#### Abstract

In this paper, we study the generic hardness of the inversion problem on a ring, which is a problem to compute the inverse of a given prime $c$ by just using additions, subtractions and multiplications on the ring. If the characteristic of an underlying ring is public and coprime to $c$, then it is easy to compute the inverse of $c$ by using the extended Euclidean algorithm. On the other hand, if the characteristic is hidden, it seems difficult to compute it. For discussing the generic hardness of the inversion problem, we first extend existing generic ring models to capture a ring of an unknown characteristic. Then we prove that there is no generic algorithm to solve the inversion problem in our model when the underlying ring is isomorphic to $\mathbb{Z}_{p}$ for a randomly chosen prime $p$ assuming the hardness of factorization of an unbalanced modulus. We also study a relation between the inversion problem on a ring and a selfbilinear map. We give a ring-based construction of a self-bilinear map, and prove that natural complexity assumptions including the multilinear computational Diffie-Hellman (MCDH) assumption hold w.r.t the resulting sef-bilinear map if the inversion problem is hard on the underlying ring.

## 1 Introduction

### 1.1 Background

Cyclic groups on which the discrete logarithm (DL) is hard to solve have been widely used in cryptography. Though the hardness of the DL is a widely used assumption, we still do not know how to prove that there does not exist a polynomial time algorithm that solves the DL problem. On the other hand, for reliability of the assumption, we want to argue a lower bound for the DL problem in some sense. For this purpose, Shoup [Sho97] introduced an idealized model called the generic group model (GGM) building on an earlier works by Babai and Szemerédi [BS84] and Nechaev [Nec94]. In the GGM, group elements are
represented by a random string, and group operations are done only through oracle accesses. Intuitively, the GGM captures adversaries that do not depend on actual representations of group elements. Shoup proved that the DL problem and its related problems are hard to solve with polynomial number of group operations in the GGM.

Though Shoup's GGM can capture most DL-related problems, that does not capture the RSA problem [RSA78], which is another commonly used problem in cryptography. The RSA problem is the problem to compute $g^{1 / c}$ given $g \in \mathbb{Z}_{N}^{*}$ and a prime $c$ where $N=P Q$ is a product of two primes $P$ and $Q$. It is wellknown that the order of $\mathbb{Z}_{N}^{*}$ is hard to compute as long as one cannot factorize $N$. On the other hand, Shoup's GGM model assumes that an order of a group is public, and this is the reason why his model does not capture the RSA problem. To address the issue, Damgård and Koprowski [DK02] extended the GGM to capture unknown order groups. Intuitively, they proved that the RSA problem is hard to solve for generic algorithms if an entropy of an order of an underlying group is large enough. ${ }^{1}$

There is another extension of the GGM called the generic ring model (GRM) [LR06,AM09,JS09,AMS11]. The GRM is defined similarly to the GGM by simply replacing a group with a ring. The motivation of considering the GRM is more precise validation of the RSA and its related problems. Specifically, since $\mathbb{Z}_{N}$ is a ring, an adversary may utilize additions on $\mathbb{Z}_{N}$ in addition to multiplications. Thus GRM is supposed to capture $\mathbb{Z}_{N}$ as an underlying ring for an RSA modulus $N$. Here, we remark the characteristic $N$ of a ring $\mathbb{Z}_{N}$ is public and known by an adversary.

While these two types of extensions have been studied, almost no research has been done for the mix of them, i.e., the GRM in an unknown characteristic setting. ${ }^{2}$ We suppose that this is because currently we have no candidate of a ring whose ring operations can be done efficiently while keeping its characteristic hidden. On the other hand, Kim et al. [KKS15] observed that if such a ring exists, then we can construct a self-bilinear map [CL09,YYHK17], which is a bilinear map whose source and target groups are identical. As observed in some works [CL09,YYHK17], a self-bilinear map is quite a powerful primitive for constructing various cryptographic schemes. For example, a self-bilinear map gives an unbounded level multilinear map, which immediately gives an improvement for some multilinear-map-based cryptographic schemes such as multi-party non-interactive key exchange and broadcast encryption [BS02]. Considering the extreme usefulness of a self-bilinear map, even with the lack of an instantiation, it is still meaningful to study more on a ring of unknown characteristic since a candidate of such a ring may be found in the future.

[^0]In addition, though Kim et al. [KKS15] gave an idea to construct a selfbilinear map based on a ring of an unknown characteristic, they did not give any formal reduction between assumptions of a resulting self-bilinear map and an underlying ring. For further understanding ring-based construction of a selfbilinear map, it would be helpful to study their relations more.

### 1.2 Our Contribution

In this work, we consider the inversion problem on a ring $R$ that is isomorphic to $\mathbb{Z}_{p}$ where $p$ is a "hidden" prime. Namely, we assume that additions, subtractions and multiplications on $R$ can be done efficiently, and consider if the inverse of a prime $c$ is efficiently computable. If $p$ is public, then it is easy to compute $c^{-1} \bmod p$ by using the extended Euclidean algorithm. However, if $p$ is unknown, then we do not know how to compute $c^{-1} \bmod p$ and it seems difficult to compute it.

To give a generic lower bound for this problem, we extend the GRM to an unknown characteristic setting. Our model is defined almost similarly to an existing GRM except that the ring is chosen according to a certain distribution and its characteristic is hidden to an adversary. We prove that the inverse of a prime $c$ is hard to compute in our model when $p$ is randomly chosen from the set of all primes smaller than $2^{\ell}$ where $\ell=\Omega(\lambda)$ if the factoring of an unbalanced modulus is hard. Moreover, we give a partial evidence that the factoring assumption (or some assumption of similar nature) is needed for proving the generic hardness of the inversion by relating it to straight-line complexity of factorials.

Then we study a relation between an inversion-hard ring and a self-bilinear map. Based on the idea of Kim et al. [KKS15], we consider a ring-based construction of a self-bilinear map. We prove that if the $c$-inversion problem is hard on the underlying ring for some prime $c$ that is coprime to the characteristic of the ring, then the resulting self-bilinear map satisfies several natural complexity assumptions including the multilinear computational Diffie-Hellman (MCDH) assumption. By combining with the generic hardness result for the inversion problem, we can conclude that these natural complexity assumptions for selfbilinear maps hold against generic adversaries if the factoring of an unbalanced modulus is hard.

Finally, we show that some existing multilinear-map-based constructions gain some advantages if they are instantiated with an unbounded-level multilinear map obtained from a self-bilinear map by showing examples of the noninteractive key exchange (NIKE) and broadcast encryption schemes proposed by Boneh and Silverberg [BS02] and the homomorphic signatures proposed by Catalano et al. [CFW14]. We believe that self-bilinear maps have further applications.

### 1.3 Discussion

Candidate instantiation. In this paper, we prove that an inversion-hard ring gives a cryprographically useful self-bilinear map. On the other hand, we are
currently unaware of any ring with efficiently computable group operations that may satisfy the $c$-inversion assumption. Here, we discuss a heuristic candidate instantiation of an inversion-hard ring based on an obfuscation [BGI+ 01 ]. Intuitively, an obfuscation is to make a program "unintelligible" while keeping its functionality. Our idea is to consider an "encrypted ring" where all ring elements are encrypted and the program that computes ring operations over ciphertexts is obfuscated. Since all ring elements are encrypted, any algorithm cannot obtain any useful information from the representation of ring elements. Therefore the ring can be treated as if that is a "generic ring", and we can expect that the inversion assumption holds for this ring. Indeed, if we assume that an underlying obfuscation satisfies the virtual black-box (VBB) security [ $\mathrm{BGI}^{+} 01$ ], then the resulting scheme satisfies the inversion assumption as shown in Appendix A.

One may think that VBB obfuscation is a too strong assumption, and we can trivially obtain whatever we want based on that. However, we remark that the existence of an inversion-hard ring is not trivial even if we assume VBB obfuscation. What we can say based on VBB obfuscation is that an "encrypted ring" as described above is as secure as a "generic ring" where an adversary can perform ring operations only through operation oracles. Therefore if there exists a generic attack against the $c$-inversion problem, then the attack also works in the VBB obfuscation-based instantiation. Thus even if we assume VBB obfuscation, it is unclear if the above construction gives an inversion-hard ring without additionally assuming the factoring assumption.

Comparison to existing works on GRM. Here, we discuss the relation between our technique and ones used in works by Altmann et al. [AJR08] and Aggarwal and Maurer [AM09]. Their techniques are similar to ours in the sense that they also related generic hardness of some problems on a ring to factoring. Namely, Altmann et al. [AJR08] reduced the ring extraction problem to factoring, and Aggarwal and Maurer [AM09] reduced the RSA problem to factoring in their models. However, a significant difference of this work from theirs is that we consider a ring of an unknown prime characteristic $p$ whereas they consider a ring of a known composite characteristic $N$ whose factorization is unknown. It looks rather natural that the factoring assumption appears in their setting because they consider a ring of characteristic $N$, which is a composite number to factorize. On the other hand, in our model, we only consider a ring of a prime characteristic, and no composite number appears in the model. Thus we believe that the relation between the inversion problem in our model and factoring is quite surprising and interesting.

Future direction. An obvious open problem is a construction of an inversionhard ring, which implies a self-bilinear map, in the standard model. A possible approach is to use indistinguishability obfuscation (iO) instead of VBB obfuscation based on a similar idea to the works by Albrecht et al. $\left[\mathrm{AFH}^{+} 16\right]$ and Farshim et al. [FHHL18], which constructed multilinear maps and graded encodings based on iO. However, a simple adoption of their techniques would not work
since we at least need that the uniform factorial conjecture is true as discussed in Sec. 2.2, whereas iO along with some other assumptions like assumptions on known order groups seem not to imply that the uniform factorial conjecture is true. Thus, to construct an inversion-hard ring, it seems that we have to assume hardness of factoring or some assumption of similar nature in addition to iO , which would require new techniques.

### 1.4 Related Work

Groups of unknown order. In this paper, we consider a ring of an unknown characteristic. If we consider an additive group of a ring, then that is a group of unknown order, which have been studied well. For example, Hohenberger [Hoh03] introduced a notion of the pseudo-freeness as a useful property of an unknown order groups, which was subsequently studied more by Rivest [Riv04] and Micciancio [Mic10]. A typical example of an unknown order group is $\mathbb{Z}_{N}^{*}$ for an RSA modulus $N=p q$. If we consider a setting where the Diffie-Hellman oracle on $\mathbb{Z}_{N}^{*}$ (with a fixed generator $g \in \mathbb{Z}_{N}^{*}$ ) is available, then that can be seen as a ring of an unknown characteristic, and the inversion problem roughly corresponds to the RSA problem. We remark that in such a setting, the characteristic $\phi(N)$ of the ring is not prime, and our results cannot be directly applied to this setting, though we believe that our results also extend to this setting.
"Restricted" GRM in [KKS15]. Sec. 3.3 of Kim et al.'s work [KKS15] can be seen as analyses of certain assumptions in a restricted variant of the GRM of an unknown characteristic. Here the term "'restricted"' means that they restrict a degree of the computation on a ring. More specifically, on a ring $\mathbb{Z}_{p}$, they restrict the degree of allowed computations to be much smaller than $p$. This is essential in their analyses because they use the Schwartz-Zippel lemma to argue that for a function $f$ with $n$ variables of degree $d$, the probability that $f\left(x_{1}, \ldots, x_{n}\right)=0$ $\bmod p$ is negligible for randomly chosen $x_{1}, \ldots, x_{n} \in \mathbb{Z}_{p}$. If $d$ is larger than $p$, this argument completely does not work. Thus their result cannot be extended to the case where there is no restriction for computations on a ring.

Self-bilinear map. The first formal study of self-bilinear maps was done by Cheon and Lee [CL09]. They showed a strong negative result on the existence of a self-bilinear map of a known order. Namely, they showed that if there exists an efficiently computable self-bilinear map on a known order group, then the computational Diffie-Hellman (CDH) assumption does not hold on the group.

Yamakawa et al. [YYHK17] gave the first positive result on a self-bilinear map. They defined a weaker variant of a self-bilinear map which they call a selfbilinear map with auxiliary information. Then they constructed it based on the factoring assumption and the existence of iO. A self-bilinear map with auxiliary information is defined as a self-bilinear map that can be computed efficiently when some auxiliary information is given. Unfortunately, a self-bilinear map with auxiliary information is not as useful as an "ideal" self-bilinear map. For
example, that cannot be used for constructing fully homomorphic signatures as done in this work.

Kim et al. [KKS15] gave a candidate construction of a cryptographic selfbilinear map. However, it turns out that their construction is not secure [Seo17].

Multilinear map from obfuscation. There are some works that shows the relation between multilinear maps and iO. Paneth and Sahai [PS15] constructed a polynomial jigsaw puzzle, which is a variant of a multilinear map, solely based on iO. However, they did not provide any application of polynomial jigsaw puzzles except iO itself and thus it is unclear how that is useful in constructions of other cryptographic primitives.

Albrecht et al. $\left[\mathrm{AFH}^{+} 16\right]$ constructed a multilinear map based on iO. The construction was recently extended to a graded encoding scheme by Farshim et al. [FHHL18]. However, the levels of multilinearity in their constructions are bounded, and they did not give unbounded-level multilinear map based on iO.

## 2 Technical Overview

In this section, we give more detailed overview of our results.

### 2.1 Generic Ring with Unknown Characteristic

To formally discuss generic hardness of the inversion problem on rings of unknown characteristic (specifically, $\mathbb{Z}_{p}$ for a hidden prime $p$ ), we extend existing GRMs to treat such cases. Our model is formalized by using a stright-line program (SLP) similarly to the one in [JS09]. Especially, since we only consider the inversion problem on a ring $R$ in which an adversary is only given a multiplicative identity $[1]_{R}$ of the ring as an input, we formalize our model by using a no-input stright-line program (NI-SLP), which is a simpler variant of a SLP that do not take any input other than $[1]_{R}$.

No-input straight-line program. An NI-SLP with length $L$ is described by a sequence of instructions $\mathrm{P}=\left(i_{1}, j_{1}, \circ_{1}\right), \ldots,\left(i_{L}, j_{L}, \circ_{L}\right)$ where $i_{k}, j_{k} \in$ $\{0,1, \ldots, k-1\}$ and $o_{k} \in\{+,-, \cdot\}$ for all $k \in[L]$. On a ring $R$, a program P does the following recursive computation.

1. Let $x_{0}:=[1]_{R}$.
2. For $1 \leq k \leq L$, let $x_{k}:=x_{i_{k}} \circ_{k} x_{j_{k}}$.
3. Output $x_{L}$.

We denote the output of P on a ring $R$ by $\mathrm{P}(R)$. That is, an NI-SLP expresses a computation on a ring that consists of additions, subtractions and multiplications starting from the, multiplicative identity $[1]_{R}$. This is essentially the same as an arithmetic circuit with fixed input $[1]_{R}$. We use the notion of NI-SLP because this is suitable for stating our model.

Our generic ring model. Here, we explain our extended GRM that captures an unknown characteristic setting. Our model is similarly defined to the GRM given by Jager and Schwenk [JS09] except that we consider a certain distribution $\mathcal{D}_{R}$ of a ring instead of considering a fixed ring. To clarify the distribution explicitly, we often denote our model by $\mathcal{D}_{R}$-GRM. In the $\mathcal{D}_{R^{\prime}}$ GRM, a ring $R$ is chosen according to the distribution $\mathcal{D}_{R}$, whose description (especially, its characteristic) is not given to an adversary. Let NI-SLP P be an SLP that is initialized to be an empty sequence (which implicitly sets $x_{0}:=[1]_{R}$ ). Then a generic algorithm $\mathcal{A}$ in the model can make the following two types of queries: operation and equal queries.
operation query: When $\mathcal{A}$ makes an operation query $(i, j, \circ) \in\{0, \ldots,|\mathrm{P}|\} \times$
$\{0, \ldots,|\mathrm{P}|\} \times\{+,-, \cdot\}$, then $\mathcal{O}_{\text {ring }}$ append $(i, j, \circ)$ to P.
equal query: When $\mathcal{A}$ makes an equal query $(i, j) \in\{0, \ldots,|\mathrm{P}|\} \times\{0, \ldots,|\mathrm{P}|\}$, then $\mathcal{O}$ returns true if $\mathrm{P}_{i}(R)=\mathrm{P}_{j}(R)$ and false otherwise.
That is, $\mathcal{A}$ makes an operation query $(i, j, \circ)$ to compute $x_{i} \circ x_{j}$ and append the value to the sequence $x_{0}, \ldots, x_{|\mathrm{P}|}$ of ring elements, and it makes an equal query $(i, j)$ to check the equality of $x_{i}$ and $x_{j}$. Intuitively, this captures everything one can generically perform on a ring. Finally, $\mathcal{A}$ outputs an index $i^{*}$, which is interpreted to output $x_{i^{*}}$. In this model, for a prime $c$, we say that the $c$-inversion assumption holds, if for any PPT algorithm $\mathcal{A}$, the probability that $\mathcal{A}$ outputs $[c]_{R}^{-1}$ (i.e., $x_{i^{*}}=[c]_{R}^{-1}$ ) is negligible where $[c]_{R}$ denotes $c \cdot[1]_{R}$ and ${ }^{-1}$ denotes a multiplicative inverse.

### 2.2 Generic Hardness of Inversion

Here, we describe how we give a lower bound for the $c$-inversion problem on the $\mathcal{D}_{R}$-GRM in the case where $\mathcal{D}_{R}$ is $\mathbb{Z}_{p}$ for randomly chosen $\ell$-bit prime $p$. For obtaining the lower bound, we introduce two assumptions on NI-SLPs. Interestingly, both of these assumptions can be reduced to the factoring assumption w.r.t. unvalanced moduli, which is seemingly unrelevant to NI-SLPs. Finally, we give a partial evidence that the factoring assumption is necessary to prove the generic hardness of the $c$-inversion problem.

New assumptions on NI-SLP. Here, we describe our new assumptions on NI-SLPs, which we call the SLP assumption 1 and 2, respectively. We prove that they hold under the factoring assumption w.r.t. unbalanced moduli. These assumptions are defined as follows, where $\mathcal{P}_{\ell}$ denotes the set of all primes smaller than $2^{\ell}$.
SLP assumption 1: We say that the SLP assumption 1 holds if for any PPT algorithm $\mathcal{A}, \operatorname{Adv}_{\mathcal{A}}^{\operatorname{SLP}-1}(\lambda):=\operatorname{Pr}\left[\mathrm{P} \leftarrow \mathcal{A}\left(1^{\lambda}\right), p \stackrel{\oiint}{\leftarrow} \mathcal{P}_{\lambda} ; \mathrm{P}(\mathbb{Z}) \neq 0 \wedge \mathrm{P}\left(\mathbb{Z}_{p}\right)=0\right]$ is negligible.
SLP assumption 2: We say that the SLP assumption 2 holds if for any PPT algorithm $\mathcal{A}, \operatorname{Adv}_{\mathcal{A}}^{\mathrm{SLP}-2}(\lambda):=\operatorname{Pr}\left[\mathrm{P} \leftarrow \mathcal{A}\left(1^{\lambda}\right), p_{1}, p_{2} \stackrel{\&}{\leftarrow} \mathcal{P}_{\lambda} ;\left(\mathrm{P}\left(\mathbb{Z}_{p_{1}}\right) \stackrel{?}{=} 0\right) \neq\right.$ $\left.\left(\mathrm{P}\left(\mathbb{Z}_{p_{2}}\right) \stackrel{?}{=} 0\right)\right]$ is negligible.

Intuitively, the SLP assumption 1 claims that for any efficiently generated NISLP P , if $\mathrm{P}(\mathbb{Z}) \neq 0$, then we also have $\mathrm{P}\left(\mathbb{Z}_{p}\right) \neq 0$ with overwhelming probability when $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$ where $\mathcal{P}_{\ell}$ denotes the set of all primes smaller than $2^{\ell}$, and the SLP assumption 2 claims that for any efficiently generated NI-SLP P, we have $\left(\mathrm{P}\left(\mathbb{Z}_{p_{1}}\right) \stackrel{?}{=} 0\right)=\left(\mathrm{P}\left(\mathbb{Z}_{p_{2}}\right) \stackrel{?}{=} 0\right)$ with overwhelming probability where $p_{1}, p_{2} \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$ and $\left(\mathrm{P}\left(\mathbb{Z}_{p_{i}}\right) \stackrel{?}{=} 0\right)$ is a variable in $\{0,1\}$ that is 1 if and only if $\mathrm{P}\left(\mathbb{Z}_{p_{i}}\right)=0$ holds for $i=1,2$.

First, it is easy to see that the SLP assumption 2 is implied by the SLP assumption 1 because $\mathrm{P}\left(\mathbb{Z}_{p_{1}}\right) \neq 0$ or $\mathrm{P}\left(\mathbb{Z}_{p_{2}}\right) \neq 0$ implies $\mathrm{P}(\mathbb{Z}) \neq 0$. Moreover, we prove that the SLP assumption 1 holds assuming the hardness of factorizing an unbalanced modulus, i.e., $N=p q$ for primes $p$ and $q$ such that $q$ is much larger than $p$. The proof outline is as follows. Suppose that there exists an adversary $\mathcal{A}$ that breaks the SLP assumption 1. Based on $\mathcal{A}$, we construct an algorithm $\mathcal{B}$ that factorizes an unbalanced modulus $N$ as follows. $\mathcal{B}$, given $N=p q$, runs $\mathcal{A}\left(1^{\lambda}\right)$ to obtain P . Since $\mathcal{A}$ breaks the SLP assumption 1 , the probability that $\mathrm{P}(\mathbb{Z}) \neq 0$ and $\mathrm{P}\left(\mathbb{Z}_{p}\right)=0$ hold is non-negligible. We can show that if $q$ is chosen from a large enough set of primes, then $\mathrm{P}(\mathbb{Z}) \neq 0$ implies $\mathrm{P}\left(\mathbb{Z}_{q}\right) \neq 0$ with overwhelming probability. (See Lemma 2 for details.) In this case, we have $\operatorname{gcd}\left(\mathrm{P}\left(\mathbb{Z}_{N}\right), N\right)=p$ since $\mathrm{P}\left(\mathbb{Z}_{p}\right)=0$ implies $p \mid \mathrm{P}\left(\mathbb{Z}_{N}\right)$ and $\mathrm{P}\left(\mathbb{Z}_{q}\right) \neq 0$ implies $q \backslash \mathrm{P}\left(\mathbb{Z}_{N}\right)$. Thus $\mathcal{B}$ can factorize $N$ by computing $\operatorname{gcd}\left(\mathrm{P}\left(\mathbb{Z}_{N}\right), N\right)$.

Generic hardness of inversion. Our main result can be stated as follows.
Theorem 1 Let $\mathcal{D}_{R}$ be the distribution of $\mathbb{Z}_{p}$ for a randomly chosen prime $p$ from $\mathcal{P}_{\ell}$. If the $S L P$ assumptions 1 holds, then the c-inversion assumption holds in the $\mathcal{D}_{R}-G R M$. Especially, if the factoring assumption w.r.t. unbalanced moduli holds, then the c-inversion assumption holds in the $\mathcal{D}_{R}-G R M$.

In the following we give a proof sketch for the theorem. We consdier the following game hops.

Game 1: This game is the original game that defines the $c$-inversion assumption. At the beginning of the game, a prime $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$ is chosen and P is initialized to be an empty sequence. When $\mathcal{A}$ makes an operation query $(i, j, \circ)$, then $(i, j, \circ)$ is appended to P . When $\mathcal{A}$ makes an equal query $(i, j)$, then the oracle returns true if $\mathrm{P}_{i}\left(\mathbb{Z}_{p}\right)=\mathrm{P}_{j}\left(\mathbb{Z}_{p}\right)$ and false otherwise. When $\mathcal{A}$ outputs $i^{*}$, we say that $\mathcal{A}$ wins if $\mathrm{P}_{i^{*}}\left(\mathbb{Z}_{p}\right)=[c]_{\mathbb{Z}_{p}}^{-1}$ holds.
Game 2: This game is the same as the above game except that the equality oracle uses a independently random prime $p_{k}$ instead of $p$ for the $k$-th equal query for each $k$. That is, when $\mathcal{A}$ makes the $k$-th equal query $(i, j)$, the oracle picks an independently random prime $p_{k} \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$ and returns true if $\mathrm{P}_{i}\left(\mathbb{Z}_{p_{k}}\right)=\mathrm{P}_{j}\left(\mathbb{Z}_{p_{k}}\right)$ and false otherwise. We note that the winning condition of $\mathcal{A}$ remains unchanged, and it is decided by using $p$.

What we want to prove is that the $\mathcal{A}$ 's winning probability in Game 1 is negligible. First, we bound the difference between its winning probabilities in Game 1 and Game 2 is negligible. In Game 2, responses by the oracle do not differ from
the original game unless we have $\left(\mathrm{P}\left(\mathbb{Z}_{p_{1}}\right) \stackrel{?}{=} 0\right) \neq\left(\mathrm{P}\left(\mathbb{Z}_{p_{2}}\right) \stackrel{?}{=} 0\right)$. The probability that such an event occurs is negligible under the SLP assumption 2, which can be reduced to the SLP assumption 1 as mentioned in the previous paragraph. Thus this modification causes a negligible difference on $\mathcal{A}$ 's winning probability. Next, we move on to proving $\mathcal{A}$ 's winning probability in Game 2 is negligible. In Game 2, a prime $p$ is not used at all except for deciding if $\mathcal{A}$ wins the game (i.e., $\mathrm{P}_{i^{*}}\left(\mathbb{Z}_{p}\right)=[c]_{R}^{-1}$ ). If we let $\mathrm{P}^{\prime}:=c \cdot \mathrm{P}_{i^{*}}-1$ where $c \cdot \mathrm{P}_{i^{*}}-1$ denotes the NI-SLP that computes $c \cdot \mathrm{P}_{i^{*}}(R)-[1]_{R}$ on any ring $R$, then the winning condition is equivalent to $\mathrm{P}^{\prime}\left(\mathbb{Z}_{p}\right)=0$. Here, it is easy to see that $\mathrm{P}^{\prime}(\mathbb{Z}) \neq 0$ holds since 1 is not a multiple of $c$. Therefore under the SLP assumption $1, \mathcal{A}$ 's winning probability (i.e., $\operatorname{Pr}\left[\mathrm{P}^{\prime}\left(\mathbb{Z}_{p}\right)=0\right]$ ) is negligible. Thus, the $c$-inversion assumption holds in the $\mathcal{D}_{R}$-GRM. Finally, since the SLP assumptions 1 and 2 hold under the factoring assumption w.r.t. unbalanced moduli as mentioned in the previous paragraph, the generic hardness of the $c$-inversion problem is proven under the same assumption.

Is factoring assumption necessary? For proving the generic hardness of the $c$-inversion assumption, we assumed the factoring assumption (or the SLP assumption 1 , which is implied by the factoring assumption). One may wonder if this can be done without assuming any unproven assumption. We give a partial evidence that the factoring assumption (or some assumption of similar nature) is necessary. Specifically, we relate the hardness of the problem to the straight-line complexity [SS95] of factorials. For an integer $N$, the straight-line complexity $\tau(N)$ of $N$ is defined as the minimum length of a NI-SLP P such that $\mathrm{P}(\mathbb{Z})=$ $N$. That is, the straight-line complexity is the smallest number of additions or multiplications to compute $N$ starting from 1 . Though it is conjectured that $\tau(n!)$ is super polynomial in $\log (n)$ [SS95,Che04,Mar13], that has been open for a long time. Here, we consider the uniform version of this conjecture.
Uniform Factorial Conjecture. There does not exist a PPT algorithm $\mathcal{A}$ that is given $n$ as input and outputs an NI-SLP $\mathrm{P}^{n}$ such that $\mathrm{P}^{n}(\mathbb{Z})=n$ ! for all $n \in \mathbb{N}$.

Though this conjecture is plausible, it still seems difficult to prove that this conjecture is true since this is just a uniform variant of the above mentioned long standing open problem. If the uniform factorial conjecture is false, then we can compute the characteristic $\operatorname{char}(R)$ of any ring $R$ as long as $\operatorname{char}(R)$ is a prime by a simple binary search algorithm (See 5.4 for the detail). If char $(R)$ is known, then the $c$-inversion assumption is trivially broken by the extended Eucledian algorithm. Therefore to prove the generic hardness of the $c$-inversion problem or even ensuring that hardness of computing a characteristic of a ring of a prime characteristic, we have to assume at least that the uniforml factorial conjecture is true, which seems difficult to unconditionally prove.

It has been widely recognized that there is a close relationship between the complexity of computing factorials and interger factorization (e.g., [Sha79,Che04]). Indeed, the uniform factorial conjecture can be easily proven true under the factoring assumption by a binary search algorithm similar to the one described
above. On the other hand, we are unaware of any other standard assumption that would imply the uniform factorial conjecture. For example, even if we assume the existence of iO , it is not clear if the uniform factorial conjecture is true or not. Thus, if we want to reduce the generic hardness of the $c$-inversion problem to a standard assumption, it is somehow unavoidable to assume the factoring assumption (unless we find any other standard assumption that implies the uniform factorial conjecture).

### 2.3 Self-Bilinear Map from Inversion-Hard Ring

Here, we explain how to obtain a self-bilinear map based on an inversion-hard ring. Conceptually, the idea is quite simple: we consider the multiplication on the underlying ring to be a self-bilinear map. Actually, this idea was already presented by Kim et al. [KKS15], but they did not give a specific condition for a ring so that natural complexity assumptions for a resulting self-bilinear map hold. In this paper, we prove that the hardness of $c$-inversion problem for a prime $c$ is sufficient to obtain useful assumptions for a resulting self-bilinear map. Specifically, we prove that several complexity assumptions for self-bilinear maps including the MCDH assumption hold if the $c$-inversion problem for some prime $c$ is hard on an underlying ring. The proof is based on the very similar idea to classical results that reduce the CDH assumption to the factoring assumption [Shm85,McC88] and its extensions [HK09,Seu13,YYHK17]. We give a rough sketch of our construction and proof below.

We first describe the construction of a group $G$ with a self-bilinear map $e$ based on a ring $R$ and prepare some notations. We let a group $G$ be an additive subgroup of $R$ generated by $[1]_{R}$ and set the generator $[1]_{G}$ to be $[c]_{R}$. Then we define $e$ by $e(X, Y):=X \cdot Y$ where $\cdot$ denotes the multiplication on $R$. For an integer $n \geq 2$, we let $e_{n}$ denote a $n$-multilinear map obtained from a self-bilinear map $e$. Namely, $e_{n}$ is defined by $e_{2}:=e$ and $e_{k}\left(X_{1}, \ldots, X_{k}\right):=$ $e\left(e_{k-1}\left(X_{1}, \ldots, X_{k-1}\right), X_{k}\right)$ for $k \geq 3$. For $x \in \mathbb{Z}$, we let $[x]_{G}:=x \cdot[1]_{G}$ and for $x \in \mathbb{Z}$ and $k \in \mathbb{N},[x]_{k}$ denotes $x \cdot e_{k}\left([1]_{G}, \ldots,[1]_{G}\right)$. (If $k=1$, then $[x]_{1}$ denotes $[x]_{G}$.) By using this notation, we have $e\left([x]_{G},[y]_{G}\right)=[c x y]_{G},[x]_{k}=\left[c^{k} x\right]_{R}$, $[x]_{k}+[y]_{k}=[x+y]_{k}$ and $e\left([x]_{k_{1}},[x]_{k_{2}}\right)=[x \cdot y]_{k_{1}+k_{2}}$ for any $x, y \in \mathbb{Z}$ and $k, k_{1}, k_{2} \in \mathbb{N}$.

For $n \in \mathbb{N}$, we say that the $n$-MCDH assumption holds if any PPT adversary given $\left[x_{1}\right]_{1}, \ldots,\left[x_{n+1}\right]_{1}$ cannot compute $\left[\prod_{i=1}^{n+1} x_{i}\right]_{n}$ with non-negligible probability where $x_{1}, \ldots, x_{n+1} \stackrel{\&}{\leftarrow}\left[2^{\ell+\lambda}\right]$ and $2^{\ell}$ is an upper bound of $\operatorname{ord}(G)^{3}$. Then we prove the following theorem.

Theorem 2 If the c-inversion assumption holds for the underlying ring $R$, then for any integer $n \geq 2$, the $n-M C D H$ assumption holds for $(G, e)$.

[^1]In this overview, we give a proof sketch for the case of $n=2$ since the basic idea is the same for the general case. Suppose that there exists a PPT algorithm $\mathcal{A}$ that breaks the $2-\mathrm{MCDH}$ assumption. Then we construct a PPT algorithm $\mathcal{B}$ that solves the $c$-inversion assumption. $\mathcal{B}$ is given $[1]_{R}$ and its goal is to compute $[c]_{R}^{-1} . \mathcal{B}$ sets $[1]_{G}:=[c]_{R}$, picks $x_{i}^{\prime} \stackrel{\Phi}{\leftarrow}\left[2^{\ell+\lambda}\right]$ and sets $[x]_{G}:=\left[c x_{i}^{\prime}+1\right]$ for $i=1,2,3$ where $\ell$ is an integer such that $\operatorname{ord}(G)<2^{\ell}$. This implicitly defines $x_{i}=x_{i}^{\prime}+c^{-1}$ $\bmod \operatorname{ord}(G)$ for $i=1,2,3$. Since $\left(x_{i}^{\prime} \bmod \operatorname{ord}(G)\right)$ is distributed almost uniformly and we have $\operatorname{gcd}(c, \operatorname{ord}(G))=1,\left(x_{i}^{\prime} \bmod \operatorname{ord}(G)\right)$ is also almost uniformly distributed for $i=1,2,3$. Thus if $\mathcal{B}$ gives $\left([1]_{G},\left[x_{1}\right]_{G},\left[x_{2}\right]_{G},\left[x_{3}\right]_{G}\right)$ generated as above to $\mathcal{A}$ as input, then $\mathcal{A}$ outputs $T=\left[x_{1} x_{2} x_{3}\right]_{2}$ with non-negligible probability. Here, we have $T=\left[x_{1} x_{2} x_{3}\right]_{2}=\left[c^{2}\left(x_{1}^{\prime}+c^{-1}\right)\left(x_{2}^{\prime}+c^{-1}\right)\left(x_{3}^{\prime}+c^{-1}\right)\right]_{R}=$ $\left[c^{2} x_{1}^{\prime} x_{2}^{\prime} x_{3}^{\prime}+c\left(x_{1}^{\prime} x_{2}^{\prime}+x_{2}^{\prime} x_{3}^{\prime}+x_{3}^{\prime} x_{1}^{\prime}\right)+\left(x_{1}^{\prime}+x_{2}^{\prime}+x_{3}^{\prime}\right)+c^{-1}\right]_{R}$. Therefore if $\mathcal{B}$ subtracts $\left[c^{2} x_{1}^{\prime} x_{2}^{\prime} x_{3}^{\prime}+c\left(x_{1}^{\prime} x_{2}^{\prime}+x_{2}^{\prime} x_{3}^{\prime}+x_{3}^{\prime} x_{1}^{\prime}\right)+\left(x_{1}^{\prime}+x_{2}^{\prime}+x_{3}^{\prime}\right)\right]_{R}$ from $T$, then it obtains $\left[c^{-1}\right]_{R}$ and succeeds in solving the $c$-inversion problem. Thus the $2-\mathrm{MCDH}$ assumption holds under the $c$-inversion assumption. In Sec. 6 we show that we can apply the similar technique for more general assumptions.

### 2.4 Applications of Self-Bilinear Maps

Here, we give some applications of self-bilinear maps. As already observed in previous works [CL09,YYHK17], self-bilinear maps imply multilinear maps (or more generally, graded encodings [GGH13]) with unbounded multilinearity. By this feature, if we instantiate existing multi-linear map-based scheme by using self-bilinear maps, then the resulting scheme gains certain advantages. Here we give example of multiparty non-interactive key exchange (NIKE), broadcast encryption, and homomorphic signatures. We believe that self-bilinear maps have further applications.

Multiparty NIKE and broadcast encryption. Boneh and Silverberg [BS02] gave constructions of non-interactive key exchange (NIKE) and broadcast encryption schemes based on a multilinear map. If we instantiate these schemes by self-bilinear maps, the resulting schemes gain the following two advantages. First, we need not bound the maximum number of users at the setup phase. Second, the public key size of each user does not depend on the number of users.

Homomorphic signatures. Here, we give a construction of homomorphic signatures based on a self-bilinear map. Our construction is based on the scheme proposed by Catalano et al. [CFW14] based on a multilinear map. Their scheme supports any polynomial of degree $p(\lambda)$ for a priori fixed polynomial $p$, and the security is proven under the $2 p(\lambda)$-APMDH assumption. Our idea is to replace a multilinear map with a self-bilinear map. The reason the scheme in [CFW14] only supports polynomials of bounded polynomial degree is that existing multilinear maps only have a polynomially bounded level of multilinearity. On the other hand, a self-bilinear map gives an exponentially unbounded level multilinear map. Therefore if we instantiate the scheme in [CFW14] with such a multilinear map, the resulting scheme supports polynomials of exponentially unbounded
degree, which is equivalent to polynomial size circuits of unbounded depth. As a result, we obtain fully homomorphic signatures that supports all polynomial size circuits of unbounded depth based on a self-bilinear map. We prove that our scheme is selectively secure under the $\ell$-APMDH assumption for all $\ell$ such that $\log (\ell)=\operatorname{poly}(\lambda)$. Since we give a candidate construction of a self-bilinear map that satisfies the above assumption in Sec. 6, we can instantiate our scheme with our self-bilinear map. To the best of our knowledge, this is the first construction of a fully homomorphic signatures for unbounded depth circuits without relying on succinct non-interactive argument of knowledge SNARK [BCCT12].

## 3 Preliminaries

### 3.1 Notations

For any natural number $n,[n]$ denotes the set $\{1, \ldots, n\} . x \stackrel{\$}{\leftarrow} S$ denotes $x$ is randomly chosen from a finite set $S$, and $x \stackrel{8}{\leftarrow} \mathcal{A}(y)$ denotes that $x$ is an output of a randomized algorithm $\mathcal{A}$ with input $y$. We say that a function $f(\cdot): \mathbb{N} \rightarrow[0,1]$ is negligible if for all positive polynomials $p(\cdot)$ and all sufficiently large $\lambda \in \mathbb{N}$, we have $f(\lambda)<1 / p(\lambda)$. We say that an algorithm $\mathcal{A}$ is probabilistic polynomial time (PPT) if there exists a polynomial $p$ such that a running time of $\mathcal{A}$ with input length $\lambda$ is less than $p(\lambda)$. We often use poly to denote an unspecified polynomial. For a polynomial $p, \operatorname{deg}(p)$ denotes the degree of $p . \mathcal{P}_{\ell}$ denotes the set of all primes smaller than $2^{\ell}$. For a ring $R,[1]_{R}$ denotes its multiplicative identity, for any integer $n,[n]_{R}$ denotes $n \cdot[1]_{R}$, and $\operatorname{char}(R)$ denotes the characteristic of $R$, i.e., the smallest positive integer $n$ such that $[n]_{R}=[0]_{R}$. We often denote $[0]_{R}$ by 0 . Similarly, for an additive cyclic group $G$ with a generator $[1]_{G}$, for any integer $n,[n]_{G}$ denotes $n \cdot[1]_{G}$, and ord $(G)$ denotes the order of $G$, i.e., the smallest positive integer $n$ such that $[n]_{G}=0$. We often denote $[0]_{G}$ by 0 . We note that this bracket notation for $G$ depends on the value of $[1]_{G}$, and thus it is well-defined only when $[1]_{G}$ is fixed.

### 3.2 Factoring Assumption

Here we define the factoring assumption. In this paper, unlike common style of the factoring assumption in cryptography, we assume the hardness of the factoring w.r.t. unbalanced moduli, which is written as $N=p q$ for primes $p$ and $q$ such that $p$ is much smaller than $q$. We note that the similar assumption was used in [Lip94]. The formal definition of our assumption is as follows.

Definition 1 We say that the factoring assumption w.r.t. unbalanced moduli holds if for any PPT algorithm $\mathcal{A}$ and any polynomial poly,

$$
\operatorname{Pr}\left[p \stackrel{\&}{\leftarrow} \mathcal{P}_{\lambda}, q \stackrel{\&}{\leftarrow} \mathcal{P}_{\text {poly }(\lambda)} ; p \leftarrow \mathcal{A}(\lambda, p q)\right]
$$

is negligible.

The best known factoring algorithm for RSA moduli of the form $N=p q$ where $p$ is much smaller than $q$ is the elliptic curve method [Len87], which works in sub-exponential time in $\log p \approx \lambda$. Therefore the above assumption is plausible.

### 3.3 Self-bilinear Map

Here, we define a self-bilinear map. We note that we use the additive notation rather than the multiplicative notation as in [CL09] for compatibility with a ring. Looking ahead, we construct a group with a self-bilinear map based on a ring and the group operation of the group is defined as the addition of the underlying ring.

Definition 2 (Self-bilinear Map [CLO9]) For a cyclic additive group $G$, a selfbilinear map e : $G \times G \rightarrow G$ has the following properties.

- For all $X, Y \in G$ and $\alpha \in \mathbb{Z}$, it holds that

$$
e(\alpha \cdot X, Y)=e(X, \alpha \cdot Y)=\alpha \cdot e(X, Y)
$$

- The map e is non-degenerate, i.e, if $X, Y \in G$ are generators of $G$, then $e(X, Y)$ is also a generator of $G$.
A self bilinear map naturally extends to an $n$-multilinear map for any integer $n \geq 2$. This is done in the following recursive way: suppose that an $n$-multilinear map $e_{n}$ can be constructed from a self-bilinear map $e$, then we can construct an $(n+1)$-multilinear map $e_{n+1}$ by defining

$$
e_{n+1}\left(X_{1}, \ldots, X_{n}, X_{n+1}\right):=e\left(e_{n}\left(X_{1}, \ldots, X_{n}\right), X_{n+1}\right)
$$

We note that for any $X \in G$ and $n \in \mathbb{Z}, e_{n}(X, \ldots, X)$ can be computed by $O(\log (n))$ times evaluations of $e$ in the similar way to the square-and-multiply algorithm for exponentiations. Especially, even if $n=2^{\text {poly }(\lambda)}, e_{n}(X, \ldots, X)$ can be computed in polynomial time in $\lambda$ as long as $e$ is computable in polynomial time in $\lambda$. Let $[1]_{G}$ be a generator of $G$. For $x \in \mathbb{Z}$ and $k \in \mathbb{N},[x]_{k}$ denotes $x \cdot e_{k}\left([1]_{G}, \ldots,[1]_{G}\right)$. (If $k=1$, then $[x]_{1}$ denotes $[x]_{G}=x \cdot[1]_{G}$.) By using this notation, for any $x, y \in \mathbb{Z}$ and $k, k_{1}, k_{2} \in \mathbb{N}$, we have

$$
[x]_{k}+[y]_{k}=[x+y]_{k}
$$

and

$$
e\left([x]_{k_{1}},[y]_{k_{2}}\right)=[x \cdot y]_{k_{1}+k_{2}} .
$$

In this way, a self-bilinear map can be seen as a graded encoding system [GGH13] with unique encodings and unbounded levels. We note that values in a bracket can be reduced modulo ord $(G)$, i.e., for any $x \in \mathbb{Z}$ and $k \in \mathbb{N}$, we have $[x]_{k}=[x$ $\bmod \operatorname{ord}(G)]_{k}$. We remark that this bracket notation depends on a generator $[1]_{G}$. Therefore when we consider a self-bilinear map on a group, we always clarify which element is set to be $[1]_{G}$ as a part of public parameters. In the above way, a self-bilinear map can be seen as a graded encoding system [GGH13] with unique encodings and exponentially unbounded levels.

## 4 Straight-line Program

Here, we define a straight-line program (SLP) which is a computation model over ring. Actually, we define a simplified variant of an SLP which we call a no-input SLP (NI-SLP). We define two complexity assumptions about NI-SLPs. We prove that these assumptions hold under the factoring assumption.

### 4.1 Definition

Here, we define an NI-SLP. An NI-SLP is defined as a usual SLP except that no ring element is given to a program as input. Actually, for an NI-SLP, a ring on which the computation is done itself is considered to be an "input" of the program. The following definition of an NI-SLP is the same as the definition of an SLP in [Bro16] except that no ring element is given to the program as input.

Definition 3 (straight-line program with no-input) A no-input straight-line program (NI-SLP) P of length $L$ is written as a sequence of instructions $\mathrm{P}=$ $\left(i_{1}, j_{1}, \circ_{1}\right), \ldots,\left(i_{L}, j_{L}, \circ_{L}\right)$ where $i_{k}, j_{k} \in\{0,1, \ldots, k-1\}$ and $\circ_{k} \in\{+,-, \cdot\}$ for all $k \in[L]$. On a ring $R$, P computes as follows.

1. Let $x_{0}:=[1]_{R}$.
2. For $1 \leq k \leq L$, let $x_{k}:=x_{i_{k}} \circ_{k} x_{j_{k}}$.
3. Output $x_{L}$.

We denote the output of P on a ring $R$ by $\mathrm{P}(R)$.
Notations. For an NI-SLP P, $|\mathrm{P}|$ denotes the length of P , and $\mathrm{P}_{k}$ denotes the NI-SLP given by the sequence of the first $k$ instructions of P . For any NI-SLPs $\mathrm{P}^{1}, \mathrm{P}^{2}$ and $\circ \in\{+,-, \cdot\}, \mathrm{P}^{1} \circ \mathrm{P}^{2}$ denotes an NI-SLP that computes $\mathrm{P}^{1}(R) \circ \mathrm{P}^{2}(R)$ over any ring $R$. For any NI-SLP P and an integer $z \in \mathbb{Z}, z \cdot \mathrm{P}$ denotes an NI-SLP that computes $[z]_{R} \circ \mathrm{P}(R)$ for any ring $R$. It is easy to see that we can define them so that we have $\left|\mathrm{P}^{1} \circ \mathrm{P}^{2}\right|=\left|\mathrm{P}^{1}\right|+\left|\mathrm{P}^{2}\right|+1$ and $|z \cdot \mathrm{P}| \leq 2 \log (z)+|\mathrm{P}|$ for any NI-SLPs $\mathrm{P}^{1}, \mathrm{P}^{2}, \mathrm{P}$ and integer $z$.

### 4.2 Complexity Assumptions

Here, we define complexity assumptions about an NI-SLP, which is used in the proof of our result in Sec. 5. Then we prove that these assumptions hold under the factoring assumption w.r.t. unbalanced moduli.

Intuitively, the first assumption claims that for any efficiently generated NISLP P , if $\mathrm{P}(\mathbb{Z}) \neq 0$, then $\mathrm{P}\left(\mathbb{Z}_{p}\right) \neq 0$ also holds with overwhelming probability when $p$ is uniformly chosen from $\mathcal{P}_{\lambda}$.

Definition 4 We say that the SLP assumption 1 holds if for any PPT algorithm

The second assumption claims that for any efficiently generated NI-SLP P, we have $\left(P\left(\mathbb{Z}_{p_{1}}\right) \stackrel{?}{=} 0\right)=\left(P\left(\mathbb{Z}_{p_{2}}\right) \stackrel{?}{=} 0\right)$ with overwhelming probability where $p_{1}$ and $p_{2}$ are uniformly chosen from $\mathcal{P}_{\lambda}$.

Definition 5 We say that the SLP assumption 2 holds if for any PPT algorithm $\mathcal{A}, \operatorname{Adv}_{\mathcal{A}}^{\operatorname{SLP-2}}(\lambda):=\operatorname{Pr}\left[\mathrm{P} \leftarrow \mathcal{A}\left(1^{\lambda}\right), p_{1}, p_{2} \stackrel{\&}{\leftarrow} \mathcal{P}_{\lambda} ;\left(\mathrm{P}\left(\mathbb{Z}_{p_{1}}\right) \stackrel{?}{=} 0\right) \neq\left(\mathrm{P}\left(\mathbb{Z}_{p_{2}}\right) \stackrel{?}{=} 0\right)\right]$ is negligible.

We prove that the above assumptions hold under the factoring assumption w.r.t. unbalanced moduli.

Theorem 3 If the factoring assumption w.r.t. unbalanced moduli holds, then the SLP assumption 1 and 2 hold.

Before proving the above theorem, we prepare some lemmas.
Lemma 1 For any NI-SLP P of length L, we have $|\mathrm{P}(\mathbb{Z})| \leq 2^{2^{L-1}}$.
Proof. We prove the lemma by the induction. When $L=1$ clearly we have $\mathrm{P}(\mathbb{Z}) \leq 2$. (The equation holds when $\mathrm{P}=(1,1,+)$.) We assume that $|\mathrm{P}(\mathbb{Z})| \leq$ $2^{2^{L-1}}$ holds for all NI-SLP P of length smaller than $L$. Suppose that P is written as $\mathrm{P}=\left(i_{1}, j_{1}, \circ_{1}\right), \ldots,\left(i_{L+1}, j_{L+1}, \circ_{L+1}\right)$. Then we let $\mathrm{P}_{1}=\left(i_{1}, j_{1}, \circ_{1}\right), \ldots,\left(i_{i_{L+1}}, j_{i_{L+1}}, \circ_{i_{L+1}}\right)$ and $\mathrm{P}_{2}=\left(i_{1}, j_{1}, \circ_{1}\right), \ldots,\left(i_{j_{L+1}}, j_{j_{L+1}}, \circ_{j_{L+1}}\right)$. Then clearly we have $\mathrm{P}(\mathbb{Z})=$ $\mathrm{P}_{1}(\mathbb{Z}) \circ_{L+1} \mathrm{P}_{2}(\mathbb{Z})$. By the assumption, we have $\left|\mathrm{P}_{i}(\mathbb{Z})\right| \leq 2^{2^{L-1}}$ for $i=1,2$. Therefore we have $|\mathrm{P}(\mathbb{Z})|=\left|\mathrm{P}_{1}(\mathbb{Z})\right| \circ_{L+1}\left|\mathrm{P}_{2}(\mathbb{Z})\right| \leq 2^{2^{L-1}} \circ_{L+1} 2^{2^{L-1}} \leq 2^{2^{L}}$. Therefore the lemma also holds for an NI-SLP with length $L+1$ and thus the lemma is proven.

Lemma 2 For any NI-SLP P of length $L$, $\operatorname{Pr}\left[q \stackrel{\&}{\leftarrow} \mathcal{P}_{2 L} ; \mathrm{P}(\mathbb{Z}) \neq 0 \wedge \mathrm{P}\left(\mathbb{Z}_{q}\right)=0\right]$ is negligible in $L$.
Proof. By Lemma 1, we have $\mathrm{P}(\mathbb{Z}) \leq 2^{2^{L-1}}$. Therefore the number of primes that divides $\mathrm{P}(\mathbb{Z})$ is at most $2^{L-1}$. On the other hand, by the prime number theorem, the number of primes smaller than $2^{2 L}$ is $\Omega\left(2^{2 L} / L\right)$. Therefore when $q$ is uniformly chosen from primes smaller than $2^{2 L}$, the probability that $q$ divides $\mathrm{P}(\mathbb{Z})$ is $O\left(L / 2^{L}\right)$, which is negligible. Clearly, $q \mid \mathrm{P}(\mathbb{Z})$ and $\mathrm{P}\left(\mathbb{Z}_{q}\right)=0$ are equivalent, and thus the probability that $\mathrm{P}\left(\mathbb{Z}_{q}\right)=0$ holds is negligible.

Lemma 3 If the SLP assumption 1 holds, then the SLP assumption 2 holds.
Proof. Let $\mathcal{A}$ be any algorithm. Then we have

$$
\begin{aligned}
& \operatorname{Adv}_{\mathcal{A}}{ }^{\mathrm{SLP}-2}(\lambda) \\
& =\operatorname{Pr}\left[\mathrm{P} \leftarrow \mathcal{A}\left(1^{\lambda}\right), p_{1}, p_{2} \stackrel{\&}{\leftarrow} \mathcal{P}_{\lambda} ;\left(\mathrm{P}\left(\mathbb{Z}_{p_{1}}\right) \stackrel{?}{=} 0\right) \neq\left(\mathrm{P}\left(\mathbb{Z}_{p_{2}}\right) \stackrel{?}{=} 0\right)\right] \\
& =\operatorname{Pr}\left[\mathrm{P} \leftarrow \mathcal{A}\left(1^{\lambda}\right), p_{1}, p_{2} \stackrel{\oplus}{\leftarrow} \mathcal{P}_{\lambda} ;\left(\mathrm{P}\left(\mathbb{Z}_{p_{1}}\right)=0 \wedge \mathrm{P}\left(\mathbb{Z}_{p_{2}}\right) \neq 0\right) \vee\left(\mathrm{P}\left(\mathbb{Z}_{p_{1}}\right) \neq 0 \wedge \mathrm{P}\left(\mathbb{Z}_{p_{2}}\right)=0\right)\right] \\
& \leq \operatorname{Pr}\left[\mathrm{P} \leftarrow \mathcal{A}\left(1^{\lambda}\right), p_{1}, p_{2} \stackrel{\&}{\leftarrow} \mathcal{P}_{\lambda} ;\left(\mathrm{P}\left(\mathbb{Z}_{p_{1}}\right)=0 \wedge \mathrm{P}\left(\mathbb{Z}_{p_{2}}\right) \neq 0\right)\right] \\
& +\operatorname{Pr}\left[\mathrm{P} \leftarrow \mathcal{A}\left(1^{\lambda}\right), p_{1}, p_{2} \stackrel{\leftrightarrow}{\leftarrow} \mathcal{P}_{\lambda} ;\left(\mathrm{P}\left(\mathbb{Z}_{p_{1}}\right) \neq 0 \wedge \mathrm{P}\left(\mathbb{Z}_{p_{2}}\right)=0\right)\right] \\
& =2 \cdot \operatorname{Pr}\left[\mathrm{P} \leftarrow \mathcal{A}\left(1^{\lambda}\right), p_{1}, p_{2} \stackrel{\leftrightarrow}{*}^{\leftarrow} \mathcal{P}_{\lambda} ; \mathrm{P}\left(\mathbb{Z}_{p_{1}}\right)=0 \wedge \mathrm{P}\left(\mathbb{Z}_{p_{2}}\right) \neq 0\right] \\
& \leq 2 \cdot \operatorname{Pr}\left[\mathrm{P} \leftarrow \mathcal{A}\left(1^{\lambda}\right), p_{1}, p_{2} \stackrel{\Phi}{\leftarrow} \mathcal{P}_{\lambda} ; \mathrm{P}\left(\mathbb{Z}_{p_{1}}\right)=0 \wedge \mathrm{P}(\mathbb{Z}) \neq 0\right] \\
& =2 \cdot \operatorname{Adv}_{\mathcal{A}}^{\mathrm{SLP}-1}(\lambda) \text {. }
\end{aligned}
$$

Therefore if the SLP assumption 1 holds, then the SLP assumption 2 holds.

Then we prove Theorem 3.
Proof. (of Theorem 3.) By Lemma 3, what we have to prove is that the SLP assumption 1 holds under the factoring assumption w.r.t. unbalanced moduli. Let $\mathcal{A}$ be a PPT adversary that breaks the SLP assumption 1 whose running time is at most $T(\lambda)$. Then we construct an algorithm $\mathcal{B}$ that factorizes $N=p q$ where $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\lambda}$ and $q \stackrel{\&}{\leftarrow} \mathcal{P}_{\text {poly }(\lambda)}$ for poly $=2 T$. The description of $\mathcal{B}$ is as follows.
$\mathcal{B}(\ell, N):$ It computes $\mathrm{P} \leftarrow \mathcal{A}\left(1^{\ell}\right)$ and $s=\mathrm{P}\left(\mathbb{Z}_{N}\right)$, and output $\operatorname{gcd}(s, N)$.
We show the correctness of the above algorithm. First, we have

$$
\begin{aligned}
& \operatorname{Pr}\left[\mathrm{P}\left(\mathbb{Z}_{p}\right)=0 \wedge \mathrm{P}\left(\mathbb{Z}_{q}\right) \neq 0\right] \\
& =\operatorname{Pr}\left[\mathrm{P}\left(\mathbb{Z}_{p}\right)=0 \wedge \mathrm{P}(\mathbb{Z}) \neq 0\right]-\operatorname{Pr}\left[\mathrm{P}\left(\mathbb{Z}_{p}\right)=0 \wedge \mathrm{P}\left(\mathbb{Z}_{q}\right)=0 \wedge \mathrm{P}(\mathbb{Z}) \neq 0\right] \\
& >\operatorname{Adv}_{\mathcal{A}}^{\mathrm{SLP}-1}(\lambda)-\operatorname{Pr}\left[\mathrm{P}\left(\mathbb{Z}_{q}\right)=0 \wedge \mathrm{P}(\mathbb{Z}) \neq 0\right]
\end{aligned}
$$

Since P is generated by $\mathcal{A}$ whose running time is at most $T(\lambda)$, the length of P is at most $T(\lambda)$. Therefore by Lemma $2, \operatorname{Pr}\left[\mathrm{P}\left(\mathbb{Z}_{q}\right)=0 \wedge \mathrm{P}(\mathbb{Z}) \neq 0\right]$ is negligible. Therefore, if $\operatorname{Adv}_{\mathcal{A}}^{\mathrm{SLP}-1}(\lambda)$ is non-negligible, then $\operatorname{Pr}\left[\mathrm{P}\left(\mathbb{Z}_{p}\right)=0 \wedge \mathrm{P}\left(\mathbb{Z}_{q}\right) \neq 0\right]$ is also non-negligible. Therefore with non-negligible probability, we have $\operatorname{gcd}(s, N)=p$, and $\mathcal{B}$ succeeds in factoring $N$.

## 5 Inversion-hard Ring

In this section, we first formalize a ring with efficient operations as a ring scheme, and for any prime $c$, define the $c$-inversion assumption for it. Next, we define the GRM that can capture unknown characteristic rings. Then we prove that for any prime $c$, the $c$-inversion assumption holds in the GRM under the factoring assumption for a certain ring distribution. Finally, we show an evidence that a certain complexity assumption is necessary for proving the generic hardness of the $c$-inversion assumption.

### 5.1 Ring Scheme

Here, we define a ring scheme and the $c$-inversion assumption for it. A ring scheme consists of PPT algorithms (RGen, Add, Sub, Mult).
$\operatorname{RGen}\left(1^{\lambda}\right) \rightarrow P P$ : This algorithm takes the security parameter $1^{\lambda}$ as input and outputs the public parameter $P P$, which specifies a ring $R$ whose characteristic is at most $2^{\ell}$ and its multiplicative identity $[1]_{R}$. We assume that $[1]_{R}$ can be computed efficiently from $P P$. Though $P P$ is input to all other algorithms, we omit them for simplicity.
$\operatorname{Add}(X, Y) \rightarrow X+Y$ : This algorithm takes two elements $X, Y \in R$ as input and outputs $X+Y \in R$.
$\operatorname{Sub}(X, Y) \rightarrow X-Y$ : This algorithm takes two elements $X, Y \in R$ as input and outputs $X-Y \in R$.
$\operatorname{Mult}(X, Y) \rightarrow X \cdot Y$ : This algorithm takes two elements $X, Y \in R$ as input and outputs $X \cdot Y \in R$.
$c$-inversion assumption. Here, for a prime $c$, we define the $c$-inversion assumption for a ring scheme. We say that the $c$-inversion assumption holds for a ring scheme if no PPT algorithm can compute $[c]_{R}^{-1}$ where ${ }^{-1}$ denotes the multiplicative inverse.

Definition 6 Let c be a prime (that may depend on $\lambda$ ). The c-inversion assumption holds for a ring scheme (RGen, Add, Sub, Mult) if for any PPT algorithm $\mathcal{A}$,

$$
\operatorname{Adv}_{\mathcal{A}, c}^{\mathrm{inv}}(\lambda):=\operatorname{Pr}\left[P P \stackrel{\&}{\leftarrow} \operatorname{GGen}\left(1^{\lambda}\right):[c]_{R}^{-1} \stackrel{\&}{\leftarrow} \mathcal{A}(P P, c)\right]
$$

is negligible where $R$ denotes the ring specified by $P P$.

### 5.2 Generic Ring Model

Here, we extend the GRM to capture rings of unknown characteristics. Our GRM is defined by modifying the model given by Jager and Schwenk [JS09] in the following three aspects. First, our model is parametrized by a distribution $\mathcal{D}_{R}$ of a ring, and ring is chosen according to $\mathcal{D}_{R}$ whereas a ring is fixed in the model in [JS09]. Second, while their model allowed a generic algorithm to compute a multiplicative inverse, our model does not allow this because that cannot be computed on a ring of unknown characteristic. Third, while a random ring element is chosen as a "secret value" at the beginning of the game in their model, there is no secret value in our model. This is because the only problem we consider in our model is the $c$-inversion problem that does not have any secret value. (In our setting, the secret is a ring itself.) The formal definition of our generic ring model is as follows.

Definition of $\mathcal{D}_{R}$-generic ring model. Let $\mathcal{D}_{R}=\left\{\mathcal{D}_{R}(\lambda)\right\}_{\lambda \in \mathbb{N}}$ be a sequence of a distribution $\mathcal{D}_{R}(\lambda)$ of a ring $R$. In the $\mathcal{D}_{R}$-generic ring model, a generic algorithm $\mathcal{A}$ is given $1^{\lambda}$ as input and given access to an oracle $\mathcal{O}_{\text {ring }}$ described below.
$\mathcal{O}_{\text {ring }}$ picks a ring $R$ according to the distribution $\mathcal{D}_{R}(\lambda)$. It maintains an NI-SLP P , which is set to be empty sequence at the beginning. $\mathcal{A}$ is allowed to make the following two kinds of query, the operation and equal queries.
operation query: When $\mathcal{A}$ makes an operation query $(i, j, \circ) \in\{0, \ldots,|\mathrm{P}|\} \times$
$\{0, \ldots,|\mathrm{P}|\} \times\{+,-, \cdot\}$, then $\mathcal{O}_{\text {ring }}$ append $(i, j, \circ)$ to P.
equal query: When $\mathcal{A}$ makes an equal query $(i, j) \in\{0, \ldots,|\mathrm{P}|\} \times\{0, \ldots,|\mathrm{P}|\}$,
then $\mathcal{O}$ returns true if $\mathrm{P}_{i}(R)=\mathrm{P}_{j}(R)$ and false otherwise.
We define the $c$-inversion assumption in this model.
Definition 7 We say that the c-inversion assumption holds in the $\mathcal{D}_{R^{-}}$generic model if for any PPT generic algorithm $\mathcal{A}$,

$$
\operatorname{Adv}_{\mathcal{A}, \mathcal{D}_{R}, c}^{\text {gen-inv }}(\lambda):=\operatorname{Pr}\left[i^{*} \stackrel{\varsigma}{\leftarrow}_{\leftarrow}^{\mathcal{A}^{\mathcal{O}_{\text {ring }}}}\left(1^{\lambda}, c\right): \mathrm{P}_{i^{*}}(R)=[c]_{R}^{-1}\right]
$$

is negligible where $\mathcal{O}_{\text {ring }}$ denotes the oracle in the $\mathcal{D}_{R}$-generic model, $R$ denotes a ring chosen by $\mathcal{O}_{\text {ring }}$ and P denotes an NI-SLP maintained by $\mathcal{O}_{\text {ring }}$ at the end of the game.

### 5.3 Generic Hardness of the $\boldsymbol{c}$-inversion Assumption

Here, we prove that the $c$-inversion assumption holds for any prime $c$ in the $\mathcal{D}_{R^{-}}$ generic ring model if the factoring assumption holds where $\mathcal{D}_{R}$ is the distribution of $R=\mathbb{Z}_{p}$ for randomly chosen prime $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$.

Theorem 4 (Parametrized version of Theorem 1.) Let $\mathcal{D}_{R}$ be the distribution of $R=\mathbb{Z}_{p}$ for randomly chosen prime $p \stackrel{\leftarrow}{\leftarrow} \mathcal{P}_{\ell}$. Then for any prime $c$ and PPT generic algorithm $\mathcal{A}$, there exist PPT algorithms $\mathcal{B}$ and $\mathcal{C}$ such that the following holds:

$$
\operatorname{Adv}_{\mathcal{A}, \mathcal{D}_{R}, c}^{\text {gen-inv }}(\lambda) \leq Q \cdot \operatorname{Adv}_{\mathcal{B}}^{\mathrm{SLP}-2}(\ell)+\operatorname{Adv}_{\mathcal{C}}^{\mathrm{SLP}-1}(\ell)
$$

where $Q$ is the maximum number of $\mathcal{A}$ 's equal query. Especially, if $\ell=\Omega(\lambda)$ and the factoring assumption w.r.t. unbalanced moduli holds, then the c-inversion assumption holds in the $\mathcal{D}_{R^{-}}$-generic ring model.

Remark 1 In an asymptotic sense, we can set $\ell=\lambda$. However, since we only give reductions for SLP assumptions 1 and 2 from the factoring, for which there exists a sub-exponential time attack, there may exist sub-exponential attack against these assumptions. In that case, we have to set larger than $\lambda$ (say, $\lambda^{3}$ ) for obtaining $\lambda$-bit security.

Proof. (of Theorem 4.) The latter part easily follows from the former part and Theorem 3. We prove the former part by considering the following sequence of games for a generic algorithm $\mathcal{A}$.

Game 1: This game is the original game that defines the $c$-inversion assumption as described in Sec. 5.2. For clarity, we describe the game again. In this
 makes an operation query $(i, j, \circ)$, then $\mathcal{O}_{\text {ring }}$ append $(i, j, \circ)$ to P . When $\mathcal{A}$ makes an equal query $(i, j)$, then $\mathcal{O}_{\text {ring }}$ returns true if $\mathrm{P}_{i}\left(\mathbb{Z}_{p}\right)=\mathrm{P}_{j}\left(\mathbb{Z}_{p}\right)$ and false otherwise. When $\mathcal{A}$ outputs $i^{*}$, we say that $\mathcal{A}$ wins if $\mathrm{P}_{i^{*}}\left(\mathbb{Z}_{p}\right)=[c]_{\mathbb{Z}_{p}}^{-1}$ holds.
Game 2: This game is the same as the above game except that $\mathcal{O}_{\text {ring }}$ uses a independently random prime $p_{k}$ instead of $p$ for the $k$-th equal query for each $k$. That is, when $\mathcal{A}$ makes the $k$-th equal query $(i, j)$, the oracle $\mathcal{O}_{\text {ring }}$ picks an independently random prime $p_{k} \stackrel{\leftrightarrow}{\leftarrow} \mathcal{P}_{\ell}$ and returns true if $\mathrm{P}_{i}\left(\mathbb{Z}_{p_{k}}\right)=$ $\mathrm{P}_{j}\left(\mathbb{Z}_{p_{k}}\right)$ and false otherwise. We note that the winning condition of $\mathcal{A}$ remains unchanged, and it is decided by using $p$.

Let $T_{k}$ be the event that $\mathcal{A}$ wins in Game $k$ for $k=1,2$. Clearly, we have $\operatorname{Adv} \mathcal{A}_{\mathcal{A}, \mathcal{D}_{R}, c}^{\text {gen-inv }}(\lambda)=\operatorname{Pr}\left[T_{1}\right]$. We prove that $\operatorname{Pr}\left[T_{1}\right]$ is negligible by the following lemmas. Let $Q$ be the maximum number of $\mathcal{A}$ 's equal query.

Lemma 4 There exists a PPT algorithm $\mathcal{B}$ such that $\left|\operatorname{Pr}\left[T_{2}\right]-\operatorname{Pr}\left[T_{1}\right]\right| \leq Q$. $\operatorname{Adv}_{\mathcal{B}}^{\operatorname{SLP}-2}(\ell)$ holds.

Proof. For $0 \leq k \leq Q$, we consider hybrids $H_{k}$. where the oracle $\mathcal{O}_{\text {ring }}$ works as in Game 2 until the $k$-th query, and as in Game 1 from the $(k+1)$-th query. Then it is clear that $H_{0}$ is equivalent to Game 1 and $H_{Q}$ is equivalent to Game 2. Let $S_{k}$ be the event that $\mathcal{A}$ wins in $H_{k}$. By the triangle inequality, we have $\left|\operatorname{Pr}\left[T_{2}\right]-\operatorname{Pr}\left[T_{1}\right]\right| \leq \sum_{k=1}^{Q}\left|\operatorname{Pr}\left[S_{k}\right]-\operatorname{Pr}\left[S_{k-1}\right]\right|$. In the following, we prove that for any $1 \leq k \leq Q,\left|\operatorname{Pr}\left[S_{k}\right]-\operatorname{Pr}\left[S_{k-1}\right]\right| \leq \operatorname{Adv}_{\mathcal{B}}^{\text {SLP-2 }}$ holds. To do so, we construct an adversary $\mathcal{B}$ against the SLP assumption 2 by using $\mathcal{A}$. The description of $\mathcal{B}$ is as follows.
$\mathcal{B}\left(1^{\lambda}\right): \mathcal{B}$ gives $1^{\lambda}$ to $\mathcal{A}$ as input. Then it simulates the oracle $\mathcal{O}_{\text {ring }}$ in $H_{k-1}$ and $H_{k}$ until $\mathcal{A}$ makes $k$-th equal query $(i, j)$ without choosing $p$. (We note that $H_{k-1}$ and $H_{k}$ are identical until this point. We also note that $p$ is not needed until this point, and thus $\mathcal{B}$ can simulate it without choosing $p$.) Let P be an NI-SLP maintained by $\mathcal{O}_{\text {ring }}$ at this point. $\mathcal{B}$ appends $(i, j,-)$ to P to generate $\mathrm{P}^{\prime}$ and outputs $\mathrm{P}^{\prime}$.

Then we prove that $\mathcal{B}$ works correctly. Let $p_{k}$ be a prime randomly chosen from $\mathcal{P}_{\ell}$ that is supposed to be chosen by $\mathcal{O}_{\text {ring }}$ when responding the $k$-th equal query in $H_{k}$. We remark that $\mathcal{B}$ halts before simulating the oracle for the $k$-th equal query, and thus it works independently of $p_{k}$. Let $F_{k}$ be the event that $\left(\mathrm{P}_{i}\left(\mathbb{Z}_{p}\right)=\right.$ $\left.\mathrm{P}_{j}\left(\mathbb{Z}_{p}\right) \wedge \mathrm{P}_{i}\left(\mathbb{Z}_{p_{k}}\right) \neq \mathrm{P}_{j}\left(\mathbb{Z}_{p_{k}}\right)\right)$ or $\left(\mathrm{P}_{i}\left(\mathbb{Z}_{p}\right) \neq \mathrm{P}_{j}\left(\mathbb{Z}_{p}\right) \wedge \mathrm{P}_{i}\left(\mathbb{Z}_{p_{k}}\right)=\mathrm{P}_{j}\left(\mathbb{Z}_{p_{k}}\right)\right)$ holds where P denotes an NI-SLP maintained by $\mathcal{O}_{\text {ring }}$ at the point of $\mathcal{A}$ 's $k$-th equal query. $H_{k-1}$ and $H_{k}$ are completely the same unless $F_{k}$ occurs. Therefore we have $\left|\operatorname{Pr}\left[S_{k}\right]-\operatorname{Pr}\left[S_{k-1}\right]\right| \leq \operatorname{Pr}\left[F_{k}\right]$. If $F_{k}$ occurs, then we have $\left(\mathrm{P}^{\prime}\left(\mathbb{Z}_{p}\right)=0 \wedge \mathrm{P}^{\prime}\left(\mathbb{Z}_{p_{k}}\right) \neq\right.$ $0)$ or $\left(\mathrm{P}^{\prime}\left(\mathbb{Z}_{p}\right) \neq 0 \wedge \mathrm{P}^{\prime}\left(\mathbb{Z}_{p_{k}}\right)=0\right)$. By the definition, the probability this event occurs is $\operatorname{Adv}_{\mathcal{B}}^{\mathrm{SLP}-2}(\ell)$. (We remark again that $\mathcal{B}$ works independently of $p$ and $p_{k}$.) Then we have $\left|\operatorname{Pr}\left[S_{k}\right]-\operatorname{Pr}\left[S_{k-1}\right]\right| \leq \operatorname{Pr}\left[F_{k}\right] \leq \operatorname{Adv}_{\mathcal{B}}^{\text {SLP-2 }}(\ell)$ and thus the lemma follows.

Lemma 5 There exists a PPT algorithm $\mathcal{C}$ such that $\operatorname{Pr}\left[T_{2}\right] \leq \operatorname{Adv}_{\mathcal{C}}^{\operatorname{SLP}-1}(\ell)$ holds.
Proof. We construct an adversary $\mathcal{C}$ against the SLP assumption 1 by using $\mathcal{A}$. the description of $\mathcal{C}$ is as follows.
$\mathcal{C}\left(1^{\lambda}\right): \mathcal{C}$ simulates Game 2 for $\mathcal{A}$ until $\mathcal{A}$ outputs $i^{*}$ without choosing $p$. (We note that Game 2 can be simulated without using $p$ until deciding if $\mathcal{A}$ wins.) Let P be an NI-SLP maintained by $\mathcal{O}_{\text {ring }}$ at this point. $\mathcal{B}$ sets $\mathrm{P}^{\prime}:=c \cdot \mathrm{P}_{i^{*}}-1$ and outputs $\mathrm{P}^{\prime}$.

We prove that $\mathcal{C}$ works correctly. If $\mathcal{A}$ wins in Game $2, \mathrm{P}_{i^{*}}\left(\mathbb{Z}_{p}\right)=[c]_{\mathbb{Z}_{p}}^{-1}$ holds, and equivalently, $\mathrm{P}^{\prime}\left(\mathbb{Z}_{p}\right)=0$ holds for $\mathrm{P}^{\prime}$ output by $\mathcal{C}$. By the definition of $\mathrm{P}^{\prime}$, we have $\mathrm{P}^{\prime}(\mathbb{Z}) \neq 0$. Therefore, the probability that $\mathrm{P}^{\prime}\left(\mathbb{Z}_{p}\right)=0$ holds is $\operatorname{Adv}_{\mathcal{C}}^{S L P-2}(\ell)$. (We remark that $\mathcal{C}$ works independently of $p$.) Thus the lemma follows.

The theorem is proven by combining the above lemmas.

Remark 2 We can also rule out generic ring algorithms based on essentially the same proof that compute $\left[b \cdot c^{-1}\right]_{R}$ for integers $b, c$ adaptively chosen by the algorithm such that $c$ does not divide $b$. We gave the proof for the simpler case where $b=1$ and $c$ is a fixed prime because this is sufficient for the application for self-bilinear maps given in Sec. 6.

### 5.4 Is Factoring Assumption Necessary?

For proving the generic hardness of the $c$-inversion assumption, we assume the factoring assumption. One may wonder if this can be done without assuming any unproven assumption. Here, we give a partial evidence that the factoring assumption (or some assumption of similar nature) is needed. Specifically, we relate the hardness of the problem to the straight-line complexity [SS95] of factorials. For an integer $N$, the straight-line complexity $\tau(N)$ of $N$ is defined as the minimum length of a NI-SLP P such that $\mathrm{P}(\mathbb{Z})=N$. That is, the straight-line complexity is the smallest number of additions or multiplications to compute $N$ starting from 1. Though it is conjectured that $\tau(n!)$ is super polynomial in $\log (n)$ [SS95,Che04,Mar13], this has been open for a long time. Here, we consider the uniform version of this conjecture ${ }^{4}$.

Uniform Factorial Conjecture. There does not exist a PPT algorithm $\mathcal{A}$ that is given $n$ as input and outputs an NI-SLP $\mathrm{P}^{n}$ such that $\mathrm{P}^{n}(\mathbb{Z})=n$ ! for all $n \in \mathbb{N}$.

Though this conjecture is plausible, it still seems difficult to prove that this conjecture is unconditionally true since this is just a uniform variant of the above mentioned long standing open problem. Here, we prove that if the above conjecture is false, i.e., if there exists a PPT algorithm $\mathcal{A}$ that is given $n$ as input and outputs an NI-SLP $\mathrm{P}^{n}$ such that $\mathrm{P}^{n}(\mathbb{Z})=n$ ! for all $n \in \mathbb{N}$, then we can compute the characteristic char $(R)$ of any ring $R$ in polynomial time in $\log (\operatorname{char}(R))$ as long as $\operatorname{char}(R)$ is a prime. If $\operatorname{char}(R)$ is known, then the $c$-inversion assumption is trivially broken by the extended Eucledian algorithm. The algorithm to compute $\operatorname{char}(R)$ is given as follows. For any integer $n$, let $\mathrm{P}^{n}$ be an NI-SLP that computes $n$ ! on $\mathbb{Z}$ such that $\left|\mathrm{P}^{n}\right|=\operatorname{poly}(\log n)$. Let $R$ be a ring whose characteristic is a prime smaller than $2^{\ell}$. First, we consider the following recursively defined procedure.
procedure $(A, B)$ : If $A=B$, it outputs $A$. Else it computes $C:=\frac{A+B}{2}$ and $\mathrm{P}^{C} \stackrel{\&}{\leftarrow}$ $\mathcal{A}(C)$. If $\mathrm{P}^{C}(R)=0$, then do procedure $(A, C)$. Else do procedure $(C, B)$.

By using this procedure, char $(R)$ can be computed by executing procedure $\left(0,2^{\ell}\right)$. This can be seen by the fact that $\mathrm{P}^{C}(R)=0$ if and only if $C \geq \operatorname{char}(R)$ and thus this algorithm gives the binary search for $\operatorname{char}(R)$. Next, we verify that this algorithm runs in polynomial time in $\ell$. It is easy to see that the recursion depth of procedure is $\ell$. In each execution of procedure, $\mathrm{P}^{C}(R)$ is computed once

[^2]for some $0 \leq C \leq 2^{\ell}$. Since we have $\left|\mathrm{P}^{C}\right|=\operatorname{poly}(\log (C)) \leq \operatorname{poly}(\ell)$ by the assumption, the whole algorithm runs in polynomial time in $\ell$.

Therefore to prove the generic hardness of the $c$-inversion problem or even ensuring that hardness of computing a characteristic of a ring of a prime characteristic, we have to assume at least that the uniform factorial conjecture is true, which seems difficult to unconditionally prove.

It has been widely recognized that there is a close relationship between the complexity of computing factorials and interger factorization (e.g., [Sha79,Che04]). Indeed, the uniform factorial conjecture can be easily reduced to the factoring assumption by a binary search algorithm similar to the one described above. On the other hand, we are unaware of any other standard assumption that would imply the uniform factorial conjecture. For example, even if we assume the existence of iO , it is not clear if the uniform factorial conjecture is true or not. Thus, if we want to reduce the generic hardness of the $c$-inversion problem to a standard assumption, it is somehow unavoidable to assume the factoring assumption (unless we find any other standard assumption that implies the uniform factorial conjecture).

## 6 Self-bilinear Map

In this section, we formalize a group with efficiently computable self-bilinear map as a self-bilinear group scheme. We define several complexity assumptions including the MCDH assumption for a self-bilinear map group scheme. We construct a self-bilinear group scheme that satisfies those assumptions based on a ring scheme that satisfies the $c$-inversion assumption for a prime $c$. We also give a definition of the generic self-bilinear map model (GSBM). By combining with the result in Sec. 5, we show that several assumptions holds in the model under the factoring assumption w.r.t. unbalanced moduli.

### 6.1 Self-bilinear group scheme.

Here, define a self-bilinear group scheme. A self-bilinear map group scheme consists of PPT algorithms (GGen, Add, Sub, Map).

GGen $\left(1^{\lambda}\right) \rightarrow P P$ : This algorithm takes the security parameter $1^{\lambda}$ as input and outputs public parameters $P P$ which specifies a cyclic group $G$ whose order is at most $2^{\ell}$, a generator $[1]_{1}$ of $G$ and a self-bilinear map $e$ on $G . e$ is required to satisfy the properties given in Def. 2. $P P$ is input to all other algorithms below, but we omit them for simplicity.
$\operatorname{Add}(X, Y) \rightarrow X+Y$ : This algorithm takes $X, Y \in G$ as input and outputs $X+$ $Y$. Equivalently, if $X=[x]_{k}$ and $[y]_{k}$ for $x, y, k \in \mathbb{Z}$, then it outputs $[x+y]_{k}$.
$\operatorname{Sub}(X, Y) \rightarrow-X$ : This algorithm takes two elements $X, Y \in G$ as input and outputs $X+Y$. Equivalently, if $X=[x]_{k}$ and $[y]_{k}$ for $x, y, k \in \mathbb{Z}$, then it outputs $[x-y]_{k}$.
$\operatorname{Map}(X, Y) \rightarrow e(X, Y)$ : This algorithm takes two elements $X, Y \in G$ as input and outputs $e(X, Y)$. Equivalently, if $X=[x]_{k_{1}}$ and $[y]_{k_{2}}$ for $x, y, k_{1}, k_{2} \in \mathbb{Z}$, then it outputs $[x \cdot y]_{k_{1}+k_{2}}$.
Hardness assumptions. Here, we define hardness assumptions for a self-bilinear group. First, we define the multilinear computational Diffie-Hellman (MCDH) assumption, which was originally defined for multilinear maps [GGH13]. We extend the definition to the one for self-blinear maps.

Definition $8 n$-MCDH assumption. For $n \in \mathbb{N}$, we say that the n-multilinear computational Diffie-Hellman ( $n-M C D H$ ) assumption holds if for any PPT adversary $\mathcal{A}$,

$$
\operatorname{Pr}\left[\left[\prod_{i=1}^{n+1} x_{i}\right]_{n} \leftarrow \mathcal{A}\left(P P,\left\{\left[x_{i}\right]_{1}\right\}_{i \in[n+1]}\right)\right]
$$

is negligible where $P P \leftarrow G \operatorname{Gen}\left(1^{\lambda}\right)$ and $x_{1}, \ldots, x_{n+1} \stackrel{\leftarrow}{\leftarrow}\left[2^{\ell+\lambda}\right]$.
Remark 3 The assumption is equivalent if we choose $x_{1}, \ldots, x_{n+1} \stackrel{\&}{\leftarrow}[\operatorname{ord}[G]]$ since the statistical distance of these distributions are negligible. Since we cannot compute $\operatorname{ord}(G)$ efficiently from $P P$, we adopt this definition. The same remark is applied to the all other assumptions w.r.t. self-bilinear maps defined in this paper.

Next, we define the augmented power multilinear Diffie-Hellman (APMDH) assumption, which was originally defined for multilinear maps [CFW14]. We extend the definition to the one for self-blinear maps.
Definition $9 \ell$-APMDH assumption. For $\ell \in \mathbb{N}$, we say that the $\ell$-augmented power multilinear Diffie-Hellman ( $\ell-A P M D H$ ) assumption holds if for any PPT adversary $\mathcal{A}$,

$$
\operatorname{Pr}\left[\left[x_{1}^{\ell-1}\left(x_{2} x_{3}\right)^{\ell}\right]_{\ell} \stackrel{\&}{\leftarrow} \mathcal{A}\left(P P,\left[x_{1}\right]_{1},\left[x_{2}\right]_{1},\left[x_{3}\right]_{1},\left[x_{1} x_{2}\right]_{1},\left[x_{1} x_{3}\right]_{1},\left[x_{1} x_{2} x_{3}\right]_{1}\right)\right]
$$

is negligible where $P P \leftarrow \operatorname{GGen}\left(1^{\lambda}\right)$ and $x_{1}, x_{2}, x_{3} \stackrel{\&}{\leftarrow}\left[2^{\ell+\lambda}\right]$.
Next, we define more general parametrized assumption which we call the multilinear generalized Diffie-Hellman (MGDH) assumption. This can be seen as a family of Diffie-Hellman type computational assumptions including the MCDH and APMDH assumptions. This is an analogue of the multilinear generalized Diffie-Hellman with auxiliary information (AI-MGDH) assumption defined for self-bilinear maps with auxiliary information [YHK16].

Definition $10\left(\mathcal{F}, f^{*}, \ell^{*}\right)$-MGDH assumption. Let $\mathcal{F}$ be a set of monic monomials with $n$ variables, $f^{*}$ be a monic monomial with $n$ variables, and $\ell^{*}$ be a natural number. We say that the $\left(\mathcal{F}, f^{*}, \ell^{*}\right)$-multilinear generalized Diffie-Hellman $\left(\left(\mathcal{F}, f^{*}, \ell^{*}\right)-M G D H\right)$ assumption holds if for any PPT adversary $\mathcal{A}$,

$$
\operatorname{Pr}\left[\left[f^{*}\left(x_{1}, \ldots, x_{n}\right)\right]_{\ell^{*}} \stackrel{\&}{\leftarrow} \mathcal{A}^{\mathcal{O}_{\mathcal{F}}}(P P)\right]
$$

is negligible where $P P \leftarrow \operatorname{GGen}\left(1^{\lambda}\right), x_{1}, \ldots, x_{n} \stackrel{\&}{\leftarrow}\left[2^{\ell+\lambda}\right]$ and $\mathcal{O}_{\mathcal{F}}$ is an oracle which is given $f \in \mathcal{F}$ and returns $\left[f\left(x_{1}, \ldots, x_{n}\right)\right]_{1}$.

### 6.2 Construction based on Inversion-hard Ring.

Here, we give a construction of a self-bilinear group scheme based on a ring scheme. Then we show that if the $c$-inversion assumption for the underlying ring scheme holds, then various hardness assumptions including the MCDH assumption and APMDH assumption hold for the resulting self-bilinear group scheme.

Let $\left(\right.$ RGen $_{\text {ring }}$, Add $_{\text {ring }}$, Sub $_{\text {ring }}$, Mult $\left._{\text {ring }}\right)$ be a ring scheme and $c$ be a prime such that $\operatorname{gcd}(c, \operatorname{char}(R))=1$ with overwhelming probability where $R$ is a ring specified by $P P \stackrel{\$}{\leftarrow} \mathrm{RGen}_{\text {ring }}\left(1^{\lambda}\right)$. The construction is as follows.
$\operatorname{GGen}_{\text {sbm }}\left(1^{\lambda}\right)$ : This algorithm computes $P P \stackrel{\leftarrow}{\leftarrow} \operatorname{RGen}_{\text {ring }}\left(1^{\lambda}\right)$ and simply outputs $P P$. Let $R$ and $[1]_{R}$ be the ring and the multiplicative identity specified by $P P$. As public parameters of self-bilinear group scheme, $P P$ specifies a group $G$, a generator $[1]_{G} \in G$ and a self-bilinear map $e$ as follows. $G$ is defined as the additive subgroup of $R$ generated by $[1]_{R}$ and let $[1]_{G}:=[c]_{R}$. The self-bilinear map $e$ is defined by $e(X, Y)=X \cdot Y$ where $\cdot$ denotes the multiplication on $R$. It is easy to verify that $e$ is actually a self-bilinear map on $G$.
$\operatorname{Add}_{\mathrm{sbm}}(X, Y)$ : This algorithm computes $\operatorname{Add}_{\text {ring }}(X, Y)$ and outputs its output. $\operatorname{Sub}_{\mathrm{sbm}}(X, Y)$ : This algorithm computes $\operatorname{Sub}_{\text {ring }}(X, Y)$ and outputs its output. $\operatorname{Map}_{\mathrm{sbm}}(X, Y)$ : This algorithm computes Mult $\mathrm{Mring}(X, Y)$ and outputs its output.

The scheme is correct if the underlying ring scheme is correct. For a selfbilinear map $e$ defined as above, we have $e\left([x]_{1},[y]_{1}\right)=[c x y]_{1}$ because we have $e\left([x]_{1},[y]_{1}\right)=e\left([c x]_{R},[c y]_{R}\right)=[c x]_{R} \cdot[c y]_{R}=\left[c^{2} x y\right]_{R}=[c x y]_{1}$. We remark that we have $[x]_{n}=\left[c^{n} x\right]_{R}$ because we have $[x]_{n}=x \cdot e_{n}\left([1]_{1}, \ldots,[1]_{1}\right)=x \cdot\left[c^{n-1}\right]_{1}=$ $x \cdot\left[c^{n}\right]_{R}=\left[c^{n} x\right]_{R}$.

Hardness assumptions. Here, we prove that the complexity assumptions defined in Sec 6.1 hold for the above scheme if the $c$-inversion assumption holds for the underlying ring scheme. Specifically, for any integers $n, \ell$, we prove that the $n$-MCDH holds under the $c$-inversion assumption and the $\ell$-APMDH assumption holds under the $c$-inversion assumption. As an extension of these results, we give a sufficient condition of parameters $\left(\mathcal{F}, f^{*}, \ell^{*}\right)$ for which the $\left(\mathcal{F}, f^{*}, \ell^{*}\right)$-MGDH assumption holds under the $c$-inversion assumption.

First, we prove that the MCDH assumptions holds under the $c$-inversion assumption.

Theorem 5 (Formal version of Theorem 2.) If the c-inversion assumption holds for the underlying ring scheme, then for any integer $n$, the $n-M C D H$ assumption holds for the above self-bilinear group scheme.

Proof. We assume that there exists a PPT adversary $\mathcal{A}$ that breaks the $n-\mathrm{MCDH}$ assumption and construct a PPT adversary $\mathcal{B}$ that breaks the $c$-inversion assumption. The description of $\mathcal{B}$ is as follows.
$\mathcal{B}(P P): \mathcal{B}$ picks $x_{1}^{\prime}, \ldots, x_{n+1}^{\prime} \stackrel{\&}{\leftarrow}\left[2^{\ell+\lambda}\right]$ and sets $\left[x_{i}\right]_{1}:=\left[c x_{i}^{\prime}+1\right]_{R}$ for $i \in[n+1]$. Then $\mathcal{B}$ runs $\mathcal{A}$ with an input $\left(P P,\left\{\left[x_{i}\right]_{1}\right\}_{i \in[n+1]}\right)$ to obtain $T$, and computes
$A:=\prod_{i=1}^{n}\left(c x_{i}^{\prime}+1\right)$ and $S:=T-\left[x_{n+1}^{\prime} \cdot A\right]_{R}-\left[c^{-1} \cdot(A-1)\right]_{R}$. Here, we remark that since $A \equiv 1 \bmod c, c^{-1} \cdot(A-1)$ is an integer and thus $\mathcal{B}$ can compute $\left[c^{-1} \cdot(A-1)\right]_{R}$. Then it outputs $S$.

We show that $\mathcal{B}$ works correctly. First, we remark that in the simulation by $\mathcal{B}$, for $i \in[n+1], x_{i}$ is defined as $x_{i}=x_{i}^{\prime}+c^{-1} \bmod \operatorname{ord}(G)$ since it sets $\left[x_{i}\right]_{1}:=$ $\left[c x_{n+1}^{\prime}+1\right]_{R}$ and we defined $[1]_{1}=[c]_{R}$. Since $\left(x_{i}^{\prime} \bmod \operatorname{ord}(G)\right)$ is distributed almost uniformly on $\mathbb{Z}_{\operatorname{ord}(G)}$ and $c$ is coprime to $\operatorname{ord}(G),\left(x_{i} \bmod \operatorname{ord}(G)\right)$ is also distributed almost uniformly on $\mathbb{Z}_{\operatorname{ord}(G)}$ and especially $\left[x_{i}\right]_{1}$ is almost uniformly distributed on $G$ as in a problem instance of the MCDH assumption. Thus if $\mathcal{A}$ breaks the $n$ - MCDH assumption, then $\mathcal{A}$ outputs $\left[\prod_{i=1}^{n+1} x_{i}\right]_{n}$ with non-negligible probability also in the simulation by $\mathcal{B}$. If $T=\left[\prod_{i=1}^{n+1} x_{i}\right]_{n}$, then we have $T=\left[\prod_{i=1}^{n+1} x_{i}\right]_{n}=\left[\prod_{i=1}^{n+1}\left(x_{i}^{\prime}+c^{-1}\right)\right]_{n}=\left[c^{n} \prod_{i=1}^{n+1}\left(x_{i}^{\prime}+c^{-1}\right)\right]_{R}=$ $\left[\left(\prod_{i=1}^{n}\left(c x_{i}^{\prime}+1\right)\right)\left(x_{n+1}^{\prime}+c^{-1}\right)\right]_{R}=\left[x_{n+1}^{\prime} \cdot A+c^{-1} \cdot(A-1)+c^{-1}\right]_{R}$. Thus we have $S=T-x_{n+1}^{\prime} \cdot A-c^{-1} \cdot(A-1)=\left[c^{-1}\right]_{R}$ and thus $\mathcal{B}$ succeeds in solving the $c$-inversion problem.

The following theorem state that the APMDH assumption holds under the $c$-inversion assumption.

Theorem 6 If the c-inversion assumption holds for the underlying ring scheme, then for any integer $\ell$ such that $\log \ell=\operatorname{poly}(\lambda)$, the $\ell-A P M D H$ assumption holds for the above self-bilinear group scheme.

We omit the proof because this theorem follows as a corollary of Theorem 7. (See Example 1).

Next, we prove a more general theorem which gives a sufficient condition of parameters $\left(\mathcal{F}, f^{*}, \ell^{*}\right)$ such that the $\left(\mathcal{F}, f^{*}, \ell^{*}\right)$-MGDH assumption holds under the $c$-inversion assumption. Before stating our theorem, we prepare some definitions.

Definition 11 For a monic monomial $f$ defined by $f\left(x_{1}, \ldots, x_{n}\right)=\prod_{i=1}^{n} x_{i}^{e_{i}}$, we define its corresponding polynomial $\bar{f}$ by $\bar{f}\left(x_{1}, \ldots, x_{n}\right):=\sum_{i=1}^{n} e_{i} \cdot x_{i}$.

Definition 12 For a family $\mathcal{F}$ of monic monomials with $n$ variables, a monic monomial $f^{*}$ with $n$ variables and an integer $\ell^{*}$, we say that $\left(\mathcal{F}, f^{*}, \ell^{*}\right)$ is MGDH-compatible if we have $n=\operatorname{poly}(\lambda), \log (\operatorname{deg}(f))=\operatorname{poly}(\lambda)$ for all $f \in \mathcal{F}$, $\log \left(\operatorname{deg}\left(f^{*}\right)\right)=\operatorname{poly}(\lambda)$ and $\log \ell^{*}=\operatorname{poly}(\lambda)$, and there exists a tuple of constant $\left(a_{1}, \ldots, a_{n}\right) \in \mathbb{Z}^{n}$ (that does not depend on $\lambda$ ) such that $\bar{f}\left(a_{1} \ldots, a_{n}\right)+1 \geq 0$ for all $f \in \mathcal{F}, \bar{f}^{*}\left(a_{1}, \ldots, a_{n}\right)+\ell^{*}+1 \leq 0$.

Then our theorem is stated as follows. Actually, a similar theorem for a selfbilinear map with auxiliary information was given in [YHK16].

Theorem 7 If the c-inversion assumption holds for the underlying ring scheme and $\left(\mathcal{F}, f^{*}, \ell^{*}\right)$ is $M G D H$-compatible, then the $\left(\mathcal{F}, f^{*}, \ell^{*}\right)-M G D H$ assumption holds for the above self-bilinear group scheme.

Proof. We assume that there exists an adversary $\mathcal{A}$ that breaks the $\left(\mathcal{F}, f^{*}, \ell^{*}\right)$ MGDH assumption. We construct an adversary $\mathcal{B}$ that breaks the $c$-inversion assumption based on $\mathcal{A}$. Let $\left(a_{1}, \ldots, a_{n}\right) \in \mathbb{Z}^{n}$ be a tuple of integers such that $\bar{f}\left(a_{1} \ldots, a_{n}\right)+1 \geq 0$ holds for all $f \in \mathcal{F}$ and $\bar{f}^{*}\left(a_{1}, \ldots, a_{n}\right)+\ell^{*}+1 \leq 0$. (Such a tuple exists because we assume that $\left(\mathcal{F}, f^{*}, \ell^{*}\right)$ is MGDH-compatible.) The description of $\mathcal{B}$ is as follows.
$\mathcal{B}(P P): \mathcal{B}$ picks $x_{1}^{\prime}, \ldots, x_{n}^{\prime} \stackrel{\&}{\leftarrow}\left[2^{\ell+\lambda}\right]$ and gives $P P$ to $\mathcal{A}$. For each $\mathcal{A}$ 's query $f \in$ $\mathcal{F}$ defined by $f\left(x_{1} \ldots x_{n}\right)=\prod_{i=1}^{n} x_{i}^{e_{i}}, \mathcal{B}$ computes $\left[c^{\left(\bar{f}\left(a_{1}, \ldots, a_{n}\right)+1\right)} \prod_{i=1}^{n}\left(c x_{i}^{\prime}+\right.\right.$ $\left.1)^{e_{i}}\right]_{R}$ and returns it to $\mathcal{A}$. (Here, $x_{1}, \ldots, x_{n}$ are implicitly defined by $x_{i}:=$ $c^{a_{i}}\left(c x_{i}^{\prime}+1\right) \bmod \operatorname{ord}(G)$.) Let $T$ be $\mathcal{A}$ 's output. Suppose that $f^{*}$ is defined by $f^{*}\left(x_{1}, \ldots, x_{n}\right)=\prod_{i=1}^{n} x_{i}^{e_{i}^{*}}$. It computes $S:=\left[\frac{\prod_{i=1}^{n}\left(c x_{i}^{\prime}+1\right)^{e_{i}^{*}}-1}{c}\right]_{R}$. Here, we remark that it is non-trivial for $\mathcal{B}$ to compute $S$ because a ring scheme only provides addition, subtraction and multiplication algorithms and does not provide a division algorithm. However, in fact, $S$ can be computed in polynomial time without using a division. We prove it later. Then $\mathcal{B}$ computes $T^{\prime}:=c^{-\left(f^{*}\left(a_{1}, \ldots, a_{n}\right)+\ell^{*}+1\right)} \cdot T-S$ and outputs $T^{\prime}$.

The above completes the description of $\mathcal{B}$. We show that $\mathcal{B}$ works correctly. First, we remark that in the simulation by $\mathcal{B}$, for $i \in[n], x_{i}$ is defined as $x_{i}=$ $c^{a_{i}}\left(c x_{i}^{\prime}+1\right) \bmod \operatorname{ord}(G)$. Since $\left(x_{i}^{\prime} \bmod \operatorname{ord}(G)\right)$ is distributed almost uniformly on $\mathbb{Z}_{\operatorname{ord}(G)}$ and $c$ is coprime to $\operatorname{ord}(G),\left(x_{i} \bmod \operatorname{ord}(G)\right)$ is also almost uniformly distributed on $\mathbb{Z}_{\operatorname{ord}(G)}$ as in the problem instance of the MGDH assumption. Then we show that $\mathcal{B}$ simulates the oracle $\mathcal{O}_{\mathcal{F}}$ correctly for $\mathcal{A}$. When $\mathcal{A}$ queries $f \in \mathcal{F}$ defined by $f\left(x_{1} \ldots x_{n}\right)=\prod_{i=1}^{n} x_{i}^{e_{i}}$, the oracle is supposed to return $\left[f\left(x_{1}, \ldots, x_{n}\right)\right]_{1}$. Here, we have

$$
\begin{aligned}
{\left[f\left(x_{1}, \ldots, x_{n}\right)\right]_{1} } & =\left[c \cdot \prod_{i=1}^{n}\left(c^{a_{i}}\left(c x_{i}^{\prime}+1\right)\right)^{e_{i}}\right]_{R} \\
& =\left[c^{\left(\bar{f}\left(a_{1}, \ldots, a_{n}\right)+1\right)} \prod_{i=1}^{n}\left(c x_{i}^{\prime}+1\right)^{e_{i}}\right]_{R} .
\end{aligned}
$$

Therefore the simulation by $\mathcal{B}$ is correct. Hence if $\mathcal{A}$ breaks the MGDH assumption, then it outputs $T=\left[f^{*}\left(x_{1}, \ldots, x_{n}\right)\right]_{\ell^{*}}$ with non-negligible probability in
the simulation by $\mathcal{B}$. Then we have

$$
\begin{aligned}
T & =\left[f^{*}\left(x_{1}, \ldots, x_{n}\right)\right]_{\ell^{*}} \\
& =\left[c^{\ell^{*}} \cdot \prod_{i=1}^{n} x_{i}^{e_{i}^{*}}\right]_{R} \\
& =\left[c^{\ell^{*}} \cdot \prod_{i=1}^{n}\left(c^{a_{i}}\left(c x_{i}^{\prime}+1\right)\right)^{e_{i}^{*}}\right]_{R} \\
& =\left[c^{\bar{f}^{*}\left(a_{1}, \ldots, a_{n}\right)+\ell^{*}} \cdot \prod_{i=1}^{n}\left(c x_{i}^{\prime}+1\right)^{e_{i}^{*}}\right]_{R} \\
& =c^{\bar{f}^{*}\left(a_{1}, \ldots, a_{n}\right)+\ell^{*}+1} \cdot\left(S+\left[c^{-1}\right]_{R}\right)
\end{aligned}
$$

Therefore we have $T^{\prime}:=c^{-\left(f^{*}\left(a_{1}, \ldots, a_{n}\right)+\ell^{*}+1\right)} \cdot T-S=\left[c^{-1}\right]_{R}$. Therefore $\mathcal{B}$ succeeds in breaking the $c$-inversion assumption.

What is left is to prove that $S=\left[\frac{\prod_{i=1}^{n}\left(c x_{i}^{\prime}+1\right)^{e_{i}^{*}}-1}{c}\right]_{R}$ can be computed in polynomial time by $\mathcal{B}$. We fix $x_{1}, \ldots, x_{n}$ and define a function $g: \mathbb{Z}^{n} \rightarrow R$ as

$$
g\left(e_{1}, \ldots, e_{n}\right):=\left[\frac{\prod_{i=1}^{n}\left(c x_{i}+1\right)^{e_{i}}-1}{c}\right]_{R}
$$

Then it is easy to see that we have

$$
\begin{aligned}
g\left(e_{1}, \ldots, e_{k}, 0, \ldots, 0\right) & =\left(c x_{k}+2\right) \cdot g\left(e_{1}, \ldots, e_{k}-1,0, \ldots, 0\right) \\
& -\left(c x_{k}+1\right) \cdot g\left(e_{1}, \ldots, e_{k}-2,0, \ldots, 0\right)
\end{aligned}
$$

for any $k \in[n], e_{1}, \ldots, e_{k-1} \in \mathbb{Z}_{\geq 0}$ and $e_{k} \in \mathbb{Z}_{\geq 2}$. We also have

$$
g\left(e_{1}, \ldots, e_{k-1}, 1,0, \ldots, 0\right)=\left(c x_{k}+1\right) \cdot g\left(e_{1}, \ldots, e_{k-1}, 0,0, \ldots, 0\right)+\left[x_{k}\right]_{R}
$$

Therefore if we let

$$
A=\left(\begin{array}{cc}
{\left[c x_{i}+2\right]_{R}} & {\left[-\left(c x_{i}+1\right)\right]_{R}} \\
{[1]_{R}} & {[0]_{R}}
\end{array}\right)
$$

then we have

$$
\begin{gathered}
\binom{g\left(e_{1}, \ldots, e_{k-1}, e_{k}, 0, \ldots, 0\right)}{g\left(e_{1}, \ldots, e_{k-1}, e_{k}-1,0, \ldots, 0\right)} \\
=A\binom{g\left(e_{1}, \ldots, e_{k-1}, e_{k}-1,0, \ldots, 0\right)}{g\left(e_{1}, \ldots, e_{k-1}, e_{k}-2,0, \ldots, 0\right)} \\
=A^{e_{k}-1}\binom{g\left(e_{1}, \ldots, e_{k-1}, 1,0, \ldots, 0\right)}{g\left(e_{1}, \ldots, e_{k-1}, 0,0, \ldots, 0\right)} \\
=A^{e_{k}-1}\binom{\left(c x_{k}+1\right) \cdot g\left(e_{1}, \ldots, e_{k-1}, 0,0, \ldots, 0\right)+\left[x_{k}\right]_{R}}{g\left(e_{1}, \ldots, e_{k-1}, 0,0, \ldots, 0\right)}
\end{gathered}
$$

By using the standard square-and-multiply algorithm, $A^{e_{k}-1}$ can be computed by $O\left(\log \left(e_{k}\right)\right)$ matrix multiplications, each of which can be computed by constant
number of additions and multiplications on $R$. Therefore if $g\left(e_{1}, \ldots, e_{k-1}, 0,0, \ldots, 0\right)$ is given, then $g\left(e_{1}, \ldots, e_{k-1}, e_{k}, 0, \ldots, 0\right)$ can be computed by polynomial number of additions and multiplications if $\log c, \log x_{1}, \ldots, \log x_{n}$ and $\log e_{1}, \ldots, \log e_{n}$ are polynomial in $\lambda$. Since we have $g(0, \ldots, 0)=[0]_{R}$, one can compute $S=$ $g\left(e_{1}^{*}, \ldots, e_{n}^{*}\right)$ in polynomial time by computing $g\left(e_{1}^{*}, 0, \ldots, 0\right), g\left(e_{1}^{*}, e_{2}^{*}, 0, \ldots, 0\right)$, $\ldots, g\left(e_{1}^{*}, \ldots, e_{n}^{*}\right)$ in order by using the above algorithm.

We give an example of implication of the above theorem. Namely, we show that Theorem 6 can be reduced to Theorem 7.

Example 1 If we set $n=3, \mathcal{F}=\left\{f_{1}, f_{2}, f_{3}, f_{4}, f_{5}, f_{6}\right\}$ and $f^{*}\left(x_{1}, x_{2}, x_{3}\right):=$ $x_{1}^{\ell-1}\left(x_{2} x_{3}\right)^{\ell}$ where $f_{1}\left(x_{1}, x_{2}, x_{3}\right):=x_{1}, f_{2}\left(x_{1}, x_{2}, x_{3}\right):=x_{2}, f_{3}\left(x_{1}, x_{2}, x_{3}\right):=x_{3}$, $f_{4}\left(x_{1}, x_{2}, x_{3}\right):=x_{1} x_{2}, f_{5}\left(x_{1}, x_{2}, x_{3}\right):=x_{1} x_{3}$, and $f_{6}\left(x_{1}, x_{2}, x_{3}\right):=x_{1} x_{2} x_{3}$, then the $\left(\mathcal{F}, f^{*}, \ell\right)-M G D H$ assumption is equivalent to the $\ell-A P M D H$ assumption. If we set $a_{1}=1, a_{2}=-1$ and $a_{3}=-1$, then we have $\bar{f}_{1}\left(a_{1}, a_{2}, a_{3}\right)+1=2$, $\bar{f}_{2}\left(a_{1}, a_{2}, a_{3}\right)+1=0, \bar{f}_{3}\left(a_{1}, a_{2}, a_{3}\right)+1=0, \bar{f}_{4}\left(a_{1}, a_{2}, a_{3}\right)+1=1, \bar{f}_{1}\left(a_{1}, a_{2}, a_{3}\right)+$ $1=1, \bar{f}_{1}\left(a_{1}, a_{2}, a_{3}\right)+1=0$, and $\bar{f}^{*}\left(a_{1}, a_{2}, a_{3}\right)+\ell+1=(\ell-1)-\ell-\ell+\ell+$ $1=0$. Therefore $\left(\mathcal{F}, f^{*}, \ell\right)$ is MGDH-compatible, and thus the the $\ell-A P M D H$ assumption holds under the generalized c-inversion assumption.

### 6.3 Generic Self-bilinear Map Model

Here, we introduce the generic self-bilinear map model (GSBM) where an algorithm is only allowed to compute group operations and evaluations of a selfbilinear map independently of actual representations of group elements. We remark that as shown in [CL09], if an order of a group with efficiently computable self-bilinear map is known, then even the CDH assumption does not hold on the group. Therefore in our model, a group is chosen from a distribution $\mathcal{D}_{S B}$ and a generic algorithm cannot know which group was chosen. Actually, our GSBM is very similar to the GRM defined in Sec 5.2. We just replace additions and multiplications in the generic ring model by additions on a group and evaluations of a self-bilinear map respectively.

Straight-line Program on Self-bilinear Group. Before describing our model, we define a straight-line program (SLP) on a self-bilinear map group. Intuitively, that is defined similarly to an SLP on a ring except that multiplications are replaced by evaluations of a self-bilinear map. The formal definition is as follows.

Definition 13 (straight-line program for self-bilinear group) A straight-line program (SLP) P of length $L$ with $n$ inputs is written as a sequence

$$
\mathrm{P}=\left(i_{1}, j_{1}, \circ_{1}\right), \ldots,\left(i_{L}, j_{L}, \circ_{L}\right)
$$

where $i_{k}, j_{k} \in\left\{\mathrm{in}_{1}, \ldots, \mathrm{in}_{n}, 0,1, \ldots, k-1\right\}$ and $\circ_{k} \in\{+,-, \cdot\}$ for all $k \in[L]$. For $\left(G,[1]_{G}, e\right)$ where $G$ is an additive cyclic group, $[1]_{G}$ is a generator of $G$ and $e$ is a self-bilinear map on $G, \mathrm{P}$ computes as follows.

1. Let $x_{0}:=[1]_{R}$.
2. For $1 \leq k \leq n$ let $x_{\mathrm{in}_{k}}:=$ input $_{k}$.
3. For $1 \leq k \leq L$, let

$$
x_{k}:= \begin{cases}x_{i_{k}} \circ_{k} x_{j_{k}} & \text { if } \circ_{k} \in\{+,-\} \\ e\left(x_{i_{k}}, x_{j_{k}}\right) & \text { if } \circ_{k}=\end{cases}
$$

4. Output $x_{L}$.

We denote the output of P with input ( input $_{1}, \ldots$, input $_{n}$ ) on a self-bilinear group $\left(G,[1]_{G}, e\right)$ by $\mathrm{P}\left(\right.$ input $_{1}, \ldots$ input $\left._{n} ;\left(G,[1]_{G}, e\right)\right)$. For an $N I-S L P \mathrm{P},|\mathrm{P}| d e-$ notes the length of P , and $\mathrm{P}_{k}$ denotes the NI-SLP given by the sequence of the first $k$ elements of P .

Generic self-bilinear map model. The definition of our GSBM is as follows.
Let $\mathcal{D}_{S B}=\left\{\mathcal{D}_{S B}(\lambda)\right\}_{\lambda \in \mathbb{N}}$ be a sequence of a distribution $\mathcal{D}_{S B}(\lambda)$ of $\left(G,[1]_{G}, e\right)$ where $G$ is an additive cyclic group such that $|G| \leq 2^{\ell},[1]_{G}$ is a generator of $G$ and $e$ is a self-bilinear map on $G$. In the $\mathcal{D}_{S B}$-GSBM, a generic algorithm $\mathcal{A}$ is given $1^{\lambda}$ as input and allowed to access an oracle $\mathcal{O}_{\text {sbm }}$ described below.
$\mathcal{O}_{\text {sbm }}$ picks a ring $R$ according to the distribution $\mathcal{D}_{S B}$, and chooses secret values $X_{1}, \ldots, X_{n}$ according to a certain distribution, which depends on a problem to consider. It maintains an SLP P, which is set to be empty sequence at the beginning. $\mathcal{A}$ is allowed to make the following two kinds of query, the operation and equal queries.
operation query: When $\mathcal{A}$ makes an operation query $(i, j, \circ) \in\left\{\mathrm{in}_{1}, \ldots, \mathrm{in}_{n}, 0, \ldots,|P|\right\} \times$
$\left\{\mathrm{in}_{1}, \ldots\right.$, in $\left._{n}, 0, \ldots,|P|\right\} \times\{+,-, \cdot\}$, then $\mathcal{O}_{\text {sbm }}$ append $(i, j, \circ)$ to P.
equal query: When $\mathcal{A}$ makes an equal query $(i, j) \in\left\{\mathrm{in}_{1}, \ldots\right.$, in $\left._{n}, 0, \ldots,|P|\right\} \times$
$\left\{\right.$ in $_{1}, \ldots$, in $\left._{n}, 0, \ldots,|P|\right\}$, then $\mathcal{O}_{\text {sbm }}$ returns true if $P_{i}\left(X_{1}, \ldots, X_{n} ;\left(G,[1]_{G}, e\right)\right)=$
$P_{j}\left(X_{1}, \ldots, X_{n} ;\left(G,[1]_{G}, e\right)\right)$ and false otherwise.

Complexity assumptions. Then we define complexity assumptions in this model.

Definition 14 We say that $n-M C D H$ assumption holds in the $\mathcal{D}_{S B}$-GSBM if for any PPT generic algorithm $\mathcal{A}$ in the model,

$$
\operatorname{Pr}\left[i^{*} \leftarrow \mathcal{A}^{\mathcal{O}_{\text {sbm }}}\left(1^{\lambda}\right) ; \mathrm{P}_{i^{*}}\left(X_{1}, \ldots, X_{n+1} ;\left(G,[1]_{G}, e\right)\right)=\left[\prod_{i=1}^{n+1} x_{i}\right]_{n}\right]
$$

is negligible where the secret values are chosen as $X_{i}:=\left[x_{i}\right]_{1}$ for $x_{i} \stackrel{\&}{\leftarrow}\left[2^{\ell+\lambda}\right]$ for $i \in[n+1]$.

Definition 15 We say that $\ell-A P M D H$ assumption holds in the $\mathcal{D}_{S B}-G S B M$ if for any PPT generic algorithm $\mathcal{A}$ in the model,

$$
\operatorname{Pr}\left[i^{*} \leftarrow \mathcal{A}^{\mathcal{O}_{\text {sbm }}}\left(1^{\lambda}\right) ; \mathrm{P}_{i^{*}}\left(X_{1}, \ldots, X_{6} ;\left(G,[1]_{G}, e\right)\right)=\left[x_{1}^{\ell-1}\left(x_{2} x_{3}\right)^{\ell}\right]_{\ell}\right]
$$

is negligible where the secret values are chosen as $X_{1}:=\left[x_{1}\right]_{1}, X_{2}:=\left[x_{2}\right]_{1}$, $X_{3}:=\left[x_{3}\right]_{1}, X_{4}:=\left[x_{1} x_{2}\right]_{1}, X_{5}:=\left[x_{1} x_{3}\right]_{1}$ and $X_{6}:=\left[x_{1} x_{2} x_{3}\right]_{1}$ for $x_{1}, \ldots, x_{3} \stackrel{\&}{\leftarrow}$ $\left[2^{\ell+\lambda}\right]$.

Definition 16 For a set $\mathcal{F}:=\left\{f_{1}, \ldots, f_{m}\right\}$ of monic monomials of n-input, a monic monomial $f^{*}$ of $n$-input and an integer $\ell^{*}$, we say that the $\left(\mathcal{F}, f^{*}, \ell^{*}\right)$ MGDH assumption holds in the $\mathcal{D}_{S B}-G S B M$ if for any PPT generic algorithm $\mathcal{A}$ in the model,

$$
\operatorname{Pr}\left[i^{*} \leftarrow \mathcal{A}^{\mathcal{O}_{\mathrm{sbm}}}\left(1^{\lambda}\right) ; \mathrm{P}_{i^{*}}\left(X_{1}, \ldots, X_{n} ;\left(G,[1]_{G}, e\right)\right)=\left[f^{*}\left(x_{1}, \ldots, x_{n}\right)\right]_{\ell}\right.
$$

is negligible where the secret values are chosen as $X_{j}:=\left[f_{j}\left(x_{1}, \ldots, x_{n}\right)\right]_{1}$ for $j \in[m]$ where $x_{i} \stackrel{\leftarrow}{\leftarrow}\left[2^{\ell+\lambda}\right]$ for $i \in[n]$.

Generic hardness of complexity assumptions. In the following, we let $\mathcal{D}_{S B}$ be a distribution of $\left(G,[1]_{G}, e\right)$ where $G$ is a additive group $\mathbb{Z}_{p},[1]_{G}:=c$, and a self-bilinear map $e$ is defined by $e\left([x]_{G},[y]_{G}\right)=[c x y]_{G}$ for a prime number $c \geq 2^{\ell}$ where $p$ is uniformly chosen from $\mathcal{P}_{\ell}$.

We can reduce the MCDH, APMDH and MGDH assumptions in $\mathcal{D}_{S B}$-generic self-bilinear group model to the $c$-inversion assumption in the $\mathcal{D}_{R}$-generic ring model based on similar arguments to proofs of Theorem 5,6 and 7 where $\mathcal{D}_{R}$ is a distribution of $R=\mathbb{Z}_{p}$ for $p \stackrel{\mathscr{}}{\leftarrow} \mathcal{P}_{\ell}$. Since the $c$-inversion assumption holds in the $\mathcal{D}_{R^{-}}$generic ring model under the factoring assumption w.r.t. unbalanced moduli as shown in Theorem 4, the above assumptions also hold under the same assumption. Therefore we obtain the following theorems.

Theorem 8 If the factoring assumption w.r.t. unbalanced moduli holds, then for any natural number $n$, then the $n-M C D H$ assumption holds in the $\mathcal{D}_{S B}-G S B M$.

Theorem 9 If the factoring assumption w.r.t. unbalanced moduli holds, then for any natural number $\ell$, the $\ell-A P M D H$ assumption holds in the $\mathcal{D}_{S B}-G S B M$.

Theorem 10 If the factoring assumption w.r.t. unbalanced moduli holds and $\left(\mathcal{F}, f^{*}, \ell^{*}\right)$ is MGDH-compatible, then $\left(\mathcal{F}, f^{*}, \ell^{*}\right)-M G D H$ assumption holds in the $\mathcal{D}_{S B}-G S B M$.

## 7 Applications of Self-bilinear Map

Here we discuss applications of a self-bilinear map.

### 7.1 Multiparty NIKE

Here, we give a definition of a multiparty NIKE. Then we give a construction of a multiparty NIKE scheme based on a self-bilinear map that satisfies the MCDH assumption. The construction can be seen as an instantiation of the scheme proposed by Boneh and Silverberg [BS02] with an unbounded level multilinear map
obtained by a self-bilinear map.
Definition. First, we formally define multiparty non-interactive key exchange (NIKE) and its security following [BZ14]. A multiparty NIKE scheme consists of three algorithms (Setup,Publish,KeyGen).
$\operatorname{Setup}\left(1^{\lambda}\right)$ : This algorithm takes a security parameter $1^{\lambda}$ as input ${ }^{5}$. It outputs public parameters params.
Publish(params): This algorithm takes public parameters params as input. It outputs a public key $p k$ and a secret key $s k$.
KeyGen(params, $\left.s k, p k_{1}, \ldots, p k_{n-1}\right)$ : This algorithm takes public parameter params, a secret key $s k$ and public keys $p k_{1}, \ldots, p k_{n-1}$. It outputs a shared key $k$.

As correctness, we require that for any $n$, params $\leftarrow \operatorname{Setup}\left(1^{\lambda}\right),\left(p k_{i}, s k_{i}\right) \leftarrow$ Publish(params) for $i \in[n]$, for any $i_{1}, i_{2} \in[n]$, we have

$$
\begin{aligned}
& \text { KeyGen }\left(\text { params, } s k_{i_{1}}, p k_{1}, \ldots, p k_{i_{1}-1}, p k_{i_{1}+1}, \ldots p k_{n}\right) \\
= & \text { KeyGen }\left(\text { params, } s k_{i_{2}}, p k_{1}, \ldots, p k_{i_{2}-1}, p k_{i_{2}+1}, \ldots p k_{n}\right) .
\end{aligned}
$$

We define the security notion for NIKE. In this paper, we consider the minimum security notion against a passive adversary.

We say that a multiparty NIKE scheme is statically secure if for any integer $n$ which is polynomial in the security parameter, for any efficient adversary $\mathcal{A}, \mid \operatorname{Pr}\left[b \stackrel{\Phi}{\leftarrow}_{\leftarrow} \mathcal{A}\right.$ (params, $\left.\left.p k_{1}, \ldots, p k_{n}, K_{b}\right)\right]-1 / 2 \mid$ is negligible, where params $\leftarrow$ $\operatorname{Setup}\left(1^{\lambda}\right),\left(p k_{i}, s k_{i}\right) \leftarrow \operatorname{Publish}($ params $)$ for $i=1, \ldots, n, K_{1}:=$ KeyGen(params, $s k_{1}$, $\left.p k_{2}, \ldots, p k_{n}\right), K_{0} \stackrel{\&}{\leftarrow}\{0,1\}^{\ell_{K}}$ and $b \stackrel{\&}{\leftarrow}\{0,1\}$.

Remark 4 In some existing works [BZ14,KRS15], they consider stronger security notion that considers adversaries actively generate malformed public keys. In this paper, we do not consider such an adversary, and we assume that an adversary only observe honestly generated public keys.

Construction. We describe the construction of multiparty NIKE scheme based on a self-bilinear map. Let (GGen, Add, Sub, Map) be a self-bilinear group scheme. Let $\ell$ be the maximum size of a representation of an element of a group generated by GGen. For $r \in\{0,1\}^{\ell} \mathrm{GL}_{r}:\{0,1\}^{\ell} \rightarrow\{0,1\}$ denotes the Goldreich-Levin hardcore bit function [GL89], i.e., for $x \in\{0,1\}^{\ell}, \mathrm{GL}_{r}(x)=\bigoplus_{i=1}^{\ell}\left(x_{i} \cdot r_{i}\right)$ where $x_{i}$ and $r_{i}$ denotes $i$-th bit of $x$ and $r$ respectively. The description of our scheme is as follows.

Setup $\left(1^{\lambda}\right)$ : This algorithm computes $P P \stackrel{\&}{\leftarrow}$ GGen $\left(1^{\lambda}\right)$, picks $r \stackrel{\&}{\leftarrow}\{0,1\}^{\ell}$ and outputs params $=(P P, r)$. We let $\left(G,[1]_{G}, e\right)$ be a group, generator and self-bilinear map specified by $P P$.

[^3]Publish(params): This algorithm randomly picks $x \stackrel{\&}{\leftarrow}\left[2^{\ell+\lambda}\right]$, computes $[x]_{G}$, sets $s k:=x$ and $p k:=[x]_{G}$ and outputs $(p k, s k)$.
KeyGen $\left(\right.$ params $\left.=(P P, r), s k, p k_{1}, \ldots, p k_{n-1}\right):$ This algorithm computes $K:=$ $\mathrm{GL}_{r}\left(s k \cdot e_{n-1}\left(p k_{1}, \ldots, p k_{n-1}\right)\right)$ and outputs $K$.

For any $n$, params $\leftarrow \operatorname{Setup}\left(1^{\lambda}\right),\left(p k_{j}=\left[x_{j}\right]_{G}, s k_{j}=x_{j}\right) \leftarrow$ Publish(params) for $j \in[n]$, for any $i \in[n]$, we have KeyGen(params, $s k_{i}, p k_{1}, \ldots, p k_{i-1}, p k_{i+1}, \ldots p k_{n}$ ) $=$ $\mathrm{GL}_{r}\left(\left[\prod_{i=1}^{n} x_{i}\right]_{n-1}\right)$. Therefore the correctness follows.

Security. The security of the above scheme can be stated as follows.
Theorem 11 If the $n-M C D H$ assumption holds for all $n \in \mathbb{N}$ for (GGen, Add, Sub, Map), then the above scheme is statically secure.

Proof. (sketch) If the ( $n-1$ )-MCDH assumption holds, any PPT algorithm given $\left[x_{1}\right]_{G}, \ldots,\left[x_{n}\right]_{G}$ cannot compute $\left[\prod_{i=1}^{n} x_{i}\right]_{n-1}$ with non-negligible probability where $x_{1}, \ldots, x_{n} \stackrel{\&}{\leftarrow}\left[2^{\ell+\lambda}\right]$. Therefore by using the Goldreich-Levin theorem [GL89], any PPT algorithm given $\left[x_{1}\right]_{G}, \ldots,\left[x_{n}\right]_{G}$ cannot distinguish $\mathrm{GL}_{r}\left(\left[\prod_{i=1}^{n} x_{i}\right]_{n-1}\right)$ from random bit for $r \stackrel{\&}{\leftarrow}\{0,1\}^{\ell}$.

### 7.2 Broadcast Encryption

Here, we define broadcast encryption. Actually, we define distributed broadcast encryption [BZ14] in which any users can join a system without any secret information. Then we show that a distributed encryption scheme can be obtained by any multiparty NIKE scheme. The conversion is similar to the one presented in [BZ14]. As a result, we obtain a distributed broadcast encryption based on a self-bilinear map secure under the MCDH assumption.

Definition. A distributed broadcast encryption scheme consists of four algorithms (Setup, Join, Enc, Dec).

Setup $\left(1^{\lambda}\right)$ : It takes the security parameter $1^{\lambda}$ as input and outputs public parameters $P P$.
Join $(P P)$ : It takes public parameters $P P$ as input and outputs a public key $p k$ and a secret key $s k$.
$\operatorname{Enc}\left(P P, p k_{1}, \ldots, p k_{n}, m s g\right)$ : It takes public parameters $P P$, a message $m s g$, and a public keys $p k_{1}, \ldots, p k_{n}$ of designated receivers and outputs a ciphertext $C T$.
$\operatorname{Dec}\left(P P, s k, p k_{1}, \ldots, p k_{n}, C T\right)$ : It takes public parameters $P P$, a secret key $s k$, public keys of designated receivers and a ciphertext $C T$ and outputs a message $m s g$.

As correctness, we require that for any security parameter $\lambda$, an integer $n$ and a message $m s g$, we have $\operatorname{Dec}\left(P P, s k, p k_{1}, \ldots, p k_{n}, C T\right)=m s g$, where $P P \leftarrow$ $\operatorname{Setup}\left(1^{\lambda}\right),\left(p k_{1}, s k_{1}\right), \ldots,\left(p k_{n}, s k_{n}\right) \leftarrow \operatorname{Join}(P P), C T \leftarrow \operatorname{Enc}\left(P P, p k_{1}, \ldots, p k_{n}, m s g\right)$.

We define the security notion. We consider the following experiment. A challenger runs $\operatorname{Setup}\left(1^{\lambda}\right)$ to generate public parameters $P P$ and runs $\operatorname{Join}(P P) n$ times to generate $\left(p k_{1}, s k_{1}\right), \ldots,\left(p k_{n}, s k_{n}\right)$. It gives $\left(P P, p k_{1}, \ldots, p k_{n}\right)$ to $\mathcal{A}$. $\mathcal{A}$ chooses two messages $m s g_{0}$ and $m s g_{1}$ to submit them to $\mathcal{C} . \mathcal{C}$ uniformly choose $b \stackrel{\S}{\leftarrow}\{0,1\}$ and runs $\operatorname{Enc}\left(P P, p k_{1}, \ldots, p k_{n}, m s g_{b}\right)$ to generate $C T$, and gives $C T$ to $\mathcal{A}$. Finally $\mathcal{A}$ outputs $b^{\prime}$. We say that $\mathcal{A}$ wins if $b=b^{\prime}$ holds.

We say that a distributed broadcast encryption scheme is statically secure if for any $n$ (polynomially bounded in $\lambda$ ) and any $\operatorname{PPT}$ adversary $\mathcal{A}, \mid \operatorname{Pr}[\mathcal{A}$ wins $]-$ $1 / 2 \mid$ is negligible.

Remark 5 At first glance, the above security notion seems weaker than the usual static security of broadcast encryption because we do not allow an adversary to corrupt receivers who are out of the target set. However, in distributed setting, secret and public keys of such receivers can be simulated efficiently by using the public parameters. Therefore we still capture the setting where the adversary may corrupt some receivers (as long as the set of corrupted users is determined at the beginning of the experiment).

Remark 6 There is stronger security notion for broadcast encryption called adaptive security, where an adversary can determine which receiver to corrupt adaptively. In this paper we only consider the static security and does not consider the adaptive security.

Construction. Here, we give a construction of distributed broadcast encryption scheme based on a multiparty NIKE scheme. This is based on the conversion proposed in [BZ14]. Let (Setup ${ }_{\text {NIKE }}$, Publish $_{\text {NIKE }}$, KeyGen $_{\text {NIKE }}$ ) be a multiparty NIKE scheme. Then we construct a distributed broadcast encryption scheme $\left(\right.$ Setup $_{\mathrm{BE}}$, Join $_{\mathrm{BE}}, \mathrm{Enc}_{\mathrm{BE}}$, Dec $\left._{\mathrm{BE}}\right)$ as follows.
$\operatorname{Setup}_{\mathrm{BE}}\left(1^{\lambda}\right)$ : It runs Setup $\operatorname{SIKE}\left(1^{\lambda}\right)$ to obtain public parameters $P P$ and outputs $P P$ as its own public parameters.
Join $_{\text {BE }}(P P)$ : It runs Publish ${ }_{\text {NIKE }}(P P)$ to obtain a public key $p k$ and a secret key $s k$, and outputs ( $p k, s k$ ).
$\operatorname{Enc}\left(P P, p k_{1}, \ldots, p k_{n}, m s g\right)$ : It runs Publish ${ }_{\text {NIKE }}(P P)$ to obtain $\left(p k^{*}, s k^{*}\right)$. Then it runs $\operatorname{KeyGen}_{\text {NIKE }}\left(\operatorname{PP}, s k,\left\{p k_{j}\right\}_{j=1, \ldots, n}\right)$ to obtain $K$. It computes $\Psi:=$ $K \oplus M$ and outputs a ciphertext $C T=\left(p k^{*}, \Psi\right)$.
$\operatorname{Dec}\left(P P, s k, p k_{1}, \ldots, p k_{n}, C T\right)$ : It parses $C T$ as $p k^{*}, \Psi$. It finds $i$ such that $s k$ is a corresponding secret key of $p k_{i}$. Then it runs $K \leftarrow \operatorname{KeyGen}_{\text {NIKE }}\left(\mathrm{PP}, s k, p k^{*}, p k_{1}, \ldots\right.$, $\left.p k_{i-1}, p k_{i+1}, \ldots, p k_{n}\right)$ and outputs $m s g:=K \oplus \Psi$.

The security of the above scheme is immediate from the security of the underlying multiparty NIKE scheme.

Theorem 12 If the multiparty NIKE scheme (Setup NIKE, Publish $_{\text {NIKE }}$ is statically secure, then the distributed broadcast encryption scheme $\left(\right.$ Setup $_{\mathrm{BE}}, \mathrm{Join}_{\mathrm{BE}}, \mathrm{Enc}_{\mathrm{BE}}$, Dec $\left._{\mathrm{BE}}\right)$ is statically secure.

### 7.3 Fully Homomorphic Signatures

Here, we construct a selectively secure fully homomorphic signatures based on a self-bilinear map that satisfies the $\ell$-APMDH assumption for all $\ell$ such that $\log \ell=\operatorname{poly}(\lambda)$. Our scheme can be seen as an instantiation of the scheme proposed by Catalano et al. [CFW14] with an unbounded level multilinear map obtained by a self-bilinear map. To the best of our knowledge, this is the first fully homomorphic signatures for unbounded depth circuits without relying on SNARKs [BCCT12].

Definition. Here, we only consider the single-data case because there is a generic conversion from single-data homomorphic signatures to multi-data homomorphic signatures [GVW15]. Moreover, we let the message space to be $\{0,1\}$. We note that this does not lose generality because if one wants to sign a longer message, one can simply sign bitwise. A single-data fully homomorphic signature scheme consists of PPT algorithms (KeyGen, Sign, Verify, Eval).
$\operatorname{KeyGen}\left(1^{\lambda}, 1^{n}\right) \rightarrow(v k, s k)$ : This algorithm takes the security parameter $1^{\lambda}$ and a data size $1^{n}$, and outputs a pair ( $v k . s k$ ) of a verification key and a signing key.
$\operatorname{Sign}(s k, i, m) \rightarrow \sigma$ : This algorithm takes a signing key $s k$, an index $i \in[n]$ and a message $m \in\{0,1\}$, and outputs a signature $\sigma$.
$\operatorname{Eval}\left(f,\left(m_{1}, \sigma_{1}\right), \ldots,\left(m_{n}, \sigma_{n}\right)\right) \rightarrow \sigma^{*}$ : This algorithm takes a function $f$ (described by a polynomial size circuit) and pairs $\left(m_{1}, \sigma_{1}\right), \ldots,\left(m_{n}, \sigma_{n}\right)$ of a message and a signature, and outputs a signature $\sigma^{*}$ for the message $f\left(m_{1}, \ldots, m_{n}\right)$.
$\operatorname{Verify}(v k, f, m, \sigma) \rightarrow 1 / 0$ : This algorithm takes a verification key $v k$, a function $f$, a message $m$ and a signature $\sigma$, and outputs 1 if accepts and 0 else

Remark 7 In the above, we only consider the verification of evaluated signature output by Eval, but one can also verify "fresh" signatures generated by Sign by setting $f$ to be the identity function.

We require a fully homomorphic signature scheme to satisfy the following properties.

Correctness For any $(v k, s k) \stackrel{\&}{\leftarrow} \operatorname{KeyGen}\left(1^{\lambda}, 1^{n}\right),\left(m_{1}, \ldots, m_{n}\right) \in\{0,1\}^{N}$ and a function $f$ (described by a polynomial size circuit), if we let $\sigma_{i} \leftarrow \operatorname{Sign}\left(s k, i, m_{i}\right)$, $m^{*}:=f\left(m_{1}, \ldots, m_{n}\right)$, and $\sigma^{*}:=\operatorname{Eval}\left(f,\left(m_{1}, \sigma_{1}\right), \ldots,\left(m_{n}, \sigma_{n}\right)\right)$, then we have $\operatorname{Verify}\left(v k, f, m^{*}, \sigma^{*}\right)=1$.

Security. In this paper, we only consider the selective security. To define the selective security, we consider the following game between an adversary $\mathcal{A}$ and a challenger.
$\mathcal{A}$ sends $\left(m_{1}, \ldots, m_{n}\right) \in\{0,1\}^{n}$ to the challenger. The challenger generates $(v k, s k) \leftarrow \operatorname{KeyGen}\left(1^{\lambda}, 1^{n}\right)$, computes $\sigma_{i} \leftarrow \operatorname{Sign}\left(s k, i, m_{i}\right)$ for $i \in[n]$ and gives $v k, \sigma_{1}, \ldots, \sigma_{n}$ to $\mathcal{A}$. $\mathcal{A}$ outputs $\left(f^{*}, m^{*}, \sigma^{*}\right)$. We say that $\mathcal{A}$ wins if
$\operatorname{Verify}\left(v k, f^{*}, m^{*}, \sigma^{*}\right)$ and $m^{*} \neq f^{*}\left(m_{1}, \ldots, m_{n}\right)$ hold. We say that the a homomorphic signature scheme is selectively secure if for any $n=\operatorname{poly}(\lambda)$ and any PPT algorithm $\mathcal{A}$, the probability that $\mathcal{A}$ wins in the above game is negligible.

Construction. Here, we construct a selectively secure single data fully homomorphic signature scheme. Our scheme is based on the idea of [CFW14]. Namely, our scheme is almost automatically obtained by replacing a multilinear map by a self-bilinear map in the scheme of [CFW14].

Before giving our construction, we prepare some notations and remarks on (arithmetic) circuits. We can convert any boolean circuit $f:\{0,1\}^{n} \rightarrow\{0,1\}$ to an equivalent arithmetic circuit $f^{\prime}: \mathbb{Z}^{n} \rightarrow \mathbb{Z}$ such that $f\left(x_{1}, \ldots, x_{n}\right)=$ $f^{\prime}\left(x_{1}, \ldots, x_{n}\right)$ for any $\left(x_{1}, \ldots, x_{n}\right) \in\{0,1\}^{n}$. For an arithmetic circuit $f$ and a wire $w$ of $f, f_{w}$ denotes an arithmetic circuit that outputs the value assigned to $w$. More precisely, if $w$ is an input gate corresponding to $i$-th input, we define $f_{w}\left(x_{1}, \ldots, x_{n}\right):=x_{i}$ and if $w$ is an output gate of the gate that computes $\circ \in\{+,-, \cdot\}$ for input wires $w_{1}$ and $w_{2}$, we define $f_{w}\left(x_{1}, \ldots, x_{n}\right):=$ $f_{w_{1}}\left(x_{1} \ldots, x_{n}\right) \circ f_{w_{2}}\left(x_{1}, \ldots x_{n}\right)$. We define $w$ 's degree as the degree of $f_{w}$. As discussed in [CFW14], without loss of generality, we can assume that incoming wires of an addition gate is the same degree. Therefore in our construction, we assume that $f$ is given as an arithmetic circuit with this property.

The construction of our scheme is as follows. We let message space to be $\{0,1\}$.
$\operatorname{KeyGen}\left(1^{\lambda}, 1^{n}\right) \rightarrow(v k, s k)$ : This algorithm generates $P P \stackrel{\&}{\leftarrow} \operatorname{GGen}\left(1^{\lambda}\right)$, chooses $r_{i} \stackrel{\&}{\leftarrow}\left[2^{\ell+\lambda}\right](i=1, \ldots, n)$ and $x, y, z \stackrel{\&}{\leftarrow}\left[2^{\ell+\lambda}\right]$, and sets $R_{i}:=\left[r_{i}\right]_{1}(i=$ $1, \ldots, n), X:=[x]_{1}, Y:=[y]_{1}, Z=[z]_{1}, S:=[x y]_{1} T:=[y z]_{1}$ and $U:=$ $[x y z]_{1}$. Then it sets $v k:=\left(P P,\left\{R_{i}\right\}_{i \in[n+1]}, X, Y, Z, S, T, U\right), s k:=(x, y, v k)$ and outputs (vk.sk).
$\operatorname{Sign}(s k, i, m) \rightarrow \sigma:$ This algorithm computes $\Lambda:=y \cdot\left(R_{i}-m \cdot Z\right), \quad \Gamma:=x \cdot \Lambda$, and outputs $\sigma:=(\Lambda, \Gamma)$.
$\operatorname{Eval}\left(p k, f,\left(m_{1}, \sigma_{1}\right), \ldots,\left(m_{n}, \sigma_{n}\right)\right) \rightarrow \sigma^{*}:$ Parse as $\left(\Lambda_{i}, \Gamma_{i}\right) \leftarrow \sigma_{i}$ for all $i \in[n]$. For all wires $w$ of $f$, this algorithm computes $\Lambda_{w}$ and $\Gamma_{w}$ as follows. If $w$ is an input wire of the circuit corresponding to $i$-th input, then it sets $\Lambda_{w}:=\Lambda_{i}$ and $\Gamma_{w}:=\Gamma_{i}$. Then it computes as follows gate by gate.
Addition Gate: Let $w$ be an output wire of an addition gate whose input gates are $w_{1}$ and $w_{2}$. It computes

$$
\Lambda_{w}:=\Lambda_{w_{1}}+\Lambda_{w_{2}}, \Gamma_{w}:=\Gamma_{w_{1}}+\Gamma_{w_{2}} .
$$

Multiplication Gate: Let $w$ be an output wire of an addition gate whose input gates are $w_{1}$ and $w_{2}$. Let $d_{1}, d_{2}, d$ be degrees of $w_{1}, w_{2}, w$ respectively. (Then we have $d=d_{1}+d_{2}$ by the definition of degree.) It computes

$$
\begin{aligned}
\Lambda_{w} & :=e\left(\Lambda_{w_{1}}, \Gamma_{w_{2}}\right)+e\left(\Lambda_{w_{1}}, f_{w_{2}}(m) \cdot U_{d_{2}}\right)+e\left(f_{w_{1}}(m) \cdot U_{d_{1}}, \Lambda_{w_{2}}\right) \\
\Gamma_{w} & :=e\left(\Gamma_{w_{1}}, \Gamma_{w_{2}}\right)+e\left(\Gamma_{w_{1}}, f_{w_{2}}(m) \cdot U_{d_{2}}\right)+e\left(f_{w_{1}}(m) \cdot U_{d_{1}}, \Gamma_{w_{2}}\right)
\end{aligned}
$$

where $U_{d_{i}}$ denotes $e_{d_{i}}(U, \ldots, U)$ and $f_{w_{i}}(m)$ denotes $f_{w_{i}}\left(m_{1}, \ldots, m_{n}\right)$ for $i=1,2$.
Let $w_{\text {out }}$ be the output wire of $f$. Then it outputs $\sigma^{*}=\left(\Lambda_{w_{\text {out }}}, \Gamma_{w_{\text {out }}}\right)$. $\operatorname{Verify}(p k, f, m, \sigma) \rightarrow 1 / 0$ : Parse $(\Lambda, \Gamma) \leftarrow \sigma$. Let $d$ be the degree of $f$. It computes $R=\left[f\left(r_{1}, \ldots, r_{n}\right)\right]_{d}, Z_{d}=e_{d}(Z, \ldots, Z)$ and $W_{d}=\left[x^{d-1} y^{d}\right]_{d}=$ $e\left(e_{d}(S, \ldots, S), X\right)$. We remark that though this algorithm does not take $r_{1}, \ldots, r_{n}$ as input, $R$ can be computed efficiently by "evaluating $f$ on $R_{1}, \ldots, R_{n}$ " where an addition gate is interpreted as an addition on $G$ and a multiplication gate is interpreted as an evaluation of $e$. If

$$
e\left(R-m \cdot Z_{d}, W_{d}\right)=e\left(\Lambda,[1]_{d}\right)
$$

and

$$
e\left(\Gamma,[1]_{1}\right)=e(\Lambda, X)
$$

hold, then it outputs 1 and otherwise outputs 0 .
This complete the description of the scheme.
We check the correctness of the scheme. In the following for any wire $w$, we denote $f_{w}\left(r_{1}, \ldots, r_{n}\right)$ and $f_{w}\left(m_{1}, \ldots, m_{n}\right)$ by $f_{w}(r)$ and $f_{w}(m)$ respectively for simplicity. For proving the correctness, we show the following claim.

Claim 1 Let $\sigma_{i}=\left(\Lambda_{i}, \Gamma_{i}\right)$ be a signature generated by $\operatorname{Sign}\left(s k, i, m_{i}\right)$. Then in the computation of $\operatorname{Eval}\left(p k, f,\left\{\left(m_{i} \sigma_{i}\right)\right\}_{i \in[n]}\right)$, for any wire $w$ of $f$ with degree $d$, we have

$$
\Lambda_{w}=\left[x^{d-1} y^{d}\left(f_{w}(r)-f_{w}(m) z^{d}\right)\right]_{d}
$$

and

$$
\Gamma_{w}=\left[x^{d} y^{d}\left(f_{w}(r)-f_{w}(m) z^{d}\right)\right]_{d}
$$

Proof. (of Claim 1.) We prove this claim by induction. First, for an input wire $w$, the claim holds since if $w$ is an output wire of the $i$-th input gate, then we have $\left[x^{0} y^{1}\left(f_{w}(r)-f_{w}(m) z^{1}\right)\right]_{1}=y\left[r_{i}-m_{i} z\right]_{1}=y \cdot\left(R-m_{i} \cdot Z\right)$ and $\left[x^{1} y^{1}\left(f_{w}(r)-\right.\right.$ $\left.\left.f_{w}(m) z^{1}\right)\right]_{1}=x y \cdot\left(R-m_{i} \cdot Z\right)$. We assume that the claim holds for all wires whose depth is smaller than $k$ and prove that the claim holds for any wire $w$ with depth $k+1$. Let $w_{1}$ and $w_{2}$ be incoming wires of the gate from which $w$ comes, and $d_{1}$ and $d_{2}$ be degrees of $w_{1}$ and $w_{2}$ respectively. Then we have $\Lambda_{w_{i}}=\left[x^{d_{i}-1} y^{d_{i}}\left(f_{w_{i}}(r)-f_{w_{i}}(m) z^{d_{i}}\right)\right]_{d_{i}}$ and $\Gamma_{w_{i}}=\left[x^{d_{i}} y^{d_{i}}\left(f_{w_{i}}(r)-f_{w_{i}}(m) z^{d_{i}}\right)\right]_{d_{i}}$. We consider the following cases depending on the type of the gate.

Addition: This is the case that $w$ is an output of an addition gate. In this case, we have

$$
\Lambda_{w}=\Lambda_{w_{1}}+\Lambda_{w_{2}}=\left[x^{d-1} y^{d}\left(f_{w}(r)-f_{w}(m) z^{d}\right)\right]_{d}
$$

and

$$
\Gamma_{w}=\Lambda_{w_{1}}+\Lambda_{w_{2}}=\left[x^{d} y^{d}\left(f_{w}(r)-f_{w}(m) z^{d}\right)\right]_{d}
$$

where we used $f_{w_{1}}(r)+f_{w_{2}}(r)=f_{w}(r), f_{w_{1}}(m)+f_{w_{2}}(m)=f_{w}(m)$ and $d_{1}=d_{2}=d$.

Multiplication: This is the case that $w$ is an output of a multiplication gate. Let $w_{1}$ and $w_{2}$ be incoming wires to the gate, and $d_{1}$ and $d_{2}$ be degrees of $w_{1}$ and $w_{2}$ respectively. Then we have

$$
\begin{aligned}
\Lambda_{w}= & e\left(\Lambda_{w_{1}}, \Gamma_{w_{2}}\right)+e\left(\Lambda_{w_{1}}, f_{w_{2}}(m) \cdot U_{d_{2}}\right)+e\left(f_{w_{1}}(m) \cdot U_{d_{1}}, \Lambda_{w_{2}}\right) \\
= & {\left[x ^ { d _ { 1 } + d _ { 2 } - 1 } y ^ { d _ { 1 } + d _ { 2 } } \left(f_{w_{1}}(r) f_{w_{2}}(r)-z^{d_{2}} f_{w_{1}}(r) f_{w_{2}}(m)\right.\right.} \\
& \left.\left.-z^{d_{1}} f_{w_{2}}(r) f_{w_{1}}(m)+f_{w_{1}}(m) f_{w_{2}}(m) z^{d_{1}+d_{2}}\right)\right]_{d_{1}+d_{2}} \\
+ & {\left[x^{d_{1}+d_{2}-1} y^{d_{1}+d_{2}} z^{d_{2}}\left(f_{w_{1}}(r) f_{w_{2}}(m)-f_{w_{1}}(m) f_{w_{2}}(m) z^{d_{1}}\right)\right]_{d_{1}+d_{2}} } \\
+ & {\left[x^{d_{1}+d_{2}-1} y^{d_{1}+d_{2}} z^{d_{1}}\left(f_{w_{2}}(r) f_{w_{1}}(m)-f_{w_{1}}(m) f_{w_{2}}(m) z^{d_{2}}\right)\right]_{d_{1}+d_{2}} } \\
= & {\left[x^{d-1} y^{d}\left(f_{w}(r)-f_{w}(m) z^{d}\right)\right]_{d} }
\end{aligned}
$$

and

$$
\begin{aligned}
\Gamma_{w} & =e\left(\Gamma_{w_{1}}, \Gamma_{w_{2}}\right)+e\left(\Gamma_{w_{1}}, f_{w_{2}}(m) \cdot U_{d_{2}}\right)+e\left(f_{w_{1}}(m) \cdot U_{d_{1}}, \Gamma_{w_{2}}\right) \\
& =x \cdot \Lambda_{w} \\
& =\left[x^{d} y^{d}\left(f_{w}(r)-f_{w}(m) z^{d}\right)\right]_{d}
\end{aligned}
$$

where we used $f_{w_{1}}(r) f_{w_{2}}(r)=f_{w}(r), f_{w_{1}}(m) f_{w_{2}}(m)=f_{w}(m)$ and $d=$ $d_{1}+d_{2}$.

Therefore, in any case, the claim also holds for $w$. Therefore the claim holds.
By the claim, if we let $(\Lambda, \Gamma) \stackrel{\&}{\leftarrow} \operatorname{Eval}\left(p k, f,\left\{\left(m_{i}, \sigma_{i}\right)\right\}_{i \in[n]}\right)$, then we have

$$
\Lambda=\left[x^{d-1} y^{d}\left(f(r)-f(m) z^{d}\right)\right]_{d}
$$

and

$$
\Gamma=\left[x^{d} y^{d}\left(f(r)-f(m) z^{d}\right)\right]_{d} .
$$

where $f(r)$ and $f(m)$ denotes $f\left(r_{1}, \ldots, r_{n}\right)$ and $f\left(m_{1}, \ldots, m_{n}\right)$ respectively and $d$ is the degree of $f$. If $m^{*}=f(m)$, then we have

$$
e\left(R-m^{*} \cdot Z_{d}, W_{d}\right)=e\left(\left[f(r)-f(m) \cdot z^{d}\right]_{d},\left[x^{d-1} y^{d}\right]_{d}\right)=e\left(\Lambda,[1]_{d}\right)
$$

and

$$
e\left(\Gamma,[1]_{1}\right)=e\left(x \cdot \Lambda,[1]_{1}\right)=e(\Lambda, X)
$$

Therefore the correctness holds.
The security of the scheme can be stated as follows.
Theorem 13 If the $\ell-A P S B D H$ assumption holds for all $\ell$ such that $\log (\ell)=$ poly $(\lambda)$ for the underlying self-bilinear map, then the above scheme is selectively secure.

Proof. We assume that there exists an adversary $\mathcal{A}$ that breaks the selective security of the scheme. Let $d_{\max }$ be the maximum degree of $f$ output by $\mathcal{A}$ as a part of a forgery. Then we construct an algorithm $\mathcal{B}$ that breaks the $d_{\text {max }}{ }^{-}$ APMDH assumption by using $\mathcal{A}$.
$\mathcal{B}\left(P P,\left[x_{1}\right]_{1},\left[x_{2}\right]_{1},\left[x_{3}\right]_{1},\left[x_{1} x_{2}\right]_{1},\left[x_{1} x_{3}\right]_{1},\left[x_{1} x_{2} x_{3}\right]_{1}\right):$ First, runs $\mathcal{A}$ to obtain a signature query $\left(m_{1}, \ldots, m_{n}\right)$. Then $\mathcal{B}$ chooses $y_{i} \stackrel{\&}{\leftarrow}\left[2^{\ell+\lambda}\right]$ and sets $R_{i}:=\left[y_{i}\right]_{1}+$ $m_{i} \cdot\left[x_{3}\right]_{1}$ for $i \in[n]$. It sets $X:=\left[x_{1}\right]_{1}, Y:=\left[x_{2}\right]_{1}, Z:=\left[x_{3}\right]_{1}, S:=\left[x_{1} x_{2}\right]_{1}$, $T:=\left[x_{1} x_{3}\right]_{1}, U:=\left[x_{1} x_{2} x_{3}\right]_{1}$ and $p k:=\left(P P,\left\{R_{i}\right\}_{i \in[n]}, X, Y, Z, S, T, U\right)$. For $i=1,2, \ldots, n$ it sets $\Lambda_{i}:=y_{i} \cdot\left[x_{2}\right]_{1}, \Gamma_{i}:=y_{i} \cdot\left[x_{1} x_{2}\right]_{1}$ and $\sigma_{i}:=\left(\Lambda_{i}, \Gamma_{i}\right)$. Then $\mathcal{B}$ gives $p k$ and $\left\{\sigma_{i}\right\}_{i \in[n]}$ to $\mathcal{A}$. Let $\left(f^{*}, m^{*}, \sigma^{*}=\left(\Lambda^{*}, \Gamma^{*}\right)\right)$ be the forgery output by $\mathcal{A}$. Let $d^{*}$ be the degree of $f^{*}$. Then $\mathcal{B}$ computes $\sigma^{\prime}=\left(\Lambda^{\prime}, \Gamma^{\prime}\right) \stackrel{\$}{\leftarrow}$ $\operatorname{Eval}\left(p k, f^{*},\left\{\left(m_{i}, \sigma_{i}\right)\right\}_{i \in[n]}\right), \alpha:=\left(f^{*}\left(m_{1}, \ldots, m_{n}\right)-m^{*}\right)\left(\Lambda^{*}-\Lambda^{\prime}\right)$ and outputs $e\left(\alpha, U_{d_{\max }-d^{*}}\right)$ where $U_{d_{\max }-d^{*}}$ denotes $e_{d_{\max }-d^{*}}(U, \ldots, U)$. (If $d_{\max }=d^{*}$, then it outputs $\alpha$.)

We show that $\mathcal{B}$ works correctly. It is easy to verify that the statistical distance between $p k$ simulated by $\mathcal{B}$ and $p k$ in the real scheme is negligible. We note that $x, y$ and $z$ are implicitly set to be $x_{1}, x_{2}$ and $x_{3}$ respectively and $r_{i}$ is set to be $y_{1}+m_{i} \cdot x_{3}$ for $i \in[n]$. We have $x_{2} \cdot\left(R_{i}-m_{i} \cdot Z\right)=x_{2} \cdot\left[y_{i}\right]_{1}=y_{i} \cdot\left[x_{2}\right]_{1}$ and $x_{1} x_{2} \cdot\left(R_{i}-m_{i} \cdot Z\right)=y_{i} \cdot\left[x_{1} x_{2}\right]_{1}$. Therefore signatures for $m_{i}$ are simulated correctly. Therefore if $\mathcal{A}$ breaks the selective security of the scheme, then it outputs $\left(f^{*}, m^{*}, \sigma^{*}=\left(\Lambda^{*}, \Gamma^{*}\right)\right)$ such that

$$
\begin{gathered}
e\left(R-m^{*} \cdot Z_{d^{*}}, W_{d^{*}}\right)=e\left(\Lambda^{*},[1]_{d^{*}}\right) \\
e\left(\Gamma,[1]_{1}\right)=e\left(\Lambda^{*}, X\right)
\end{gathered}
$$

and $m^{*} \neq f^{*}\left(m_{1}, \ldots, m_{n}\right)$ hold with non-negligible probability where we have $R=\left[f\left(r_{1}, \ldots, r_{n}\right)\right]_{d^{*}}, Z_{d}=\left[x_{3}\right]_{d^{*}}$ and $W_{d}=\left[x_{1}^{d^{*}-1} x_{2}^{d^{*}}\right]_{d^{*}}$. On the other hand, by the correctness of the scheme, we have

$$
\begin{gathered}
e\left(R-f^{*}\left(m_{1}, \ldots, m_{n}\right) \cdot Z_{d^{*}}, W_{d^{*}}\right)=e\left(\Lambda^{\prime},[1]_{d^{*}}\right) \\
e\left(\Gamma^{\prime},[1]_{1}\right)=e\left(\Lambda^{\prime}, X\right)
\end{gathered}
$$

Therefore we have

$$
e\left(\left(f^{*}\left(m_{1}, \ldots, m_{n}\right)-m^{*}\right) \cdot Z_{d^{*}}, W_{d^{*}}\right)=e\left(\Lambda^{*}-\Lambda^{\prime},[1]_{d^{*}}\right)
$$

This is equivalent to $\Lambda^{*}-\Lambda^{\prime}=\left(f^{*}\left(m_{1}, \ldots, m_{n}\right)-m^{*}\right) \cdot\left[x_{1}^{d^{*}-1}\left(x_{2} x_{3}\right)^{d^{*}}\right]_{d^{*}}$. Since $f^{*}\left(m_{1}, \ldots, m_{n}\right)-m^{*} \in\{1,-1\}$, we have $\alpha=\left(f^{*}\left(m_{1}, \ldots, m_{n}\right)-m^{*}\right) \cdot\left(\Lambda^{*}-\right.$ $\left.\Lambda^{\prime}\right)=\left(f^{*}\left(m_{1}, \ldots, m_{n}\right)-m^{*}\right)^{2} \cdot\left[x_{1}^{d^{*}-1}\left(x_{2} x_{3}\right)^{d^{*}}\right]_{d}=\left[x_{1}^{d^{*}-1}\left(x_{2} x_{3}\right)^{d^{*}}\right]_{d^{*}}$ and thus $e\left(\alpha, U_{d_{\max }-d^{*}}\right)=\left[x_{1}^{d_{\max }-1}\left(x_{2} x_{3}\right)^{d_{\max }}\right]_{d_{\max }}$. Therefore $\mathcal{B}$ succeeds in breaking the $d_{\text {max }}-\mathrm{APMDH}$ assumption.

## A Instantiation of Inversion-hard Ring via VBB Obfuscation

Here, we give a concrete instantiation of a ring scheme that satisfies the $c$ inversion assumption based on a VBB obfuscation. Since it is known that there does not exist a VBB obfuscation, we consider our construction just as a proof of concept.

## A. 1 Definitions

Here, we give definitions needed for stating our construction.
Pseudorandom permutation. Here, we define a pseudorandom permutation (PRP). A pseudorandom permutation on $\{0,1\}^{\ell}$ consists of PPT algorithms (PRPGen, PRP, $\mathrm{PRP}^{-1}$ ).
$\operatorname{PRPGen}\left(1^{\lambda}\right) \rightarrow K$ : This algorithm takes the security parameter $1^{\lambda}$ as input and output a key $K$.
$\operatorname{PRP}(K, x) \rightarrow y$ : This algorithm takes a key $K$ and $x \in\{0,1\}^{\ell}$ as input, and outputs $y \in\{0,1\}^{\ell}$.
$\operatorname{PRP}(K, y) \rightarrow x$ : This algorithm takes a key $K$ and $y \in\{0,1\}^{\ell}$ as input and outputs $x \in\{0,1\}^{\ell}$

As correctness we require that for every $\lambda \in \mathbb{N}$, every $K \stackrel{\$}{\leftarrow} \operatorname{KeyGen}\left(1^{\lambda}\right)$ and every $x \in\{0,1\}^{\ell}$, we have $\operatorname{PRP}^{-1}(K, \operatorname{PRP}(K, x))=x$.

As security, we require the following. For any PPT distinguisher $\mathcal{D}$,

$$
\operatorname{Pr}\left[1 \stackrel{\left.\$ \mathcal{D}^{\operatorname{PRP}(K, \cdot), \operatorname{PRP}^{-1}(K, \cdot)}\right]-\operatorname{Pr}\left[1 \stackrel{\$}{\leftarrow} \mathcal{D}^{\sigma(\cdot), \sigma^{-1}(\cdot)}\right], ~}{\text {. }}\right.
$$

is negligible where $K \stackrel{\$}{\leftarrow} \operatorname{PRPGen}\left(1^{\lambda}\right)$ and $\sigma$ is chosen from the set of all permutations over $\{0,1\}^{\ell}$. It is known that there exists a PRP if there exists a one-way function [LR88,GGM86,HILL99].

Virtual black-box obfuscation We define a virtual black-box (VBB) obfuscation.

Definition 17 (Virtual black-box obfuscation [BGI+ 01].) For a circuit class $\left\{\mathcal{C}_{\lambda}\right\}_{\lambda \in \mathbb{N}}$, we say that a PPT oracle machine $\mathcal{O}$ is a virtual black-box (VBB) obfuscator if the following conditions are satisfied.

Functionality: For every $\lambda \in \mathbb{N}$, every $C \in \mathcal{C}_{\lambda}$ and every input $x$ to $C$, there exists a negligible function negl such that

$$
\operatorname{Pr}[\mathcal{O}(C)(x) \neq C(x)] \leq \operatorname{negl}(|C|)
$$

where the probability is over the coins of $\mathcal{O}$.
Virtual black-box: For every PPT adversary $\mathcal{A}$, there exists a PPT simulator $\mathcal{S}$ and a negligible function $\mu$ such that for every $\lambda \in \mathbb{N}$ and every $C \in \mathcal{C}_{\lambda}$,

$$
\left|\operatorname{Pr}[1 \stackrel{\&}{\leftarrow} \mathcal{A}(\mathcal{O}(C))]-\operatorname{Pr}\left[1 \stackrel{\&}{\leftarrow}_{\leftarrow} S^{C}\left(1^{|C|}\right)\right]\right| \leq \mu(|C|)
$$

where the probabilities are over the coins of $\mathcal{D}, \mathcal{A}, \mathcal{S}$ and $\mathcal{O}$.
Definition 18 (VBB obfuscation for P/poly.) We say that $\mathcal{O}$ is a VBB obfuscator for $P /$ poly $i f$ for every circuit class $\mathcal{C}=\left\{\mathcal{C}_{\lambda}\right\}_{\lambda \in \mathbb{N}}$ such that every circuit in $\mathcal{C}_{\lambda}$ is of size $\operatorname{poly}(\lambda), \mathcal{O}$ is a VBB obfuscator for $\mathcal{C}$.

Barak et al. proved that a VBB obfuscator for $P /$ poly does not exist in the standard model. On the other hand, Garg et al. [GMM $\left.{ }^{+} 16\right]$ proved that there exists a VBB obfuscator for $P /$ poly in the weak multilinear map model [MSZ16] if there exists a pseudorandom function (PRF) computable in $N C^{1}$.

## A. 2 Construction

Construction. We construct a ring scheme based on a pseudorandom permutation (PRP) (PRPGen, PRP, $\mathrm{PRP}^{-1}$ ) on $2^{\ell^{\prime}}$ where we assume $\ell^{\prime} \geq \ell+\lambda$ and a VBB obfuscator $\mathcal{O}$ in the weak multilinear map model. The definition of a PRP is given in Appendix A.1. For any prime $c$, we construct a ring scheme as follows.
$\operatorname{GGen}\left(1^{\lambda}\right) \rightarrow P P$ : This algorithm generates $p \stackrel{\$}{\leftarrow}_{\leftarrow}^{\mathcal{P}_{\ell}}$ and $K \leftarrow \operatorname{KGen}\left(1^{\lambda}\right)$, and computes $\tilde{C}_{\text {ring }} \stackrel{\&}{\leftarrow} \mathcal{O}\left(C_{\text {ring }}\right)$ where the description of $C_{\text {ring }}$ is given in Fig. 1. This specifies a ring $R:=\left\{\operatorname{PRP}(K, X): X \in \mathbb{Z}_{p}\right\}$ whose multiplicative identity is $[1]_{R}:=\operatorname{PRP}(K, 1)$ and whose ring operations are defined by $\operatorname{PRP}(K, X) \circ \operatorname{PRP}(K, Y):=\operatorname{PRP}(K,(X \circ Y \bmod p))$ for $X, Y \in \mathbb{Z}_{p}$ and $\circ \in\{+,-, \cdot\}$. Intuitively, the circuit $C_{\text {ring }}$ makes it possible to compute operations on this ring efficiently. More precisely, it has three modes that are identity, operation and test modes depending on the first component of an input. In the identity mode, it outputs the multiplicative identity of a ring, in the operation mode, it simulates a ring operation and in the test mode, the circuit tests whether the $c$-inversion assumption was broken or not. It outputs $P P:=\tilde{C}_{\text {ring }}$.
$\operatorname{Add}\left(\mathrm{Enc}_{1}, \mathrm{Enc}_{2}\right) \rightarrow \mathrm{Enc}^{\prime}:$ This algorithm computes Enc ${ }^{\prime} \leftarrow \tilde{C}_{\text {ring }}\left(\mathrm{Enc}_{1}, \mathrm{Enc}_{2},+\right)$ and output Enc ${ }^{\prime}$.
$\operatorname{Sub}\left(\mathrm{Enc}_{1}, \mathrm{Enc}_{2}\right) \rightarrow \mathrm{Enc}^{\prime}:$ This algorithm computes Enc ${ }^{\prime} \leftarrow \tilde{C}_{\text {ring }}\left(\mathrm{Enc}_{1}, \mathrm{Enc}_{2},-\right)$ and outputs Enc ${ }^{\prime}$.

| Circuit $C_{\text {ring }}[p, K]$ (mode, in): | Circuit $C_{\text {ring }}^{\prime}[p, K]$ (mode, in): |
| :---: | :---: |
| If mode $=$ identity | If mode $=$ identity |
| Output PRP ( $K, 1$ ) | Output PRP(K,1) |
| If mode $=$ operation | If mode $=$ operation |
| Parse (Enc $\left.{ }_{1}, \mathrm{Enc}_{2}, 0\right) \leftarrow$ in | Parse (Enc $\left.{ }_{1}, \mathrm{Enc}_{2}, \mathrm{o}\right) \leftarrow$ in |
| $X_{1} \leftarrow \mathrm{PRP}^{-1}\left(K, \mathrm{Enc}_{1}\right)$ | $X_{1} \leftarrow \mathrm{PRP}^{-1}\left(K, \mathrm{Enc}_{1}\right)$ |
| $X_{2} \leftarrow \mathrm{PRP}^{-1}\left(K, \mathrm{Enc}_{2}\right)$ | $X_{2} \leftarrow \mathrm{PRP}^{-1}\left(K, \mathrm{Enc}_{2}\right)$ |
| If $X_{1} \notin \mathbb{Z}_{p}$ or $X_{2} \notin \mathbb{Z}_{p}$ Output $\perp$ | $\begin{aligned} & \text { If } X_{1} \notin \mathbb{Z}_{p} \text { or } X_{2} \notin \mathbb{Z}_{p} \\ & \text { Output } \perp \end{aligned}$ |
| Else | Else |
| $X^{\prime}:=X_{1} \circ X_{2} \bmod p$ | $X^{\prime}:=X_{1} \circ X_{2} \bmod p$ |
| $\mathrm{Enc}^{\prime} \leftarrow \operatorname{PRP}\left(K, X^{\prime}\right)$ | $\mathrm{Enc}^{\prime} \leftarrow \operatorname{PRP}\left(K, X^{\prime}\right)$ |
| Output Enc ${ }^{\prime}$ | Output Enc ${ }^{\prime}$ |
| If mode $=$ test | If mode $=$ test |
| Parse $\left(\overline{\mathrm{P}}\right.$, Enc $\left.^{*}\right) \leftarrow$ in | Output $\perp$ |
| $X^{*} \leftarrow \mathrm{PRP}^{-1}\left(K, \mathrm{Enc}^{*}\right)$ |  |
| If $X^{*} \notin \mathbb{Z}_{p}$ Output $\perp$ |  |
| Else |  |
| If $X^{*}=[c]_{\mathbb{Z}_{p}}^{-1} \cdot \overline{\mathrm{P}}\left(\mathbb{Z}_{p}\right)$ and $\overline{\mathrm{P}}\left(\mathbb{Z}_{c}\right) \neq 0$ Output 1 |  |
| Else |  |
| Output 0 |  |

Fig. 1. Description of circuits $C_{\text {ring }}[p, K]$ and $C_{\text {ring }}^{\prime}[p, K]$.

Mult $\left(\mathrm{Enc}_{1}, \mathrm{Enc}_{2}\right) \rightarrow \mathrm{Enc}^{\prime}:$ This algorithm computes $\mathrm{Enc}^{\prime} \leftarrow \tilde{C}_{\text {ring }}\left(\mathrm{Enc}_{1}, \mathrm{Enc}_{2}, \cdot\right)$ and outputs Enc ${ }^{\prime}$.

Remark 8 The test mode of $C_{\text {ring }}[p, K]$ is not necessary for the correctness of the scheme. This mode is used only in the security proof.

We prove that the $c$-inversion assumption holds for the above ring scheme under the factoring assumption w.r.t. unbalanced moduli.

Theorem 14 If the factoring assumption w.r.t. unbalanced moduli holds, then the c-inversion assumption holds for the above ring scheme.

Proof. Let $C_{\text {ring }}^{\prime}[p, K]$ be a circuit that works similarly to $C_{\text {ring }}[p, K]$ except that it always outputs $\perp$ when mode $=$ test. (The full description is given in Fig. 1.) Let $\mathcal{A}$ be a PPT algorithm against the $c$-inversion assumption for the scheme. Then we consider another PPT algorithm $\mathcal{B}$ that distinguish obfuscations of $C_{\text {ring }}[p, K]$ and $C_{\text {ring }}^{\prime}[p, K]$. The description of $\mathcal{B}$ is as follows.
$\mathcal{B}(\tilde{C}) \mathcal{B}$ is given an obfuscated circuit $\tilde{C}$ as input and runs $\left(\overline{\mathrm{P}}, \mathrm{Enc}^{*}\right) \stackrel{\&}{\leftarrow} \mathcal{A}(\tilde{C})$. It outputs as $\tilde{C}\left(\right.$ test, $\left(\overline{\mathrm{P}}\right.$, Enc $\left.\left.^{*}\right)\right)$ outputs.

If $\tilde{C}$ is an obfuscation of $C_{\text {ring }}[p, K], \mathcal{B}$ outputs 1 in the test mode if and only if $\mathcal{A}$ succeeds in breaking the $c$-inversion assumption, and if $\tilde{C}$ is an obfuscation of $C_{\text {ring }}[p, K], \mathcal{B}$ never outputs 1 . Therefore we have

$$
\operatorname{Adv}_{\mathcal{A}}^{\text {gen-inv }}(\lambda)=\operatorname{Pr}\left[1 \stackrel{\mathcal{B}}{\leftarrow}(\tilde{C}): \tilde{C} \stackrel{\&}{\leftarrow} \mathcal{O}\left(C_{\text {ring }}[p, K]\right)\right]
$$

and

$$
0=\operatorname{Pr}\left[1 \stackrel{\&}{\leftarrow} \mathcal{B}(\tilde{C}): \tilde{C} \stackrel{\&}{\leftarrow} \mathcal{O}\left(C_{\mathrm{ring}}^{\prime}[p, K]\right)\right]
$$

where $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$ and $K \stackrel{\&}{\leftarrow} \operatorname{KGen}\left(1^{\lambda}\right)$.
On the other hand, by the property of a VBB obfuscation, there exists a PPT algorithm $\mathcal{S}$ such that

$$
\left|\operatorname{Pr}\left[1 \stackrel{\&}{\leftarrow} \mathcal{B}(\tilde{C}): \tilde{C} \stackrel{\&}{\leftarrow} \mathcal{O}\left(C_{\text {ring }}[p, K]\right)\right]-\operatorname{Pr}\left[1 \stackrel{\&}{\leftarrow} \mathcal{S}^{C_{\text {ring }}[p, K]}\left(1^{M}\right)\right]\right|
$$

and

$$
\left|\operatorname{Pr}\left[1 \stackrel{\S}{\leftarrow} \mathcal{B}(\tilde{C}): \tilde{C} \stackrel{\&}{\leftarrow} \mathcal{O}\left(C_{\text {ring }}^{\prime}[p, K]\right)\right]-\operatorname{Pr}\left[1 \stackrel{\&}{\leftarrow} \mathcal{S}^{C_{\text {ring }}^{\prime}[p, K]}\left(1^{M}\right)\right]\right|
$$

are negligible where $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$ and $K \stackrel{\&}{\leftarrow} \mathrm{KGen}\left(1^{\lambda}\right)$ and $M$ denotes the maximum size of $C_{\text {ring }}[p, K]$ and $C_{\text {ring }}^{\prime}[p, K]$.

Therefore we have

$$
\operatorname{Adv}_{\mathcal{A}}^{\text {gen-inv }}(\lambda) \leq\left|\operatorname{Pr}\left[1 \stackrel{\&}{\leftarrow} \mathcal{S}^{C_{\text {ring }}[p, K]}\left(1^{\lambda}, 1^{M}\right)\right]-\operatorname{Pr}\left[1 \stackrel{\&}{\leftarrow} \mathcal{S}^{C_{\text {ring }}^{\prime}[p, K]}\left(1^{\lambda}, 1^{M}\right)\right]\right|+\operatorname{negl}(\lambda)
$$

where negl is a negligible function, $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$ and $K \stackrel{\&}{\leftarrow} \operatorname{KGen}\left(1^{\lambda}\right)$. Here, we prove the following lemma.

Lemma $6\left|\operatorname{Pr}\left[1 \stackrel{\&}{\leftarrow} \mathcal{S}^{C_{\text {ring }}[p, K]}\left(1^{\lambda}, 1^{M}\right)\right]-\operatorname{Pr}\left[1 \stackrel{\&}{\leftarrow}_{\leftarrow}^{\mathcal{S}_{\text {ring }}^{\prime}}{ }^{[p, K]}\left(1^{\lambda}, 1^{M}\right)\right]\right|$ is negligible where $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$ and $K \stackrel{\&}{\leftarrow} \operatorname{KGen}\left(1^{\lambda}\right)$.

It is clear that Theorem 14 is proven if the above lemma is proven. Intuitively, Lemma 6 can be reduced to the $c$-inversion assumption in the $\mathcal{D}_{R^{-}}$generic ring model because $\mathcal{S}$ is only allowed to compute ring operations in a black-box manner through its oracle, and unless $\mathcal{S}$ queries the witness that it breaks the $c$-inversion assumption in the test mode, $C_{\text {ring }}[p, K]$ and $C_{\text {ring }}^{\prime}[p, K]$ works completely the same. The full proof of Lemma 6 is given below.

Proof. (of Lemma 6) We prove it by considering the following sequence of games.

Game 0: In this game, $\overline{\mathcal{S}}$ is given $1^{M}$ as input and allowed to access the oracle $C_{\text {ring }}[p, K]$ described in Fig 1 where $p \stackrel{\$}{\leftarrow} \mathcal{P}_{\ell}$ and $K \stackrel{\Phi}{\leftarrow} \operatorname{KeyGen}\left(1^{\lambda}\right)$.
Game 1: In this game, the oracle is replaced by $\mathcal{O}_{\text {ring }}^{(1)}[p, \sigma]$ described in Fig. 2 where $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$ and $\sigma$ is a random permutation on $\{0,1\}^{\ell^{\prime}} . \mathcal{O}_{\text {ring }}^{(1)}[p, \sigma]$ works similarly to $C_{\text {ring }}[p, K]$ except that $\operatorname{PRP}(K, \cdot)$ and $\operatorname{PRP}^{-1}(K, \cdot)$ are replaced by $\sigma$ and $\sigma^{-1}$ respectively.

| Oracle $\mathcal{O}_{\text {ring }}^{(1)}[p, \sigma]$ (mode, in): | Oracle $\mathcal{O}_{\text {ring }}^{(2)}[p, \sigma]$ (mode, in): |

Fig. 2. Description of oracles $\mathcal{O}_{\text {ring }}^{(1)}[p, \sigma]$ and $\mathcal{O}_{\text {ring }}^{(2)}[p, \sigma]$.

Game 2: In this game, the oracle is replaced by $\mathcal{O}_{\text {ring }}^{(2)}[p, \sigma]$ described in Fig. 2 where $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}, \sigma$ is a random permutation on $\{0,1\}^{\ell^{\prime}}$, and a set $L \subset\{0,1\}^{\ell^{\prime}}$ is initialized to be $\{\sigma(1)\}$ at the beginning of the game. Intuitively, $L$ records ciphertexts issued by the oracle, and $\mathcal{O}_{\text {ring }}^{(2)}[p, \sigma]$ works similarly to $\mathcal{O}_{\text {ring }}^{(1)}[p, \sigma]$ except that it returns $\perp$ if an operation or test query contains a ciphertext outside of $L$.

Game 3: In this game, the oracle is replaced by $\mathcal{O}_{\text {ring }}^{(3)}\left[p\right.$, Enc $\left._{0}\right]$ described in Fig. 4 where $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}, \operatorname{Enc}_{0} \stackrel{\&}{\leftarrow}\{0,1\}^{\ell^{\prime}}$, a set $L^{\prime} \subset \mathbb{Z}_{p} \times\{0,1\}^{\ell^{\prime}}$ is initialized to be $\left\{\left(1, \mathrm{Enc}_{0}\right)\right\}$ at the beginning of the game and $L_{2}^{\prime}$ denotes the set of all Enc $\in\{0,1\}^{\ell^{\prime}}$ such that $(X$, Enc $) \in L^{\prime}$ for some $X \in \mathbb{Z}_{p}$. We note that if there exists $X, Y$ such that $(X$, Enc $),(Y$, Enc $) \in L^{\prime}$, then we always have $X=Y$, and thus the step to find $X_{1}, X_{2}$ such that $\left(X_{1}, \operatorname{Enc}_{1}\right),\left(X_{2}, \operatorname{Enc}_{2}\right) \in L^{\prime}$ is well-defined. $\mathcal{O}_{\text {ring }}^{(3)}\left[p\right.$, Enc $\left._{0}\right]$ works similarly to $\mathcal{O}_{\text {ring }}^{(2)}[p, \sigma]$ except that instead of choosing $\sigma$ at the beginning of the game, the oracle $\mathcal{O}_{\text {ring }}^{(3)}\left[p, \mathrm{Enc}_{0}\right]$ simulates $\sigma$ by a "lazy sampling" [BCLO09] where a value of $\sigma$ is assigned whenever that is needed in the game. Intuitively, $(X$, Enc $) \in L$ means that Enc is assigned to be $\sigma(X)$.

Fig. 3. Description of oracles $\mathcal{O}_{\text {ring }}^{(3)}\left[p\right.$, Enc $\left._{0}\right]$ and $\mathcal{O}_{\text {ring }}^{(4)}\left[p\right.$, Enc $\left._{0}\right]$.

Game 4: In this game, the oracle is replaced by $\mathcal{O}_{\text {ring }}^{(4)}\left[p, \mathrm{Enc}_{0}\right]$ described in Fig. 4 where $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$, Enc $_{0} \stackrel{\$}{\leftarrow}\{0,1\}^{\ell^{\prime}}$, a set $L^{\prime \prime} \subset \mathbb{Z} \times\{0,1\}^{\ell^{\prime}}$ is initialized to be $\left\{\left(0, \mathrm{Enc}_{0}\right)\right\}$, an NI-SLP P is initialized to be an empty string at the beginning of the game, and $L_{2}^{\prime \prime}$ denotes the set of all Enc $\in\{0,1\}^{\ell^{\prime}}$ such that $(i$, Enc $) \in L^{\prime \prime}$ for some $i \in \mathbb{Z}$. In the step to find $i_{1}, i_{2}$ such that $\left(i_{1}, \mathrm{Enc}_{1}\right),\left(i_{2}, \mathrm{Enc}_{2}\right) \in L^{\prime \prime}$, if there exist multiple such $i_{1}, i_{2}$, the oracle picks the smallest one. $\mathrm{P} \|\left(i_{1}, i_{2}, \circ\right)$ means to append $\left(i_{1}, i_{2}, \circ\right)$ to P. $\mathcal{O}_{\text {ring }}^{(4)}\left[p\right.$, Enc $\left._{0}\right]$ works similarly to $\mathcal{O}_{\text {ring }}^{(3)}[p, \sigma]$ except that it maintains assigned values of $\sigma$ in another way by using $L^{\prime \prime}$ and P . Intuitively, $(i$, Enc $) \in L^{\prime \prime}$ means that Enc is assigned to be $\sigma\left(\mathrm{P}_{i}\left(\mathbb{Z}_{p}\right)\right)$.
Game 5: In this game, the oracle is replaced by $\mathcal{O}_{\text {ring }}^{(5)}\left[p, \mathrm{Enc}_{0}\right]$ described in Fig. 3 where $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$, Enc $_{0} \stackrel{\&}{\leftarrow}\{0,1\}^{\ell^{\prime}}, L^{\prime \prime} \subset \mathbb{Z} \times\{0,1\}^{\ell^{\prime}}$ is initialized to be $\left\{\left(0, \mathrm{Enc}_{0}\right)\right\}$, an NI-SLP P is initialized to be an empty string at the beginning of the game, and $L_{2}^{\prime \prime}$ denotes the set of all Enc $\in\{0,1\}^{\ell^{\prime}}$ such that $(i$, Enc $) \in$

Fig. 4. Description of oracles $\mathcal{O}_{\text {ring }}^{(5)}\left[p\right.$, Enc $\left._{0}\right]$ and $\mathcal{O}_{\text {ring }}^{(6)}\left[p\right.$, Enc $\left._{0}\right]$.
$L^{\prime \prime}$ for some $i \in \mathbb{Z}$. We note that $\mathcal{O}_{\text {ring }}^{(5)}\left[p\right.$, Enc $\left._{0}\right]$ is the same as $\mathcal{O}_{\text {ring }}^{(4)}\left[p\right.$, Enc $\left._{0}\right]$ except that it always returns $\perp$ if mode $=$ test.
Game 6: In this game, the oracle is replaced by $\mathcal{O}_{\text {ring }}^{(6)}\left[p\right.$, Enc $\left._{0}\right]$ described in Fig. 3 where $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$, Enc $_{0} \stackrel{\&}{\leftarrow}\{0,1\}^{\ell^{\prime}}$, a set $L^{\prime} \subset \mathbb{Z}_{p} \times\{0,1\}^{\ell^{\prime}}$ is initialized to be $\left\{\left(1, \mathrm{Enc}_{0}\right)\right\}$, at the beginning of the game and $L_{2}^{\prime}$ denotes the set of all Enc $\in\{0,1\}^{\ell^{\prime}}$ such that $(X$, Enc $) \in L^{\prime}$ for some $X \in \mathbb{Z}_{p}$. We note that $\mathcal{O}_{\text {ring }}^{(6)}\left[p, \mathrm{Enc}_{0}\right]$ is the same as $\mathcal{O}_{\text {ring }}^{(3)}\left[p, \mathrm{Enc}_{0}\right]$ except that it always returns $\perp$ if mode $=$ test.
Game 7: In this game, the oracle is replaced by $\mathcal{O}_{\text {ring }}^{(7)}[p, \sigma]$ described in Fig. 5 where $p \stackrel{\Phi}{\leftarrow} \mathcal{P}_{\ell}, \sigma$ is a random permutation on $\{0,1\}^{\ell^{\prime}}$, and a set $L \subset\{0,1\}^{\ell^{\prime}}$ is initialized to be $\{\sigma(1)\}$ at the beginning of the game. We note that $\mathcal{O}_{\text {ring }}^{(7)}[p, \sigma]$ is the same as $\mathcal{O}_{\text {ring }}^{(2)}[p, \sigma]$ except that it always returns $\perp$ if mode $=$ test.
Game 8: In this game, the oracle is replaced by $\mathcal{O}_{\text {ring }}^{(8)}[p, \sigma]$ described in Fig. 5 where $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$ and $\sigma$ is a random permutation on $\{0,1\}^{\ell^{\prime}}$. We note that $\mathcal{O}_{\text {ring }}^{(8)}[p, \sigma]$ is the same as $\mathcal{O}_{\text {ring }}^{(1)}[p, \sigma]$ except that it always returns $\perp$ if mode $=$ test.
Game 9: In this game, the oracle is replaced by $C_{\text {ring }}^{\prime}[p, K]$ where $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$ and $K \stackrel{\&}{\leftarrow} \operatorname{PRPGen}\left(1^{\lambda}\right)$.

We let $T_{i}$ be the event that $\mathcal{S}$ outputs 1 , and let $Q$ be the maximum number of $\mathcal{S}$ 's queries. What we have to prove is that $\left|\operatorname{Pr}\left[T_{9}\right]-\operatorname{Pr}\left[T_{1}\right]\right|$ is negligible. We prove this by the following lemmas.

```

Fig. 5. Description of oracles $\mathcal{O}_{\text {ring }}^{(7)}[p, \sigma]$ and $\mathcal{O}_{\text {ring }}^{(8)}[p, \sigma]$.

Lemma 7 If (PRPGen, PRP, $\mathrm{PRP}^{-1}$ ) is a secure $P R P$, then $\operatorname{Pr}\left[T_{1}\right]-\operatorname{Pr}\left[T_{0}\right]$ is negligible.
Proof. Game 1 is the same as Game 0 except that $\operatorname{PRP}(K, \cdot)$ and $\operatorname{PRP}^{-1}(K, \cdot)$ are replaced by $\sigma$ and $\sigma^{-1}$. Since $\mathcal{S}$ only accesses to them as oracles, they are computationally indistinguishable by the security of a PRP.
Lemma 8 We have $\left|\operatorname{Pr}\left[T_{2}\right]-\operatorname{Pr}\left[T_{1}\right]\right| \leq \frac{Q \cdot 2^{\ell}}{2^{\ell^{\prime}}-Q-1}$. Especially, $\left|\operatorname{Pr}\left[T_{2}\right]-\operatorname{Pr}\left[T_{1}\right]\right|$ is negligible.

Proof. Since at most one element is added to $L$ at each query, we have $|L| \leq Q+1$ throughout the game. For any Enc $\{0,1\}^{\ell^{\prime}} \backslash L, \mathcal{S}$ cannot obtain any information about $\sigma^{-1}(\mathrm{Enc})$, and thus the probability that $\sigma^{-1}(\mathrm{Enc}) \in \mathbb{Z}_{p}$ is $\frac{p-|L|}{2^{\ell^{\prime}}-|L|} \leq$ $\frac{2^{\ell}}{2^{\ell^{\prime}}-Q-1}$. Therefore the probability that $\mathcal{S}$ makes at least one query that contains Enc $\in\{0,1\}^{\ell^{\prime}} \backslash L$ such that $\sigma^{-1}($ Enc $) \notin \mathbb{Z}_{p}$ is at most $\frac{Q \cdot 2^{\ell}}{2^{\ell^{\prime}}-Q-1}$. Unless this occurs, Game 1 and Game 2 are identical. Since we assume $\ell^{\prime} \geq \ell+\lambda$ and $Q$ is polynomial in $\lambda, \frac{Q \cdot 2^{\ell}}{2^{\ell^{\prime}}-Q-1}$ is negligible.

The following two lemmas are easy to verify because the modifications from Game 2 to Game 3 and from Game 3 to Game 4 are just conceptual.
Lemma 9 We have $\operatorname{Pr}\left[T_{3}\right]=\operatorname{Pr}\left[T_{2}\right]$.
Lemma 10 We have $\operatorname{Pr}\left[T_{4}\right]=\operatorname{Pr}\left[T_{3}\right]$.
Lemma 11 There exists a PPT generic algorithm $\overline{\mathcal{S}}$ in the $\mathcal{D}_{R}$-generic model such that $\left|\operatorname{Pr}\left[T_{5}\right]-\operatorname{Pr}\left[T_{4}\right]\right| \leq Q \cdot \operatorname{Adv}_{\overline{\mathcal{S}}, \mathcal{D}_{R}, c}^{\text {gen-inv }}(\lambda)$ where $\mathcal{D}_{R}$ is a distribution of a ring $R=\mathbb{Z}_{p}$ for $p \stackrel{\&}{\leftarrow} \mathcal{P}_{\ell}$. Especially, if the factoring assumption w.r.t. unbalanced moduli holds, then $\left|\operatorname{Pr}\left[T_{5}\right]-\operatorname{Pr}\left[T_{4}\right]\right|$ is negligible.

Proof. The latter part of the lemma follows from the former part and Theorem 4. We prove the former part in the following. We construct a generic algorithm $\overline{\mathcal{S}}$ against the $c$-inversion assumption in the $\mathcal{D}_{R^{-}}$-generic ring model. Recall that $\mathcal{\mathcal { S }}$ has access to the oracle $\mathcal{O}_{\text {ring }}$ defined in Sec.5.2. As a building block, we use an algorithm $\mathcal{S}$ that accesses to an oracle $\mathcal{O}$ (which is supposed to be either of $\mathcal{O}_{\text {ring }}^{(4)}\left[p, \mathrm{Enc}_{0}\right]$ or $\left.\mathcal{O}_{\text {ring }}^{(5)}\left[p, \mathrm{Enc}_{0}\right]\right)$.
$\overline{\mathcal{S}}^{\mathcal{O}_{\text {ring }}}\left(1^{\lambda}\right)$ : This algorithm picks $\operatorname{Enc}_{0} \stackrel{\&}{\leftarrow}_{\leftarrow}^{\leftarrow}\{0,1\}^{\ell^{\prime}}$, generates a list $L^{\prime \prime}:=\left\{\left(0\right.\right.$, Enc $\left.\left._{0}\right)\right\}$, sets $\operatorname{ctr}:=0$ and gives $1^{M}$ to $\mathcal{S}$ as input. When $\mathcal{S}$ makes a query (mode, in), $\overline{\mathcal{S}}$ simulates the oracle as follows. If mode $=$ identity, then $\overline{\mathcal{S}}$ returns $\mathrm{Enc}_{0}$. If mode $=$ operation and in $=\left(\mathrm{Enc}_{1}, \mathrm{Enc}_{2}, \circ\right), \overline{\mathcal{S}}$ finds $i_{1}, i_{2}$ such that $\left(i_{1}, \mathrm{Enc}_{1}\right)$, $\left(i_{2}, \mathrm{Enc}_{2}\right) \in L^{\prime \prime}$. If such $i_{1}$ or $i_{2}$ does not exist, then $\mathcal{S}^{\prime}$ returns $\perp$ to $\mathcal{S}$ as a response of $\mathcal{S}$ 's oracle $\mathcal{O}$. Otherwise $\overline{\mathcal{S}}$ makes a operation query $\left(i_{1}, i_{2}, \circ\right)$ to its own oracle $\mathcal{O}_{\text {ring }}$ and increments $c t r \leftarrow c t r+1$. Then for $j \in\{0,1, \ldots, c t r-1\}, \overline{\mathcal{S}}$ makes an equal query $(c t r, j)$ to its own oracle $\mathcal{O}_{\text {ring }}$. If there exists $j \in\{0,1, \ldots, c t r-1\}$ such that $\mathcal{O}_{\text {ring }}$ returns true for an equal query $(c t r, j)$, then $\overline{\mathcal{S}}$ sets $\mathrm{Enc}_{c t r}:=\mathrm{Enc}_{j}$. (If there exist multiple such $j$, it simply takes the smallest one.) If there does not exist such $j$, then $\overline{\mathcal{S}}^{\prime}$ chooses Enc $_{c t r} \stackrel{\Phi}{\leftarrow}\{0,1\}^{\ell^{\prime}} \backslash L_{2}^{\prime \prime}$. Then $\overline{\mathcal{S}}$ adds $\left(c t r\right.$, Enc $\left._{c t r}\right)$ to $L^{\prime \prime}$ and returns Enc ${ }_{c t r}$ to $\mathcal{S}$ as a response by the $\mathcal{S}$ 's oracle $\mathcal{O}$. If mode $=$ test, $\overline{\mathcal{S}}$ returns $\perp$ as a response by $\mathcal{O}$. When the execution of $\mathcal{S}$ halts, $\mathcal{\mathcal { S }}$ picks $k \stackrel{{ }^{\&}}{\leftarrow}[Q]$ where $Q$ denotes the number of $\mathcal{S}$ 's test query. Let in $=$ Enc* be the $\mathcal{S}$ 's $k$-th test query. $\overline{\mathcal{S}}$ finds $i^{*}$ such that $\left(i^{*}\right.$, Enc $\left.^{*}\right) \in L^{\prime \prime}$ and outputs $i^{*}$.

First, we remark that responses from $\mathcal{O}_{\text {ring }\left[p, \text { Enc }_{0}\right]}^{(4)}$ and $\mathcal{O}_{\text {ring }\left[p, \text { Enc }_{0}\right]}^{(5)}$ are identical unless $\mathcal{S}$ queries (test, Enc $\left.{ }^{*}\right)$ such that $\mathrm{P}_{i^{*}}\left(\mathbb{Z}_{p}\right)=[c]_{\mathbb{Z}_{p}}^{-1}$ where $i^{*}$ is an integer such that $\left(i^{*}\right.$, Enc $\left.^{*}\right) \in L^{\prime \prime}$ and P is an NI-SLP maintained by an oracle. We denote the event that $\mathcal{S}$ makes such a query by $F$. Then we have $\mid \operatorname{Pr}[1 \underset{\leftarrow}{\leftarrow}$ $\mathcal{S}^{\left.\mathcal{O}_{\text {ring }}{ }^{(4)}{ }_{\left[p, \text { Enc }_{0}\right]}\left(1^{\lambda}, 1^{M}\right)\right]-\operatorname{Pr}\left[1 \stackrel{\&}{\leftarrow} \mathcal{S}^{\mathcal{O}_{\text {ring }}^{(5)}\left[p, \text { Enc }_{0}\right]}\left(1^{\lambda}, 1^{M}\right)\right] \mid \leq \operatorname{Pr}[F] \text {. Here, we notice }}$ that unless $F$ occurs, $\overline{\mathcal{S}}$ perfectly simulates the environment for $\mathcal{S}$ that accesses to $\mathcal{O}_{\text {ring }}^{(4)}\left[p, \mathrm{Enc}_{0}\right]$ or $\mathcal{O}_{\text {ring }}^{(5)}\left[p, \mathrm{Enc}_{0}\right]$. Thus the probability that the output $i^{*}$ by $\overline{\mathcal{S}}$ satisfies $\mathrm{P}_{i^{*}}\left(\mathbb{Z}_{p}\right)=[c]_{\mathbb{Z}_{p}}^{-1}$ where P is an NI-SLP maintained by the oracle $\mathcal{O}_{\text {ring }}$, is $\operatorname{Pr}[F] / Q$. This probability is defined to be $\operatorname{Adv}_{\overline{\mathcal{S}}, \mathcal{D}_{R}, c}^{\text {gen inv }}(\lambda)$. Therefore we have $\operatorname{Adv}_{\overline{\mathcal{S}}, \mathcal{D}_{R}, c}^{\text {gen-inv }}(\lambda)=\operatorname{Pr}[F] / Q$. Therefore the lemma follows.

The following lemmas can be proven similarly to Lemma 7 to 11.
Lemma 12 If (PRPGen, $\mathrm{PRP}, \mathrm{PRP}^{-1}$ ) is a secure $\operatorname{PRP}$, then $\left|\operatorname{Pr}\left[T_{9}\right]-\operatorname{Pr}\left[T_{5}\right]\right|$ is negligible.

By combining the above lemmas, Lemma 6 is proven, and thus Theorem 14 is proven.

[^0]:    ${ }^{1}$ In the real world, the order of $\mathbb{Z}_{N}^{*}$ has no entropy given $N$ though that is hard to compute. They consider an idealized setting where the order has an information theoretical entropy.
    2 To the best of our knowledge, the only work that is relevant to this setting is the work by Kim et al. [KKS15] that considered a "restricted" variant of the model. See Sec 1.4 for the details.

[^1]:    ${ }^{3}$ In our definition of the MCDH assumption, $x_{1}, \ldots, x_{n+1}$ are chosen from $\left[2^{\ell+\lambda}\right]$ instead of $[\operatorname{ord}(G)]$ because $\operatorname{ord}(G)$ is unknown in our setting. However, this causes a negligible difference (See Remark 3)

[^2]:    ${ }^{4}$ A related discussion can be found in [Che04, Sec. 5]

[^3]:    ${ }^{5}$ In our definition, the setup algorithm does not take the number of maximum users as input. This means that our scheme admits unbounded number of users.
