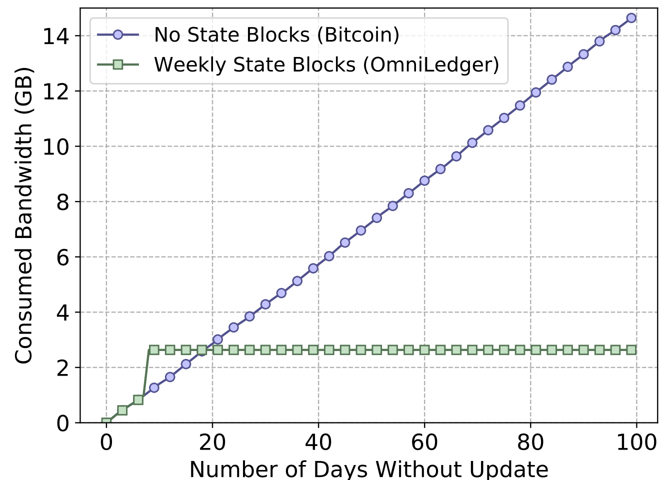

Fig. 12: Bootstrap bandwidth consumption with state blocks.

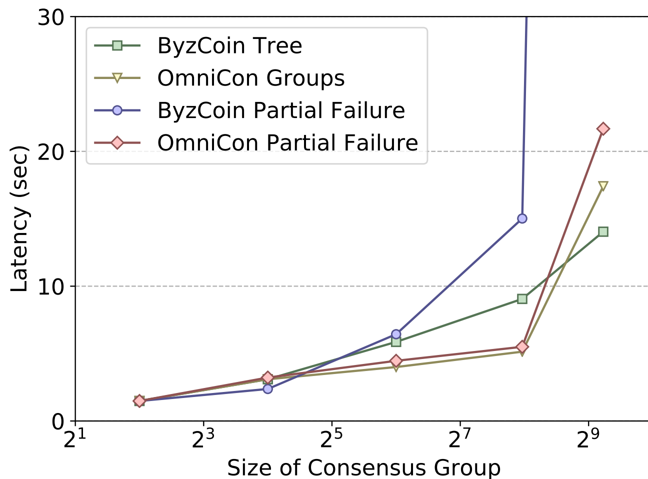

Fig. 11: Omnicon communication pattern latency.

be attributed to the higher resource utilization of the system, when blocks arrive more frequently for validation. When the concurrency further increases, we can see a slight drop in performance, meaning that the overhead of the parallel consensus outweighs the parallelization benefits, due to the constant number of cryptographic operations per block.

Figure 11 illustrates the scalability of ByzCoin's [32] tree and fall-back flat topology, versus Omnicon's more fault-tolerant (group-based) topology and its performance when failures occur. As expected the tree topology scales better, but only after the consensus is run among more than 600 nodes, which assumes an adversary stronger than usual (see Figure 5).

For a group size below 600, Omnicon's communication pattern actually performs better than ByzCoin's. This is due to Omnicon's communication pattern that can be seen as a shallow tree where the round-trip from root to leaves is faster than in the tree of ByzCoin. Hence, whereas ByzCoin has a fixed branching factor and an increasing depth, Omnicon has a fixed depth and an increasing branching factor. The effect of these two choices leads to better latencies for a few hundred nodes for fixed depth. However, the importance of the group topology is that it is more fault tolerant, because when failures occur the performance is not seriously affected. This is not true for ByzCoin; it switches to a flat topology in case of failure that does not scale after a few hundred nodes, due to the huge branching factor. This experiment was run with 1 MB blocks, the non-visible data point is at 300 seconds.

F. Bandwidth Costs for State Block Bootstrapping

In this experiment, we evaluate the improvements that state blocks offer to new validators during bootstrapping. Recall, that during an epoch transition, a new validator first crawls the identity blockchain, after which he needs to download only the latest state block instead of replaying the full blockchain to create the UTXO state. For this experiment, we reconstructed Bitcoin's blockchain [5] and created a parallel OmniLedger blockchain with weekly state blocks. We recovered the state size from [41].

Figure 12 depicts the bandwidth overhead of a validator that did not follow the state for the first 100 days. As we can, see the state block approach is better if the validator is outdated for more than 19 days or 2736 Bitcoin blocks.

The benefit might not seem substantial for Bitcoin, but in OmniLedger, 2736 blocks are created in less than 8 hours, meaning that for one day-long epoch, the state block approach is significantly better. This can provide further benefits when the peak throughput is needed and 16 MB blocks are deployed. In this case, the bandwidth benefit of state blocks is expected to be close to two orders of magnitude.

IX. Related Work

The growing interests in scaling blockchains have produced a number of prominent systems that we compare in Table IV.

TABLE IV: Comparison of Distributed Ledger Systems

System	Scale-Out	Cross-Shard Transaction Atomicity	State Blocks	Measured Scalability (# of Validators)	Estimated Time to Fail	Measured Latency
RsCoin [16]	In Permissioned	Partial	No	30	N/A	1 sec
Elastico [34]	In PoW	No	No	1600	1 hour	800 sec
ByzCoin [32]	No	N/A	No	1008	19 years	40 sec
Bitcoin-NG [21]	No	N/A	No	1000	N/A	600 sec
PBFT [9], [11]	No	N/A	No	16	N/A	1 sec
Nakamoto [36]	No	N/A	No	4000	N/A	600 sec
OmniLedger	Yes	Yes	Yes	2400	68.5 years	1.5 sec

ByzCoin [32] is a first step to scalbale BFT consensus, but cannot scale-out. Elastico, is the first open scale-out DL, however it suffers performance and security challenges that we have already analyzed in Section II. In the permissioned setting, sharding is proposed as a scalable approach for centrally banked cryptocurrency. RSCoin [16] uses a trusted source of randomness for sharding and auditing making the system problematic to use in a trustless setting. Each shard coordinates with the client to validate his transactions. RSCoin does not run BFT, rather a simplified two-phase commit protocol, assuming that if the majority of validators are honest, safety is preserved. However, it implicitly trusts the clients and does not provide security from a malicious client who colludes with one validator and sends two conflicting transactions to two disjoint halves of validators to achieve two majorities.

In short, prior solutions [16], [32], [34] achieve only two out of the three desired properties; decentralization, long-term security, and scale-out, as illustrated in Figure 1. OmniLedger overcomes this issue by scaling-out as far as throughput is concerned and maintaining consistency to the level required for safety, without imposing a global total order.

Bitcoin-NG scales Bitcoin without changing the consensus algorithm by observing that the PoW process does not have to be the same as the transaction validation process, resulting in two separate timelines: one slow for PoW and one fast for transaction validation. Although Bitcoin-NG significantly increases the throughput of Bitcoin, it is still susceptible to the same attacks as Bitcoin [24], [3].

Industry efforts to scale blockchain include Tendermint [9], a protocol similar to PBFT for shard-level consensus which does not scale due to its similarities to PBFT, and the Lightning Network [40], a protocol compatible with OmniLedger that aims to scale Bitcoin by limiting the number of transactions exposed to a ledger.

Finally, Chainspace [2], a closely related system that has been developed concurrently to OmniLedger, enhances RsCoin with a more general smart-contract capability. Chainspace also recognizes the need for cross-shard atomic commit but devises a rather complicated algorithm. The system takes a different path to scalability and chooses to have the shards run the protocol without the use of a client, which increases the cross-shard communication. Our approach is synergistic to Chainspace as we focus on an open scalable UTXO style DL, whereas Chainspace focuses on sharded smart-contracts and small-scale shards that can be deployed only under weak adversaries (*e.g.*, in a permissioned setting). As a result, combining OmniLedger and Chainspace has great potential to create an open, scalable smart-contract platform that provides scalability and security under strong adversaries.

X. Limitation and Future Work

OmniLedger is still a proof-of-concept and has limitations that we want to address in future work. First, even if the epoch bootstrap does not interfere with the normal operation, its cost (in the order of minutes) is significant. We leave to future work the use of advanced cryptography, such as BLS [6] for performance improvements. Additionally, the actual throughput is dependent on the workload (see Appendix C). If all transactions touch all the shards before committing, then the system is better-off with only one shard. We leave to future work the exploration of alternative ways of sharding, using locality measures instead of randomly. Furthermore, we rely on the fact that honest validators will detect that transactions are unfairly censored and change the leader in the case of censorship. However, further anti-censorship guarantees are needed. We provide a protocol sketch in Appendix A and leave to future work its implementation and further combination with secret sharing techniques to provide stronger guarantees. Finally the system is not suitable for very adaptive adversaries, as the bootstrap time of an epoch is substantial and scales only moderately leading to the need for day-long epochs.

XI. Conclusion

OmniLedger is the first DL that securely scales-out to offer a Visa-level throughput and a latency of seconds while preserving full decentralization and protecting against a Byzantine adversary. OmniLedger achieves this through a novel approach consisting of three steps. First, OmniLedger is designed with concurrency in mind; both the full system (through sharding) and each shard separately (through Omnicon) validate transactions in parallel, maximizing the resource utilization while preserving safety. Second, OmniLedger enables any user to transact safely with any other user, regardless of the shard they use, by deploying *Atomix*, an algorithm for cross-shard transactions as well as real-time validation with the introduction of a trust-but-verify approach. Finally, OmniLedger enables validators to securely and efficiently switch between shards, without being bound to a single anti-Sybil attack method and without stalling between reconfiguration events.

We have implemented and evaluated OmniLedger and each of its sub-components, as they can be deployed separately. Omnicon improves against ByzCoin both in performance, with 20% more throughput and 35% less latency, and in robustness against failures. Atomix offers a secure processing of cross-shard transactions and its overhead is minimal compared to intra-shard consensus. Finally, we have thoroughly evaluated the full OmniLedger deployment and shown that it can achieve Visa level throughput, given enough willing validators exist.

APPENDIX A
CENSORSHIP RESISTANCE PROTOCOL

One issue existing in prior work [32], [34] that OmniLedger partially addresses is when a malicious shard leader censors transaction. This attack can be undetectable from the rest of the shard's validators. A leader who does not propose a transaction is acceptable as far as the state is concerned, but this attack can compromise the fairness of the system or be used as a coercion tool.

For this reason, we enable the validators to request transactions to be committed, because they think the transactions are censored. They can either collect those transactions via the normal gossiping process or receive a request directly from a client. This protocol can be run periodically (*e.g.*, once every 10 blocks). We denote $N = 3f+$ validators exist where at most f are dishonest.

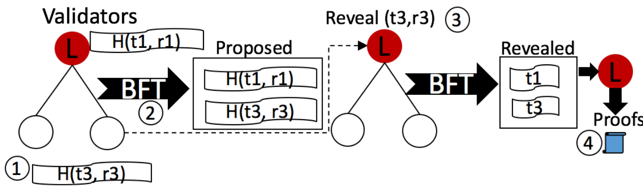

Fig. 13: Anti-censorship mechanism OmniLedger

The workflow (Figure 13), starts ① with each validator proposing a few (e.g 100) blinded transactions for anti-censorship, which initiates a consensus round. The leader should add in the blocks all the proposals, however he can censor f of the honest proposers. Nevertheless, he is blind on the f inputs he has to add from the honest validators he will reach consensus with. Once the round ends, there is a list ② of transactions that are eligible for anti-censorship, which is a subset of the proposed. As the transactions are blinded, no other validator knows which ones are proposed before the end of the consensus. Each validators reveals ③ his chosen transactions, the validators check that the transactions are valid and run consensus on which ones they expect the leader to propose. The leader is then obliged to include ④ the transactions that are consistent with the state, otherwise the honest validators will cause a view-change [13].

APPENDIX B
BREAKING THE NETWORK MODEL

Although DL protocols that assume a non-static group of validators have similar synchrony [34], [36] assumptions, in this section we discuss what can happen if the adversary manages to break them [3]. In such a case we can detect the attack and provide a back-up randomness generation mechanism which is not expected to scale but guarantees safety even in asynchrony.

Given that RandHound guarantees safety without the need for synchrony an adversary manipulates the network can at most slow down any validator he does not control, winning the leadership all the time. However this does not enable the adversary to manipulate RandHound, it just gives him the advantage of being able to restart the protocol if he does not like the random number. This restart will be visible to the network, and the participants can suspect a bias-attempt, when multiple consecutive RandHound rounds start to fail.

OmniLedger can provide a "safety valve" mechanism in order to mitigate this problem. When 5 RandHound views fail in a row, which under normal circumstances could happen with less than 1% probability, the validators switch from RandHound to running a fully asynchronous coin-tossing protocol [12] that uses Publicly Verifiable Secret Sharing [43], in order to produce the epoch's randomness. This protocol scales poorly ($O(n^3)$), but it will be run when the network is anyway under attack and liveness is not guaranteed, in which case safety is more important.

APPENDIX C
PROBABILITY OF CROSS-SHARD TRANSACTIONS

This section explores the limitations cross-shard transactions pose to the performance of the system. When splitting the state into disjoint parts, the common practice [16], [34] is to assign UTXOs to shards, based on the first bits of their hash. For example, one shard manages all UTXOs whose first bit is 0, and the second shard all UTXOs whose first bit is 1. Then each shard is managed by a group of validators who keep the state consistent and commit updates.

For an intrashard transaction we want all the inputs and outputs of the transaction to be assigned at the shame shard. The probability of assigning a UTXO in a shard is uniformly random from the randomness guarantees of cryptographic hash functions. Let m be the total number of shards, n the sum of input and output UTXOs and k the number of shards that need to participate in the cross-shard validation of the transaction. The probability can be calculated as:

$$P(n,k,m) = \begin{cases} 1, n=1, k=1 \\ 0, n=1, k\neq 1 \\ \frac{m-k}{m} P(n-1,k-1,m) + \\ \frac{k}{m} P(n-1,k,m), n\neq 1, k>0 \end{cases} \quad (3)$$

For a typical transaction with two inputs and one output and a three-shard setup, the probability of a transaction being intra-shard is $P(3,1,3) = 3.7\%$, rendering the assumption that transactions touch only one shard [34] problematic. As a result if all transactions had this format the expected speed-up from an 1-shard to a 4-shard configuration would be $4*(0.015 + \frac{0.328}{2} + \frac{0.56}{3} + \frac{0.09}{4}) = 1.56$

Generalizing this we can see that the expected speed-up of experiment VIII would look a bit different (Figure 14), as the speed-up is lower at the beggining when more transactions become cross-shard and later stabilizes back to linear.

APPENDIX D
ATOMIX FOR STATE-FULL OBJECTS

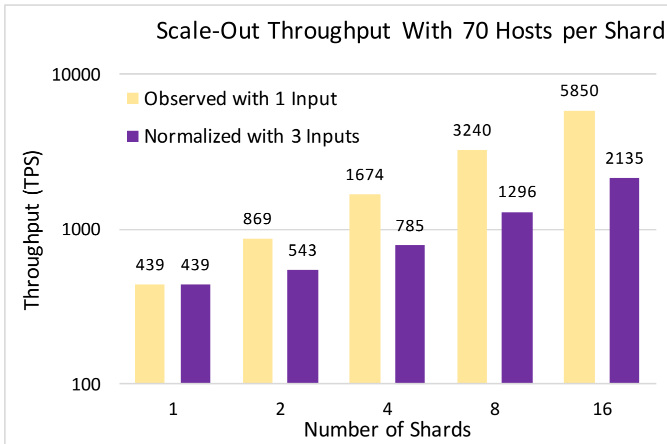

Fig. 14: Scale-Out throughput with a fixed adversary

The original Atomix protocol in Section IV implements a state machine as depicted in Figure 15

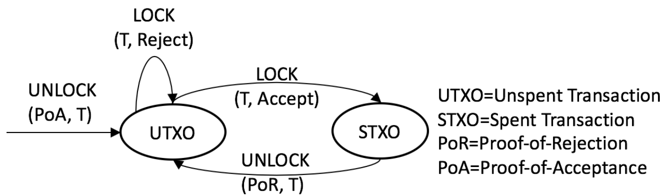

Fig. 15: State-Machine for state-full objects. Pessimistic locking is necessary

To enable the use of such an algorithm in smart contracts we need to account on the fact that a smart-contract object is mutable and can be accessed concurrently for a legitimate reason. As a result we need to modify the algorithm in two ways: a) the Unlock transactions should be send to both Input and Output shards and b) the state machine should have one more state as the shards need to wait for confirmation before unlocking. This is necessary because there is the chance that the (state-full) object will be accessed again and this could violate the input-after-output dependency if Atomix decides to abort.

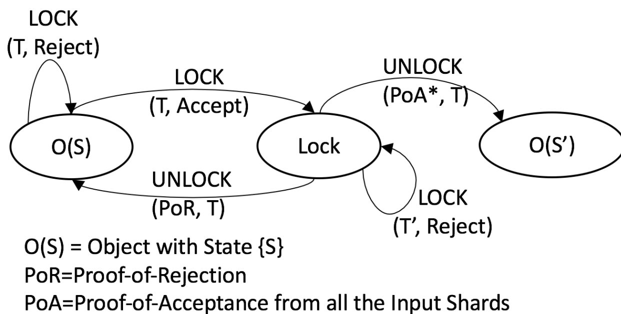

Fig. 16: State-Machine for state-full objects. Pessimistic locking is necessary

In Figure 16, we can see that an object will Lock for a specific transaction (T) and will reject any concurrent T', until T is committed and the new state S' is logged, or aborted and the old state S is open for change again.
