#### Abstract

Zero-knowledge arguments have become practical, and widely used, especially in the world of Blockchain, for example in Zcash.

This work revisits zero-knowledge proofs in the discrete logarithm setting. First, we identify and carve out basic techniques (partly being used implicitly before) to optimise proofs in this setting. In particular, the linear combination of protocols is a useful tool to obtain zero-knowledge and/or reduce communication. With these techniques, we are able to devise zero-knowledge variants of the logarithmic communication arguments by Bootle et al. (EUROCRYPT '16) and Bünz et al. (S\&P '18) thereby introducing almost no overhead. We then construct a conceptually simple commit-and-prove argument for satisfiability of a set of quadratic equations. Unlike previous work, we are not restricted to rank 1 constraint systems (R1CS). This is, to the best of our knowledge, the first work demonstrating that general quadratic constraints, not just R1CS, are a natural relation in the dlog (or ideal linear commitment) setting. This enables new possibilities for optimisation, as, e.g., any degree $n^{2}$ polynomial $f(X)$ can now be "evaluated" with at most $2 n$ quadratic constraints.

Our protocols are modular. We easily construct an efficient, logarithmic size shuffle proof, which can be used in electronic voting.

Additionally, we take a closer look at quantitative security measures, e.g. the efficiency of an extractor. We formalise short-circuit extraction, which allows us to give tighter bounds on the efficiency of an extractor.

## 1 INTRODUCTION

Zero-knowledge arguments (of knowledge) (ZKAoK) allow a party $\mathscr{P}$, the prover, to convince another party $V$, the verifier, of the truth of a statement (and knowledge of a witness) without revealing any other information. For example, one may prove knowledge of a valid signature on some message, without revealing the signature. The ability to ensure correctness without compromising privacy makes zero-knowledge arguments a powerful tool, which is ubiquitous in theory and application of cryptography. Since the first practical construction of succinct non-interactive arguments of knowledge (SNARK) [25], and their application to Blockchain and related
areas, research in theory and applications of efficient ZKAoKs has progressed significantly, see the works $[3,10,13,18,22,25-27$, 48] to name a few. Arguably, zero-knowledge proofs have become practical for many applications. As efficiency improved and demand for privacy increased, possible use cases and applications have grown explosively.

In this paper, we revisit a line of works $[13,17,29]$ in the discrete logarithms setting. From an abstract point of view, in terms of [33], one part of our work is in the world of ideal linear commitments (ILC). That is, our verifier can do "matrix-vector queries" on a committed value $\boldsymbol{w}$, e.g. request an opening for a matrix-vector product $\Gamma \boldsymbol{w}$. A priori, this is more powerful than other settings like PCP or IOP, where the verifier's queries are restricted to point or inner-product queries [33]. Nonetheless, the ILC-arguments in [13, 17, 29] only work for the language R1CS "natively", which is also covered by more restricted verifiers. We show that with ILC, one can directly handle systems of quadratic equations, of which R1CS is a special case. This broadens possible optimisation from (already used [1]) R1CS-friendly to quadratics-friendly cryptography. Yet, even for R1CS, our performance improves upon Bulletproofs [17].

Another part of this work treats proofs of knowledge of preimages of group homomorphisms. For example, proving knowledge of the decryption of an ElGamal ciphertext. This does not fit into the ILC setting. Hence we do not use the ILC abstractions in this work. Combining this with our proofs for quadratic equations is efficient. Thus one can generically construct primitives such as shuffle proofs, which are important for electronic voting.

### 1.1 Basic techniques

We identify and present basic design principles underlying most efficient zero-knowledge arguments in the group setting.

In the following, we use implicit representation for group elements, see Section 2. Let us recall (a slight variant of) the standard $\Sigma$-Protocol ( $\Sigma_{\mathrm{std}}$ ) for proving knowledge of a preimage $\boldsymbol{w}$ for $[A] \boldsymbol{w}=[t]$ for $[A] \in \mathbb{G}^{m \times n}$. This proof covers a large class of statements, including dlog relations, knowing the opening of a commitment, etc. The protocol works as follows:

- Prover: Pick $r \leftarrow \mathbb{F}_{p}^{n}$, let $[\boldsymbol{a}]:=[A] \boldsymbol{r}$, send $[\boldsymbol{a}]$.
- Verifier: Pick and send $\boldsymbol{x}=\left(x_{1}, x_{2}\right) \leftarrow \mathbb{F}_{p}^{2}\left(\right.$ with $\left.x_{2} \neq 0\right)$.
- Prover: Send $z:=x_{1} \boldsymbol{w}+x_{2} \boldsymbol{r}$.
- Verifier: Accept iff $[A] z=x_{1}[\boldsymbol{t}]+x_{2}[\boldsymbol{a}]$.

Intuitively, this is zero-knowledge since $r$ completely masks $w$ in $z=x_{1} \boldsymbol{w}+x_{2} \boldsymbol{r}$ (since $x_{2} \neq 0$ ), and finding $r$ from $[\boldsymbol{a}]$ is hard. It is extractable, since two linearly independent challenges $\boldsymbol{x}_{1}, \boldsymbol{x}_{2}$ with
answers $z_{1}, z_{2}$ (for fixed $[\boldsymbol{a}]$ ) allow to reconstruct $\boldsymbol{w}, \boldsymbol{r}$. But Proto$\operatorname{col} \Sigma_{\text {std }}$ is not particularly communication-efficient, as it sends the full masked witness $z \in \mathbb{F}_{p}^{n}$ as well as $[\boldsymbol{a}] \in \mathbb{G}^{m}$. Using probabilistic verification, one can often improve this.
1.1.1 Probabilistic verification. The underpinning of efficient arguments of knowledge (without zero-knowledge) is probabilistic verification of the claim. For instance, instead of verifying $[A] \boldsymbol{w}=[\boldsymbol{t}]$ directly, the verifier could send a random $y \leftarrow \mathbb{F}_{p}$. Both parties compute $\boldsymbol{y}=\left(y^{i}\right)_{i} \in \mathbb{F}_{p}^{m}$ and verify $[\widehat{A}] \boldsymbol{w}=[\hat{t}]$ for $[\widehat{\boldsymbol{A}}]=\boldsymbol{y}^{\top}[A] \in$ $\mathbb{G}^{1 \times n}$ and $[\widehat{t}]=\boldsymbol{y}^{\top}[t] \in \mathbb{G}$ instead. This would result in a communication complexity which is independent of $m$ as $[\widehat{\boldsymbol{a}}]=[\widehat{A}] \boldsymbol{r} \in \mathbb{G}$.

Not all probabilistic verifications are alike. To work well with zero-knowledge, we need "suitable" verification procedures, so that techniques to attain zero-knowledge can be applied. This essentially means that the verification should be linear, i.e. all tested equations should be linear. (Abstract groups only allow linear operations anyway.)

Figure 1: Linear Combination of Protocols. Left: The trivial proof of knowledge: Send the witness. Middle: Send a random statement. Then send the witness. Grayed out: Terms for linear combination. Right: The linear combination with verifier's randomness.
1.1.2 Linear combinations of protocols. A core insight for achieving zero-knowledge (and reducing communication) in our setting efficiently is that protocols can often be linearly combined, see Fig. 1 for an illustration. This exploits the linearity of the computations and checks of verifier and prover in each round. By running an "umasked non-zero-knowledge argument" (Fig. 1, left) and linearly combining it with an argument for a "masking randomness" (middle), one can achieve zero-knowledge (right). All of our zeroknowledge compilations rely on this strategy. We typically consider random linear combinations of protocols, where the verifier picks the randomness ( $x_{1}, x_{2}$ in Fig. 1), as this often achieves extractability. In fact, this kind of linear combination recovers the batch proofs of [46], see Appendix B. Non-randomised linear combinations are also used, e.g. Protocols A. 3 and A.12, or [17].
1.1.3 Uniform(-or-unique) responses. In our setting, for simulation it is typically enough to ensure that the prover's messages are distributed uniformly at random. More concretely, the responses should be either uniformly distributed (conditioned on all later messages, not previous messages), such as $z$ in Protocol $\Sigma_{\text {std }}$. Or they should be uniquely determined and efficiently computable from the challenges and all later messages, such as $[\boldsymbol{a}]$ in Protocol $\Sigma_{\text {std }}$. This allows to construct a trivial simulator, which constructs the transcript in reverse: Starting with the final messages, and working its way towards the beginning, the simulator picks
the uniformly distributed messages itself, and computes the uniquely determined ones. All simulators in this paper work like this.
1.1.4 Kernels and redundancy. Many interesting statements are non-linear. For example, for polynomial commitments [15], we want to show that $[c] \in \mathbb{G}^{m}$ is a commitment to a polynomial $f \in \mathbb{F}_{p}[X]$ (of degree at most $d-1$ ) and $f(x)=t$, where $x \in \mathbb{F}_{p}$ is a random challenge. Naively, one commits to the coefficients of the polynomial with monomial basis $X^{i}$ for $i=0, \ldots, n-1$. Suppose we have a (linear) protocol which proves $f(x)=t$. We could hope that running a random linear combination as in Fig. 1 should give us uniform-or-unique responses (and hence zero-knowledge). However, we are in a predicament: For random $g \in \mathbb{F}_{p}[X]$, we have $(f+g)(x) \neq f(x)$ and thus we have to let $\mathcal{V}$ know $y=g(x)$ somehow. To ensure the prover does not send arbitrary $y$, we have to rely on a proof again! But if this proof leaks information we cannot use it to randomise the response. We can escape by having a way to randomise without changing the statement. In other words, we need some $g$ with $g(x)=0$ for all $x \in \mathbb{F}_{p}$. Clearly, that means $g=0$, and there's nothing random anymore! Another dead end.

One solution is to add redundancy, which does not "influence" soundness: Here, we artificially create a non-trivial kernel of the "evaluate at $x$ "-map. We can do so by representing $f(X)$ as $\sum_{i}\left(\alpha_{i}+\right.$ $\left.\beta_{i}\right) X^{i}$ and commit to all $\alpha_{i}$ and $\beta_{i}$. Now we can mask with $g(X)$ where $\alpha_{i} \leftarrow \mathbb{F}_{p}$ and $\beta_{i}=-\alpha_{i}$. Thus, we successfully injected randomness into the response. Generally, adding just enough redundancy to achieve uniformly random responses is our goal.
1.1.5 Composition of arguments systems. By committing to and then sharing intermediate results in multiple argument systems, one can combine the most efficient arguments for each task.

Example 1.1. In our logarithmic communication zero-knowledge inner product argument $\mathrm{IPA}_{\text {almZK }}$ for $\exists \boldsymbol{x}, \boldsymbol{y}:\langle\boldsymbol{x}, \boldsymbol{y}\rangle=t$, we randomise as $\langle\boldsymbol{x}+\boldsymbol{r}, \boldsymbol{y}+\boldsymbol{s}\rangle=t$ so that $\langle\boldsymbol{r}, \boldsymbol{y}\rangle=\langle\boldsymbol{r}, \boldsymbol{s}\rangle=\langle\boldsymbol{x}, \boldsymbol{s}\rangle=0$ with only logarithmically many (specially chosen) random components in $\boldsymbol{r}, \boldsymbol{s}$. This is an application of the "redundancy/kernel" technique. The "uniform-or-unique" guideline ensures that it is enough that each response is random. Hence a logarithmic number of (wellchosen) random components in $r, s$ does suffice.

On the other hand, our logarithmic communication linear map preimage argument LMPA ZK $_{\text {for }} \exists \boldsymbol{w}:[A] \boldsymbol{w}=[\boldsymbol{t}]$ uses a linear combination of a non-zero-knowledge argument for $[A]$, plus a similar argument for a different $[A]$ and $[t]$ (of the same size). Finally, for our logarithmic communication shuffle argument $\Pi_{\text {shuffle }}$ (Appendix C), we compose QESA $_{\text {ZK }}$ (our quadratic equation argument) and LMPA ${ }_{\text {ZK }}$ by sharing a commitment to the witness.

### 1.2 Contribution

To the best of our knowledge, there is no work which presents these techniques, in particular linear combination of protocols, as unifying guidelines. Implicitly, these techniques are used in many works [13, 15, 17, 29, 46]. We follow the above guidelines for constructing and explaining our zero-knowledge arguments.

See Appendix G for protocol diagrams.
1.2.1 Linear map preimage argument (LMPA). We give in two steps an argument for $\exists \boldsymbol{w}:[A] w=[t]$ for $[A] \in \mathbb{G}^{m \times n}$ with communication $O(\log (n))$. The idea is to first use batch verification. Essentially, $\mathrm{LMPA}_{\text {batch }}$ multiplies the equation with a random vector $\boldsymbol{y} \in \mathbb{F}_{p}^{m}$ from the left to obtain $[\widehat{A}]=\boldsymbol{y}^{\top}[A] \in \mathbb{G}^{1 \times n}$ and $[\widehat{t}]=$ $\boldsymbol{y}^{\top}[\boldsymbol{t}] \in \mathbb{G}$. Thus, communication is independent of $m$. Now, we prove $\exists \boldsymbol{w}:[\widehat{\boldsymbol{A}}] \boldsymbol{w}=[\widehat{t}]$ using $\mathrm{LMPA}_{\mathrm{ZK}}$, which is derived from [13]. It is enhanced with zero-knowledge for overhead which is constant w.r.t. communication and logarithmic w.r.t. computation (in $n$ ).
1.2.2 Quadratic equation commit-and-prove. First of all, we derive $\mathrm{a}\left(\mathrm{n}\right.$ almost) zero-knowledge inner product argument $\mathrm{IPA}_{\text {almZK }}$ from [13, 17], again with constant communication and logarithmic computational overhead compared to $[13,17]$. From IPA almZK we obtain an argument for proving $\exists \boldsymbol{w}: \forall i:\left\langle\boldsymbol{w}, \boldsymbol{\Gamma}_{i} \boldsymbol{w}\right\rangle=0$, where $\Gamma_{i} \in$ $\mathbb{F}_{p}^{n \times n}$ and $w$ is committed to. For efficiency, we carry out a batch proof, i.e. we prove $\langle\boldsymbol{w}, \Gamma \boldsymbol{w}\rangle$ with $\Gamma:=\sum_{i} r_{i} \Gamma_{i}$ for random $r_{i} \in \mathbb{F}_{p}$. The resulting argument, $\mathrm{QESA} \mathrm{ZK}_{\mathrm{K}}$, is "adaptive commit-and-prove", i.e. the statement $\Gamma_{i}$ may be chosen after the commitment to $\boldsymbol{w}$.

The commit-and-prove system QESA ${ }_{Z K}$ is conceptually simple and can be efficiently combined with other arguments. We leave as an open question whether its strategies can be adapted by linear IOPs or whether they are unique to ILC.
1.2.3 Sets of quadratic equations. Being able to prove arbitrary quadratic equations instead of R1CS equations, i.e. equations of the form $\left(\sum a_{i} x_{i}\right)\left(\sum b_{i} x_{i}\right)+\sum c_{i} x_{i}=0$, gives much flexibility. To the best of our knowledge, expressing the quadratic equation $\langle\boldsymbol{x}, \boldsymbol{x}\rangle=$ $\sum x_{i}^{2}=t$ as R1CS requires $n$ equations: $y_{i}=x_{i}^{2}(i=1, \ldots, n-1)$ and $x_{n}^{2}=t-\sum_{i} y_{i}$, where $y_{i}$ are additionally introduced variables. Requiring $n$ equations is surprising for $[13,17]$ which build on an inner product argument. Obviously, QESA ${ }_{\mathrm{ZK}}$ needs one (quadratic) equation to express $\langle\boldsymbol{x}, \boldsymbol{x}\rangle=t$.

Using general quadratic equations, one can evaluate any (univariate) polynomial $f(X)=\sum_{i=0}^{d^{2}-1} a_{i} X^{i}$ of degree $d^{2}-1$ with $2 d$ equations and intermediate variables. Concretely, let $y_{i}=x^{i}=$ $y_{i-1} x, z_{i}=x^{d i}=z_{1} z_{i-1}$, for $i=2, \ldots d-1$ and $z_{1}=y_{d-1} x$ and $z_{0}=1$. Then $f(x)=\sum_{i, j=0}^{d} a_{i+j d} y_{i} z_{j}$. This can speed up "table lookups", which are typically encoded as polynomial evaluation.

For S(N)ARK-friendly cryptography [38], supporting quadratic equations is very useful. Matrix-vector multiplications are efficient even when both matrix and vector are secret. "Embedding" an elliptic curve (see Jubjub [1]), is also more efficient than for R1CS. For general point addition in a (twisted) Edwards curve, we need 5 instead of 8 constraints per bit.

Similar to SNARK- and MPC-friendly cryptography, quadraticsfriendly cryptography may enable significant speedups. A prime candidate is multi-variate quadratic cryptography, where suitably adapted schemes might integrate very well with our proof system.
1.2.4 Correctness of a shuffle. By instantiating the shuffle proof of Bayer and Groth [6] with LMPA $\mathrm{ZK}_{\mathrm{ZK}}$ and QESA ZK as sub-protocols, we obtain an argument $\Pi_{\text {shuffle }}$ for correctness of a shuffle (of ciphertexts). To the best of our knowledge, ${ }^{\text {a }}$ this is the first efficient

[^0]argument with proof size $O(\log (N))$. Our computational efficiency is comparable to [6], which has proof size $O(\sqrt{N})$. More concretely, we (very roughly) estimate at worst $2-3 \times$ the computation.
1.2.5 Knowledge errors, tightness and short-circuit extraction. From a quantitative perspective, our notion of testing distributions and their soundness errors, are useful to separate study of knowledge errors and extraction in the setting of special soundness. Testing distributions have associated soundness errors, which (up to technical difficulties we state as open problems) translate to knowledge errors of the protocol. Explicit knowledge errors achieve tuneable levels of soundness, e.g. $2^{-120}$ instead of $2^{-256}$, which impacts runtime positively.

Short-circuit extraction. We give a definition of short-circuit extraction. This treats extraction assertions such as "Ext either finds a witness or it solves a hard problem". It formalises the (common) behaviour of an extractor to either find a witness with few transcripts, or solve the hard problem (e.g. equivocating a commitment). Without distinguishing these cases, the bounds on the necessary number of transcripts for extraction is much higher. For example, we show that the extractor for the $\mathrm{LMPA}_{\mathrm{ZK}}$ and $\mathrm{IPA}_{\text {almZK }}$ (and also $[13,17])$ needs a tree of transcripts of size $O(\log (n) n)$ in the worst case. For QESA ${ }_{\mathrm{ZK}}$, extracting a proof for $N$ quadratic equations in $n$ variables requires $O(\log (n) n N)$ transcripts. The extractor in [17] needs $O\left(n^{3} N\right)$ transcripts, which for $n, N \approx 2^{16}$ implies a security loss of $\approx 2^{64}$ instead of $\approx 2^{34}$. This also opens the possibility for using small exponents as challenges, further improving our argument systems performance. Note that, due to their structure, Bulletproofs [17] are not well-suited for small exponents.

In Appendix D, we give a conjectured relation between communication efficiency and extraction efficiency, which implies that extraction from $O\left(\frac{n}{\log (n)}\right)$ transcripts would be optimal. We also elaborate on a loophole in above security estimates, namely how to efficiently obtain the transcripts.
1.2.6 Dual testing distributions. Dual testing distributions are a technical tool which allow us to sample a "new" commitment key from a given one, such that knowledge (e.g. commitment opening) cannot be transferred. This turns out to be more communication efficient than letting the verifier send a new commitment key. To the best of our knowledge, this is a new technique.
1.2.7 Theoretical comparison to [17] and improved inner product argument (IPA). In Table 1, we compare our argument systems with related work in the group setting. In Table 2, we give precise efficiency measures for LMPA ${ }_{\mathrm{ZK}}$ and $\mathrm{QESA}_{\mathrm{ZK}}$. In any case, $n=|\boldsymbol{w}|$ is the size of the witness $\boldsymbol{w} \in \mathbb{F}_{p}^{n}$. Since it is statement dependent, we ignore that QE is more powerful than R1CS, possibly allowing smaller witness size (as seen in the example $\langle\boldsymbol{x}, \boldsymbol{x}\rangle=t$ above). In Table 2, we omit the verifier's computation, since after optimisations [17], both are almost identical. For the prover, we do not optimise (e.g. we use no multi-exponentiations), and are not aware of non-generic optimisation. Much of our theoretical improvement is due to our improvements to the IPA. Using [17] with our IPA yields identical asymptotics. Even then, QESA ${ }_{\mathrm{ZK}}$ covers general quadratic equations, while Bulletproofs [17] which only cover R1CS.

Table 2: Estimates in terms of the group elements and exponentiations. By " $\approx f$ " we denote $f+O(\log (f))$.
1.2.8 Comparison with other proof systems. It is hard to make a fair comparison of proof systems. There are many relevant parameters, such as setup, assumptions, quantum resistance, native languages, etc. beyond mere proof size and performance. See Section 1.3 for a high-level discussion. To draw (non-trivial) conclusions from comparisons on an implementation level, one should compare fully optimised implementations. Thus, we restrict ourselves to a comparison with Bulletproofs (which we reimplemented with the same optimisation level as our proof systems). For somewhat concrete numbers regarding (implementation) performance, as well as other factors relevant to the comparison of proof systems, we refer to [10, Figure 2]. Our proof systems are similar enough to Bulletproofs for these comparisons to still hold.
1.2.9 Implementation. In Section 5, we compare our implementations of (aggregate) range proofs. The theoretical prediction of $0.75 \times$ prover runtime compared to [17] is close to measurements, which suggest $0.7 \times$. Using 140 bit exponents, we experimentally attain $\approx 0.63 \times$ compared to [17] on the same platform. As an important remark, we compare the dedicated range proofs of [17] with our generic instantiation of QESA ${ }_{\mathrm{ZK}}$.

### 1.3 Related work

Due to space constraints, we only elaborate on the most important concepts and related work. We refer to [33] for an overview and a general taxonomy.

The dlog setting and ILC. Very closely related works are [13, 15, 17, 29], which are efficient proofs in the dlog setting. Many zeroknowledge proofs in the group setting are instantiations of [20, 42]. The possibilities of our setting, namely ability to apply linear transformations to a committed witness has been abstracted in the ideal linear commitment model [14]. (Our techniques for QESA ZK are amenable to ILC.)

Knowledge assumptions. Another line of work [12, 22, 25, 30, 31, 41] gives non-interactive arguments using knowledge of exponent
assumptions. They attain constant size proofs for arithmetic circuits and sublinear verification costs, but require a trusted setup.

PCPs, IOPs, MPC-in-the-head. Techniques, such as probabilistically checkable proofs (PCP), MPC-in-the-head [37], interactive oracle proofs (IOP) and more, construct efficient zero-knowledge proofs without relying on public key primitives. The possible performance gain (and quantum resistance) is interesting from a practical point of view. There is much progress on improving these techniques [ $3,10,18,26,48$ ], which until recently suffered from relatively large proof size or unacceptable constants. In [10], BenSasson et al. present a logarithmic communication IOP for R1CS, which, by avoiding public key primitives, likely outperforms our QESA ${ }_{\text {ZK }}$ by order(s) of magnitude. Still, according to [10], proof sizes for R1CS statements of size $N=10^{6}$ are about 130 kb whereas our proofs, like Bulletproofs, stay well below 2 kb . For combining proofs in the "symmetric key" setting with efficient proofs for "public key" algebraic statements, [2] can be used. Our proofs can be directly combined with algebraic statements over the same group $\mathfrak{G}$.

## 2 PRELIMINARIES

For a set $S$ and probability distribution $\chi$ on $S$ we write $s \leftarrow \chi$ for drawing $s$ according to $\chi$. We write $s \leftarrow S$ for a uniformly random element. We also write $y \leftarrow \mathcal{A}(x ; r)$ for running an algorithm $\mathcal{A}$ with randomness $r$ and $y \leftarrow \mathcal{A}(x)$ for running $\mathcal{A}$ with (uniformly) random $r \leftarrow R$ (where $R$ is the randomness space). We let $\kappa$ denote the security parameter and note that almost all objects are implicitly parameterised by it. By negl we denote some (fixed) negligible function, i.e. a function with $\lim _{\kappa \rightarrow \infty} \kappa^{c}$ negl $(\kappa)=0$ for any $c \in \mathbb{N}$. We assume we can sample uniformly random from any $\{1, \ldots, n\}$. The number $p \in \mathbb{N}$ will always denote a prime, $\mathbb{F}_{p}:=\mathbb{Z} / p \mathbb{Z}$, and $\mathbb{G}$ is a (cyclic abelian) group of order $p$. We use additive implicit notation for $\mathbb{G}$ as introduced in [24]. That is, we write [1] for some (fixed public) generator associated with $\mathbb{G}$ and $[x]:=x[1]$. We extend this notation to vectors and matrices, i.e. for compatible $A, B, C$ over $\mathbb{F}_{p}$, we write $A[B] C=[A B C]$. Matrices are bold, e.g. [a], components not, e.g. $\left[a_{i}\right]$. By $\boldsymbol{e}_{i}$ we denote the $i$-th standard basis vector. We write $\operatorname{diag}\left(\boldsymbol{M}_{1}, \ldots, \boldsymbol{M}_{n}\right)$ for a block-diagonal matrix. By $\operatorname{id}_{n}$ we denote the $n \times n$ identity matrix.

### 2.1 Matrix kernel assumptions and Pedersen commitments

Instead of discrete logarithm assumptions, the generalisation of hard (matrix) kernel assumptions [43], but for right-kernels, better suits our needs.

Definition 2.1. Let $\mathbb{G} \leftarrow \operatorname{GrpGen}\left(1^{\kappa}\right)$ be a group generator (we let [1] and $p$ be implicitly given by $\mathbb{G}$ ). Let $\mathscr{D}_{m, n}$ be a (efficiently samplable) distribution over $\mathbb{G}^{m \times n}$ (where $m$ and $n$ may depend on $\kappa$ ). We say $\mathscr{D}_{m, n}$ has a hard kernel assumption if for all efficient adversaries $\mathcal{A}$, we have

$$
\mathbb{P}\binom{\mathbb{G} \leftarrow \operatorname{GrpGen}\left(1^{\kappa}\right) ;[A] \leftarrow \mathscr{D}_{m, n} ;}{x \leftarrow \mathcal{A}\left(1^{\kappa}, \mathbb{G},[A]\right):[A] x=0 \wedge x \neq 0} \leq \operatorname{negl}(\kappa)
$$

For simplicity, we will often only implicitly refer to $\mathscr{D}_{m, n}$ and just say $[A]$ has hard kernel assumption. Matrix kernel assumptions generalise DLOG assumptions: A non-trivial kernel element of $[h, 1] \in \mathbb{G}^{2}$ immediately yields the discrete logarithm $h$ of $[h]$.

If $\mathscr{D}_{m, n}$ is a matrix distribution with hard kernel assumption, then $[A] \leftarrow \mathscr{D}_{m, n}$ is a (Pedersen) commitment key ck. Commit to $\boldsymbol{x} \in \mathbb{F}_{p}^{n}$ via $\operatorname{Com}_{\mathrm{ck}}(\boldsymbol{x})=[\boldsymbol{c}] \in \mathbb{G}^{m}$. Breaking the binding property of the commitment is equivalent to finding non-trivial elements in $\operatorname{ker}([A])$. The common case will be $[\boldsymbol{g}] \in \mathbb{G}^{1 \times(n+1)}$ drawn uniformly as commitment key ck. Breaking the hard kernel assumption for $[g]$ is tightly equivalent to breaking the dlog assumption in $\mathbb{G}$. Write $\boldsymbol{x}=\left(r_{\boldsymbol{w}}, \boldsymbol{w}\right)$ with $r_{\boldsymbol{w}} \in \mathbb{F}_{p}, \boldsymbol{w} \in \mathbb{F}_{p}^{n}$. If $r_{\boldsymbol{w}} \leftarrow \mathbb{F}_{p}$ is drawn uniformly, it is evident that $[c]=[g] x$ perfectly hides $\boldsymbol{w}$, i.e. $[c]$ is uniformly distributed in $\mathbb{G}$.

### 2.2 Interactive arguments, extractability and zero-knowledge

Our setting will be the common reference string model, i.e. there is some CRS crs, typically a commitment key, set up by a trusted party. In the following $\mathscr{R}$ denotes a binary relation for which (st, w) $\in$ $\mathscr{R}$ is efficiently decidable. We call st the statement and w the witness. ( $\mathscr{R}$ does depend on crs, i.e. actually we consider (crs, st, w) tuples, but we suppress this.) The (NP-)language $\mathcal{L}$ defined by $\mathscr{R}$ is the language of statements in $\mathscr{R}$, i.e. $\mathcal{L}=\{\mathrm{st} \mid \exists \mathrm{w}:(\mathrm{st}, \mathrm{w}) \in \mathscr{R}\}$.

Definition 2.2. An (interactive) argument system for a relation $\mathscr{R}$ is a protocol between two parties, a prover $\mathscr{P}$ and a verifier $\mathcal{V}$. We use the name (interactive) proof system interchangably. The transcript of the interaction of $\mathscr{P}$ and $V$ on inputs $x$ and $y$ is denoted $\langle\mathscr{P}(x), V(y)\rangle$ where both parties have a final "output" message. We write $b=\langle\mathscr{P}(x), V(y)\rangle$, for the bit $b$ indicating whether an (honest) verifier accepts $(b=1)$ the argument.

Definition 2.3 (Completeness). An interactive argument system for (st, w) $\in \mathscr{R}$ is (computationally) complete if for all efficient adversaries $\mathcal{A}$, the probability

$$
\mathbb{P}\binom{\mathrm{crs} \leftarrow \operatorname{GenCRS}\left(1^{\kappa}\right) ;(\mathrm{st}, \mathrm{w}) \leftarrow \mathcal{A}(\mathrm{crs}):(\mathrm{st}, \mathrm{w}) \notin \mathscr{R} \text { or }}{\langle\mathscr{P}(\mathrm{st}, \mathrm{w}), \mathcal{V}(\mathrm{st})\rangle=1}
$$

is overwhelming, i.e. bounded below by $1-\operatorname{negl}(\kappa)$. It is perfectly complete if negl $=0$.

In Appendix D, we give a definition of witness-extended emulation [13, 32] with extraction error (i.e. knowledge error). It turns out that preserving a good extraction error over multiple rounds is non-trivial. See Sections 2.3 and 2.4.

Definition 2.4 (Public coin). An interactive argument system for $\mathscr{R}$ is public coin if all of the verifier's challenges are independent of any other messages or state (essentially $V$ makes his random coins public). Furthermore, $V$ 's verdict is a function Verify $(\operatorname{tr})$ of the transcript.

Honest verifier zero-knowledge guarantees the existence of a simulator which, without the witness, generates transcripts which are indistinguishable from transcripts of a real interaction with an honest verifier. Hence, an honest verifier learns nothing from the proof.

Definition 2.5. Let $(\mathscr{P}, \mathcal{V})$ be an interactive argument system for $\mathscr{R}$. We call ( $\mathscr{P}, V)$ ( $\varepsilon$-statistical) honest-verifier zero-knowledge (HVZK), if there exists an expected polynomial-time simulator Sim such that for all expected polynomial-time $\mathcal{A}$ the probabiliy distributions of (crs, tr, state), where

- $\mathrm{crs} \leftarrow \operatorname{GenCRS}\left(1^{\kappa}\right) ;(\mathrm{st}, w) \leftarrow \mathcal{A}(\mathrm{crs}) ; \operatorname{tr} \leftarrow\langle\mathscr{P}(\mathrm{st}, w), \mathcal{V}(\mathrm{st})\rangle$
- crs $\leftarrow \operatorname{GenCRS}\left(1^{\kappa}\right) ;(\mathrm{st}, w) \leftarrow \mathcal{A}(\mathrm{crs}) ; \operatorname{tr} \leftarrow \operatorname{Sim}(\mathrm{st}, \rho)$;
are indistinguishable (have statistical distance at most $\varepsilon$ ), assuming $\operatorname{tr}:=\perp$ if $(\mathrm{st}, w) \notin \mathscr{R}$.

Remark 2.6. We focus on HVZK, not special HVZK, The latter states that even if the adversary chooses statement, witness and the verifier's randomness ( $\rho$ in Definition 2.5), the special simulator will "succeed". Our security proofs make use of honest challenges. Different (more complex) security proofs may be possible.
2.2.1 Full-fledged zero-knowledge. To obtain security against dishonest verifiers, i.e. full-fledged zero-knowledge, simple transformations exist [19, 21, 28, 40] for public coin HVZK arguments. The most straightforward one is to use an equivocable coin toss between prover and verifier to generate the challenge.
2.2.2 The Fiat-Shamir heuristic. In the random-oracle model (ROM), public coin arguments can be converted to non-interactive arguments by computing the (verifier's) challenges as the hash of the transcript (and relevant "context") up to that point. The statement of the argument should be part of the "context" [11].

### 2.3 Testing distributions

Intuitively, testing distributions are a special form of probabilistic verification where one can efficiently recover the "tested" value given enough "tests". Thus, they are used to recover the witness in proofs of knowledge. We only define testing distributions over $\mathbb{F}_{p}^{m}$.

Example 2.7. To test if a vector $[\boldsymbol{c}] \in \mathbb{G}^{m}$ is $[0]$, test if $\boldsymbol{x}^{\top}[\boldsymbol{c}] \stackrel{?}{=}$ [0] for random $\boldsymbol{x} \in \mathbb{F}_{p}^{m}$. The soundness error is $1 / p$.

Definition 2.8 (Subdistribution). Let $\chi$ and $\psi$ be distributions on $\mathbb{F}_{p}^{m}$. We call $\psi$ a subdistribution of $\chi$ of weight $\varepsilon$ if

- there exists a subdensity $\rho_{\psi}: \mathbb{F}_{p}^{m} \rightarrow[0,1]$. (It is important that $\rho_{\psi}(x) \leq 1$.)
- $\varepsilon=\sum_{x \in \mathbb{F}_{p}^{n}} \rho_{\psi}(x) \chi(x)$, and
- $\psi$ has probability $\psi(x)=\frac{1}{\varepsilon} \rho_{\psi}(x)$ to pick $x$. (That is, $\psi$ has density $\frac{1}{\varepsilon} \rho_{\psi}$ w.r.t. $\chi$.)
The definition of a subdistribution is constructed to deal with adversaries. As a concrete example consider extraction by rewinding: It may happen that the adversary does not correctly answer a challenge. Thus, the challenges which are answered are a subset, or more generally a subdistribution. An adversary with success probability $\varepsilon$ must succeed on a subdistribution of weight $\varepsilon$.

Definition 2.9. A testing distribution $\chi_{m}$ for $\mathbb{F}_{p}^{m}$ with soundness $\delta_{\text {snd }}(\kappa)$ is a distribution over $\mathbb{F}_{p}^{m}$ with following property: For all subdistributions $\psi$ of $\chi_{m}$ with weight $\varepsilon \geq \delta_{\text {snd }}:=\delta_{\text {snd }}\left(\chi_{m}\right)$, we have

$$
\mathbb{P}\left(\boldsymbol{x}_{i} \leftarrow \psi, \boldsymbol{X}=\left(\boldsymbol{x}_{1}, \ldots, \boldsymbol{x}_{m}\right): \operatorname{det}(\boldsymbol{X})=0\right) \leq \frac{1}{\varepsilon} \delta_{\text {snd }}
$$

We write $\delta_{\text {snd }}\left(\chi_{m}\right)$ for some (fixed) soundness error of $\chi_{m}$.
Note that $\operatorname{det}(\boldsymbol{X}) \neq 0$, is equivalent to all $\boldsymbol{x}_{i}$ being linearly independent, and to $\bigcap_{i=1}^{m} \operatorname{ker}\left(\boldsymbol{x}_{i}^{\top}\right)=\{0\}$. These interpretations allow to generalise in different directions. For more about testing distributions, see Appendix E. Typically, we want that $\delta_{\text {snd }}(\chi)$ is very small, e.g. $2^{-100}$ in practice.

For our examples, we need a minor generalisation of the lemma of Schwartz-Zippel. For details, see Appendix A.1.

Example 2.10 (Polynomial testing). The distribution induced by $\boldsymbol{x}=\left(x^{0}, \ldots, x^{m-1}\right)$, where $x \leftarrow \mathbb{F}_{p}$, is a testing distribution. This follows from $X$ being a Vandermonde matrix, hence invertible except if the same $x$ was chosen twice. It is easy to see that $\delta_{\text {snd }}(\chi) \leq$ $\frac{m}{p}$.

Example 2.11. For the special case $m=2$, and testing distribution with $\boldsymbol{x}=(\alpha, 1)$ where $\alpha \leftarrow \delta$ for some $\mathcal{\delta} \subseteq \mathbb{F}_{p}$ we write $\chi^{(\beta)}$ and $\alpha \leftarrow \chi^{(\beta)}$. If $\mathcal{S} \subseteq \mathbb{F}_{p}^{\times}$, i.e. $\alpha \neq 0$, we write $\chi^{(\beta \neq 0)}$.

Example 2.12 (Random testing). The uniform distribution over $\mathbb{F}_{p}^{m}$ is a testing distribution. The Lemma of Schwartz-Zippel immediately yields $\delta_{\text {snd }}(\chi) \leq \frac{m}{p}$. Drawing from a set $\delta$ of "small exponents", e.g. from $\delta=\{1, \ldots, \ell\}$, still has soundness $\delta_{\text {snd }}(\chi) \leq \frac{m}{\ell}$.

Example 2.13 (Pseudo-random testing). The verifier can replace truly random choices, e.g. $\boldsymbol{x} \leftarrow \mathbb{F}_{p}^{m}$ as above, by pseudorandom choices, e.g. $\boldsymbol{x} \leftarrow \operatorname{PRG}(s)$ for $s \leftarrow\{0,1\}^{\kappa}$. This allows the verifier to compress such challenges to a random seed $s$.

It is heuristically plausible, that any non-pathological PRG has distribution with soundness error (negligibly close) to that of the respective uniform distributions. In fact, for a PRG which is secure against non-uniform adversaries, this is easy to see. However, this is a strong assumption and there are distributions $\chi$ which are pseudorandom (under plausible assumptions), but where the soundness error $\delta_{\text {snd }}(\chi)$ is large, e.g. greater than $\frac{1}{2}$. This motivates some computational notion of soundness error, which is discussed in Appendix E.

Note that soundness of testing distributions is a combinatorial property. No pseudorandomness property is required, as illustrated by Example 2.10. Thus, there may be better options to use "small exponents" than (pseudo)random testing.
2.3.1 Dual testing distributions. Due to space constraints, dual testing distributions are not explicitly used in the main body, so we omit their definition. Morally, testing distributions test whether some $\boldsymbol{z} \in \mathbb{F}_{p}^{m}$ is 0 . Dual testing distributions enforce $\boldsymbol{z}=0$. Dual testing distributions can be used to derive fresh (Pedersen) commitment keys, and guarantee that no commitment generated prior can be opened (except to 0 ).

### 2.4 Special soundness

In the main body, we only consider special soundness and give extractors which produce a witness given a suitable tree of accepting transcripts, see also [13].

Definition $2.14\left(\mu\right.$-special soundness $\left(\right.$ over $\left.\left.\mathbb{F}_{p}\right)\right)$. Let (GenCRS, $\left.\mathscr{P}, \mathcal{V}\right)$ be a public coin argument system for $\mathscr{R}$. Suppose the verifier sends $n$ challenges and $\mu=\left(\mu_{0}, \ldots, \mu_{n-1}\right) \in \mathbb{N}^{n}$. Furthermore, suppose
the challenges are vectors in $\mathbb{F}_{p}^{n_{i}}$. Then the protocol is $\mu$-special sound if there exists an extractor Ext such that given any good $\mu$ tree tree $\mu_{\mu}$ of transcripts, Ext(st, tree $\mu_{\mu}$ ) returns a witness w with (st, w) $\in \mathscr{R}$. A $\mu$-tree of transcripts is a (directed) tree where nodes of depth $i$ have $\mu_{i}$ children, with edges labelled with the $i$-th challenge, and nodes labelled with the prover's $i$-th answer, and every path along the tree constitutes an accepting transcript. We call a $\mu$ tree good if for every node, all its challenges (i.e. outgoing edges) are in general position. ${ }^{1}$

Given a TreeFind algorithm, which produces good $\mu$-trees (with oracle access to a successful prover), and an extractor as above, one obtains witness extended emulation by plugging the tree into the extractor. To be able to speak about the security of the resulting protocol, one needs success and runtime guarantees of TreeFind. We do not deal with this here as it is a separate issue. See $[13,49]$ for TreeFinders and Appendix D for more details.
2.4.1 Short-circuit extraction. Suppose TreeFind produces the tree's nodes and leaves on demand, and Ext queries TreeFind as an oracle, and traverses the tree in depth-first order. Moreover, suppose Ext either extracts a witness for some statement, or a solution to a (supposedly) hard problem, or both. Concretely, we have statements like "we extract $w$ such that either $[g] w=[c]$ is a valid commitment opening, or $[g] w=[0]$ breaks the hard kernel assumption for [g]." In such a situation, short-circuit extraction with $\mu^{\prime} \leq \mu$ asserts that, extraction either finds the opening $w$ using only the $\mu^{\prime}$-subtree of tree ${ }_{\mu}$, or for one layer $i$, all $\mu_{i}$ children are examined, and the extractor finds a non-trivial $w$ in $\operatorname{ker}([g])$.

Definition 2.15. Consider the situation in Definition 2.14. Suppose $\mathscr{R}$ is $\operatorname{OR}\left(\mathscr{R}_{1}, \mathscr{R}_{2}\right)$, i.e.

$$
\mathscr{R}=\left\{\left(\left(\mathrm{st}_{1}, \mathrm{st}_{2}\right),\left(\mathrm{w}_{1}, \mathrm{w}_{2}\right)\right) \mid\left(\mathrm{st}_{i}, \mathrm{w}_{i}\right) \in \mathscr{R}_{i} \text { for } i=1 \text { or } i=2\right\} .
$$

Suppose there is some $\mu^{\prime} \leq \mu$ (i.e. $\mu_{i}^{\prime} \leq \mu_{i}$ for all $i$ ) such that extractor Ext has following property. For any good $\mu$-tree tree ${ }_{\mu}$, Ext(st, tree $_{\mu}$ ) we have either:

- Ext finishes after exploring a $\mu^{\prime}$-subtree of tree $\mu_{\mu}$ and returns a witness for $\mathrm{st}_{1}$. We call this quick-extraction.
- If in layer $\ell$ of the tree, Ext must explore more than $\mu_{\ell}^{\prime}$ children of some node, then after exploring all $\mu_{\ell}$ children, Ext returns a witness for $\mathrm{st}_{2}$ (and perhaps $\mathrm{st}_{1}$ ). (That is, Ext short-circuits in layer $\ell$.)
We say that such an Ext has short-circuit extraction with $\mu^{\prime} \leq$ $\mu$ for finding a witness to $\mathrm{st}_{1}$ or to $\mathrm{st}_{2}$. (Note that order of the statements matters!)

Our definition is ad-hoc and tailored to our needs. We leave a solid definition and precise treatment of short-circuit extraction for future work.

Corollary 2.16. If Ext as in Definition 2.15 traverses a good tree tree $\mu$ in depth-first order, we have following "runtime" guarantees: Let $\mu^{\prime}=\left(\mu_{0}^{\prime}, \ldots, \mu_{n-1}^{\prime}\right) \leq\left(\mu_{0}, \ldots, \mu_{n-1}\right)=\mu$. In case of quickextraction, at most $\prod_{i=0}^{n-1} \mu_{i}^{\prime}$ leaves are explored. In case of shortcircuit extraction, at most $s_{0}+1$ leaves are explored, where $s_{0}=$ $\sum_{i=0}^{n-1}\left(\mu_{i}-1\right) \prod_{j=i+1}^{n-1} \mu_{j}^{\prime}$. In particular, $s_{0} \leq\left(\sum_{i=0}^{n-1} \mu_{i}\right)\left(\prod_{i=0}^{n-1} \mu_{i}^{\prime}\right)$.

[^1]We note that since the tree tree ${ }_{\mu}$ is randomised (or Ext might explore children in random order), the above worst-case analysis is very conservative.

## 3 HVZK ARGUMENTS FOR [ $A$ ] $\boldsymbol{w}=[\boldsymbol{t}]$

Let $\mathrm{ck}:=[\boldsymbol{g}]=\left[g_{0}, \overline{\boldsymbol{g}}\right] \leftarrow \mathbb{G}^{1 \times n+1}$ be a Pedersen commitment key, where $\left[g_{0}\right] \in \mathbb{G}$ and $[\bar{g}] \in \mathbb{G}^{n}$. Define $\operatorname{Com}_{\boldsymbol{g}}(\boldsymbol{w} ; r):=\left[g_{0}\right] r+[\bar{g}] \boldsymbol{w}$ for $r \in \mathbb{F}_{p}, \boldsymbol{w} \in \mathbb{F}_{p}^{n}$. In the whole section, we work with matrices $[A] \in \mathbb{G}^{m \times n}$, and vectors $\boldsymbol{w} \in \mathbb{F}_{p}^{n}$ and $[t] \in \mathbb{G}^{m}$. The dimensions are as above, unless otherwise specified. Our witness relation $\mathscr{R}$ is st $=([A],[t])$ and $\mathrm{w}=w$ such that $(\mathrm{st}, \mathrm{w}) \in \mathscr{R} \Longleftrightarrow[A] w=[t]$.

### 3.1 Intuition

In this section, we devise communication efficient public-coin HVZK arguments for knowledge of a preimage of a linear map, i.e. $\exists \boldsymbol{w}$ : $[A] \boldsymbol{w}=[t]$. We follow two principles: "Use probabilistic (batch) verification to check many things at once" and "If messages are too long, replace them by a shorter proof (of knowledge)." For this, we use shrinking commitments, to keep the messages small.

Our strategy is as follows: First, we recall the well-known general HVZK protocol $[20,42]$ for proving $\exists \boldsymbol{w}:[A] \boldsymbol{w}=[\boldsymbol{t}]$ where $[A] \in \mathbb{G}^{m \times n}$. Then, we show how to apply batch verification to reduce the argument for $([A],[t])$ to another an argument for some ( $[\boldsymbol{B}],[\boldsymbol{u}])$ with $[\boldsymbol{B}] \in \mathbb{G}^{2 \times n}$. This makes communication independent of the number $m$ of rows of [A]. After this, we revisit the arguments from [13] which recursively batch statement and witness, i.e. they reduce the number $n$ of columns of $[A]$. Unlike [ 13,17 ], we need a zero-knowledge version of these arguments. We provide a very efficient conversion with constant communication and logarithmic computational overhead. Taken together, we can for any [A] prove knowledge of $\boldsymbol{w}$ in communication $O(\log (n))$ now.

### 3.2 Step 0: A standard $\Sigma$-protocol for $[A] \boldsymbol{w}=[\boldsymbol{t}]$

We recall the prototypical $\Sigma$-protocol in a group setting [20, 42].
Protocol $3.1\left(\Sigma_{\text {std }}\right)$. The following is a protocol to prove $\exists \boldsymbol{w}:[\boldsymbol{t}]=$ $[A] \boldsymbol{w}$, using testing distribution $\chi^{(\beta)}$ for challenges, c.f. Example 2.11. Common input is $([A],[t]) \in \mathbb{G}^{m \times n} \times \mathbb{G}^{n}$. The prover's witness is some $\boldsymbol{w} \in \mathbb{F}_{p}^{n}$.

- $\mathscr{P} \rightarrow V:$ Pick $\boldsymbol{r} \leftarrow \mathbb{F}_{p}^{n}$ and let $[\boldsymbol{a}]=[A] \boldsymbol{r}$. Send $[\boldsymbol{a}] \in \mathbb{G}^{m}$.
- $V \rightarrow \mathscr{P}$ : Pick $\beta \leftarrow \chi^{(\beta)}$. Send $\beta \in \mathbb{F}_{p}$.
- $\mathscr{P} \rightarrow V$ : Compute $z=\beta \boldsymbol{w}+\boldsymbol{r}$. Sends $z \in \mathbb{F}_{p}^{n}$.
- $V$ : Check if $[A] z=\beta[t]+[a]$. (Accept/reject if true/false.)

It is straightforward to show that any $\left(x_{1}, x_{2}\right) \leftarrow \chi_{2}$ can be used instead of $\chi^{(\beta)}$, as long as $x_{2} \neq 0$, so that $x_{1} \boldsymbol{w}+x_{2} r$ is uniformly distributed, c.f. Section 1.1.

Lemma 3.2. Protocol $\Sigma_{\text {std }}$ is a HVZK-PoK for $\exists w$ : $[A] w=[t]$. It is perfectly complete, has perfect HVZK and is 2-special sound.

Proof. Completeness is straightforward. Extraction: We are given two accepting transcripts $([\boldsymbol{a}], \beta, \boldsymbol{z})$, and $\left([\boldsymbol{a}], \beta^{\prime}, \boldsymbol{z}^{\prime}\right)$ with $\beta$ $\beta^{\prime} \neq 0$. Due to the final check of the verifier, we obtain $\frac{1}{\beta-\beta^{\prime}}[A](z-$ $\left.z^{\prime}\right)=[t]$. Consequently, $\boldsymbol{w}:=\frac{1}{\beta-\beta^{\prime}}\left(z-z^{\prime}\right)$ is a witness.

HVZK: Pick $\beta \leftarrow \chi^{(\beta)}$ and $\boldsymbol{z} \leftarrow \mathbb{F}_{p}^{m}$. Then $[\boldsymbol{a}]:=[A] z-\beta[\boldsymbol{t}]$ is uniquely defined. Since the distribution of $\beta$ and $z$ is as in an honest execution, this yields a perfect simulation.

Now, we improve communication efficiency. We apply the techniques mentioned in the introduction, using shrinking commitments to keep messages small. Composition of proof systems is implicit due the following remark.

Remark 3.3. AND-proofs for statements of the form $\exists \boldsymbol{w}:[\boldsymbol{A}] \boldsymbol{w}=$ $[\boldsymbol{t}]$ are trivial. Namely, to prove $\exists \boldsymbol{w}:\left[\boldsymbol{A}_{1}\right] \boldsymbol{w}=\left[\boldsymbol{t}_{1}\right] \wedge\left[\boldsymbol{A}_{2}\right] \boldsymbol{w}=$ $\left[t_{2}\right]$, it suffices to define $[A]=\left[\begin{array}{l}A_{1} \\ A_{2}\end{array}\right]$ and $[t]=\left[\begin{array}{c}t_{1} \\ t_{2}\end{array}\right]$ and prove $\exists \boldsymbol{w}:[A] \boldsymbol{w}=[t]$. This AND-compilation technique will be used without explicit mention. Evidently, many trivial optimisations are possible, e.g. removing duplicate rows.

### 3.3 Step 1: Batching all equations together

In this step, we devise a HVZK-AoK for $\exists \boldsymbol{w}:[A] \boldsymbol{w}=[t]$, where $\mathscr{P}$ 's communication is independent of $m$, the "number of equations". Thus, we have to shrink the message $[a] \in \mathbb{G}^{m}$ somehow. We would like to batch all $m$ linear equations (given by $[A]$ ) into a single linear equation, i.e. replace $[A]$ by a random linear combination of its rows. We do not know whether this is sound or not, c.f. Question 3.5 . Nevertheless, if $\mathscr{P}$ has explicitly committed to the witness $\boldsymbol{w}$ (or $[\boldsymbol{a}]$ ), the statement - excluding the commitment can be batched, as $\mathscr{P}$ cannot change his mind anymore. Note that the value $[t]$ is in general not a commitment, since the adversary may supply (parts of) $[A]$ in the soundness experiment. Thus, he may know dlogs and generate preimages of $[t]$ freely. By adding a commitment to $\boldsymbol{w}$, we get around this problem. Using a shrinking (Pedersen) commitment to $\boldsymbol{w}$, keeps the communication overhead small. Now, the verifier can send batching randomness, and a HVZK-AoK for the batched statement is carried out. Details are in Appendix A. 3 We thus reduced general $[A]$ to $[B] \in \mathbb{F}_{p}^{2 \times n}$, where the (say top) row of $[B]$ is a commitment key.

Remark 3.4 (Commitment extending). When working with adversarial $[A]$ (and $[t]$ ), one can not rely on hardness assumptions. Extending $[A]$ to, for example, $[B]=\left[\begin{array}{l}g \\ A\end{array}\right]$ with commitment key $[g]$ is one way to circumvent problems. For the sake of referencing, we call this commitment extending $[A]$. If $[A]$ already contains a commitment submatrix, there is an obvious adaption of Protocol LMPA batch .

Note that commitment extending $[A]$ was not necessary for Protocol $\Sigma_{\text {std }}$, where extraction is unconditional. This raises following (to the best of our knowledge open) question.

Question 3.5. Is batch-verification without an (unbatched) commitment sound? That is, $V$ initiates LMPA $_{\text {batch }}$ and sends $\boldsymbol{x}$ immediately. Then $\exists w:[\widehat{A}] w=[\widehat{t}]$ is proven. Since the statements are adversarially chosen, this is essentially an information-theoretic question. Partial results show that soundness holds at least in certain (very) special cases. The gist of this question recurs in different guises, and culminates in the question whether many of the presented arguments (and many in the literature) may in fact be proofs of knowledge.

### 3.4 Step 2: "Batching" the witness

In this section, we show how to "batch" the witness, i.e. proving $\exists \boldsymbol{w}:[A] \boldsymbol{w}=[\boldsymbol{t}]$ for $[A] \in \mathbb{G}^{m \times n}$ with communication sublinear in $n$. For the introduction, one may assume $m=1$, e.g. $[A]=[g]$.

Remark 3.6. We can also reduce to $m=1$ conceptually. Namely, let $\mathbb{H}:=\mathbb{G}^{m}$. Then $[A]$ and $[t]$ can be interpreted as $[A] \in \mathbb{H}^{1 \times n}$, $[\boldsymbol{t}] \in \mathbb{H}$, and $[A] \boldsymbol{w}=[\boldsymbol{t}]$. Using $\mathbb{H}$ means working over a vector space of dimension $m>1$. This is a relevant difference, but mostly affects zero-knowledge. ${ }^{2}$
3.4.1 The general idea. We present the technique of [13], but in our situation and notation. For the motivation, let us ignore zeroknowledge, and only construct an argument (of knowledge). We add zero-knowledge later.

In general, one can achieve a size reduction of $k \in \mathbb{N}$ recursive step. For proof size, $k=2$ is optimal, so we restrict ourselves to that. The full version [36] deals with general $k$. Assume for simplicity that $2 \mid n$, i.e. $n / 2 \in \mathbb{N}$. We will reduce the equation $[A] \boldsymbol{w}=[\boldsymbol{t}]$ to $[\widehat{A}] \widehat{\boldsymbol{w}}=[\widehat{\boldsymbol{t}}]$, where $[\widehat{\boldsymbol{A}}] \in \mathbb{G}^{m \times n / 2}, \widehat{\boldsymbol{w}} \in \mathbb{F}_{p}^{n / 2},[\widehat{\boldsymbol{t}}] \in \mathbb{G}^{m}$. To do so, divide $[A]$ and $w$ into 2 equal blocks, ${ }^{3}$ obtaining vectors/matrices of vectors/matrices i.e. $[\boldsymbol{A}]=\left[\boldsymbol{A}_{1} \mid \boldsymbol{A}_{2}\right] \in(\mathbb{G} m \times n / 2)^{1 \times 2}$ with $\left[\boldsymbol{A}_{i}\right] \in$ $\mathbb{G} m \times n / 2$, and likewise $\boldsymbol{w}=\binom{\boldsymbol{w}_{1}}{\boldsymbol{w}_{2}} \in\left(\mathbb{G}^{n / 2}\right)^{2}$. We want to prove $\sum_{i=1}^{2}\left[\boldsymbol{A}_{i}\right] \boldsymbol{w}_{i}=[\boldsymbol{t}]$.

Still, the techniques from Section 3.3 are not applicable, because $[t] \in \mathbb{G}($ if $m=1)$. The trick of [13] is to embed our problem into a different one which can be batch-verified. Namely, we exploit that the scalar product is the sum of the diagonal entries (i.e. the trace) of the outer product:

$$
\left[\begin{array}{l}
\boldsymbol{A}_{1}  \tag{3.1}\\
\boldsymbol{A}_{2}
\end{array}\right]\left(\boldsymbol{w}_{1}, \boldsymbol{w}_{2}\right)=\left[\begin{array}{ll}
\boldsymbol{A}_{1} \boldsymbol{w}_{1} & \boldsymbol{A}_{1} \boldsymbol{w}_{2} \\
\boldsymbol{A}_{2} \boldsymbol{w}_{1} & \boldsymbol{A}_{2} \boldsymbol{w}_{2}
\end{array}\right] \in \mathbb{G}^{2 \times 2}
$$

Now we can send all terms $\left[\boldsymbol{A}_{i}\right] \boldsymbol{w}_{j}$ to the verifier. Our probabilistic test has to map both $[A]$ and $\boldsymbol{w}$ to a new (smaller) statement. We can do that by multiplying from the left by $\boldsymbol{x} \in \mathbb{F}_{p}^{2}$ and from the right by $\boldsymbol{y} \in \mathbb{F}_{p}^{2}$ where $\boldsymbol{x}, \boldsymbol{y} \leftarrow \chi_{2}$. Consequently, we obtain

$$
\begin{aligned}
& \boldsymbol{x}^{\top}\left(\left[\begin{array}{l}
\boldsymbol{A}_{1} \\
\boldsymbol{A}_{2}
\end{array}\right]\left(\boldsymbol{w}_{1}, \boldsymbol{w}_{2}\right)\right) \boldsymbol{y} \\
= & \underbrace{\left(\boldsymbol{x}^{\top}\left[\begin{array}{l}
\boldsymbol{A}_{1} \\
\boldsymbol{A}_{2}
\end{array}\right]\right)} \underbrace{\left(\left(\boldsymbol{w}_{1}, \ldots, \boldsymbol{w}_{k}\right) \boldsymbol{y}\right)}_{:=\sum_{i} y_{i} \boldsymbol{w}_{i}=:[\widehat{\boldsymbol{w}}]}=\underbrace{\sum_{i, j} x_{i} y_{j}\left[\boldsymbol{A}_{i}\right] \boldsymbol{w}_{j}}_{=:[\widehat{t}]}
\end{aligned}
$$

The prover thus sends the (purported) $\left[\boldsymbol{A}_{\boldsymbol{i}} \boldsymbol{w}_{j}\right]$, denoted $\left[\boldsymbol{u}_{i, j}\right]$, and $\widehat{\boldsymbol{w}}$, the shrunk witness. The verifier checks $\sum_{i}\left[\boldsymbol{u}_{i, i}\right] \stackrel{?}{=}[\boldsymbol{t}]$ and $[\widehat{A}] \widehat{\boldsymbol{w}} \stackrel{?}{=}$ $[t]=\sum_{i, j} x_{i} y_{j}\left[\boldsymbol{u}_{i, j}\right]$.

If each $\left[\boldsymbol{A}_{i}\right]$ satisfies a hard kernel assumption, the prover is committed to $\boldsymbol{w}_{1}, \boldsymbol{w}_{2}$. It is not hard to see that given enough (linearly independent) challenges, one can extract $\boldsymbol{w}$. We will show this for a more efficient special case. All in all, we reduced the statement $([A],[t])$ to $([\widehat{A}],[\widehat{t}])$ which is smaller by a factor of $k=2$. This can be applied recursively.

[^2]3.4.2 Refining the testing distribution. It turns out, that by a good choice of testing distribution, we can reduce communication. Namely, we can pick testing distributions with $x_{i} y_{j}=z_{j-i}$ for all $i, j$. Then it is sufficient for the verifier to know the sum of the off-diagonals i.e. $\left[\boldsymbol{A}_{2}\right] \boldsymbol{w}_{1}$ and $\left[\boldsymbol{A}_{1}\right] \boldsymbol{w}_{2}$ (and $\left.[\boldsymbol{t}]\right)$. We denote the (purported) $\left[\boldsymbol{A}_{i}\right] \boldsymbol{w}_{j}$, sent by the prover, as $\left[\boldsymbol{u}_{\ell}\right]$, i.e. $\left[\boldsymbol{u}_{-1}\right]:=\left[\boldsymbol{A}_{2}\right] \boldsymbol{w}_{1}$ and $\left[\boldsymbol{u}_{1}\right]:=\left[\boldsymbol{A}_{1}\right] \boldsymbol{w}_{2}$. Note that $\left[\boldsymbol{u}_{0}\right]=[\boldsymbol{t}]$ need not be sent. From the testing distribution $\widetilde{\chi}_{3}$ we require that $z=\left(z_{-1}, z_{0}, z_{1}\right) \leftarrow \widetilde{\chi}_{3}$, belongs to a pair $(\boldsymbol{x}, \boldsymbol{y})$.

One testing distribution with this property comes from monomials $\xi^{i}$, e.g. $\boldsymbol{x}=(1, \xi)$ and $\boldsymbol{y}=\left(1, \xi^{-1}\right) .^{4}$ In this case, $z_{\ell}=\xi^{-\ell}$.

For efficiency, picking $\boldsymbol{x}$ as above, but $\boldsymbol{y}=(\xi, 1)$ is useful, since this preserves small $\xi$. In this case, $\boldsymbol{z}=\left(z_{-1}, z_{0}, z_{1}\right)=\left(\xi^{2}, \xi, 1\right)$.

Protocol 3.7 ( $\mathrm{LMPA}_{\text {noZK }}$ ). The following is a protocol to prove $\exists \boldsymbol{w}:[\boldsymbol{t}]=[A] \boldsymbol{w}$. Let $\widetilde{\chi}_{3}$ be a testing distributions with the properties described above. Common input is $([A],[t]) \in \mathbb{G}^{m \times n} \times \mathbb{G}^{m}$. We assume $n=2^{d}$. The prover's witness is some $\boldsymbol{w} \in \mathbb{F}_{p}^{n}$.

Recursive step. Suppose $n=2^{d}>2$.

- Notation: Let $[A]=\left[\boldsymbol{A}_{1}, \boldsymbol{A}_{2}\right]$ and $\boldsymbol{w}=\binom{\boldsymbol{w}_{1}}{\boldsymbol{w}_{2}}$ be as above.
- $\mathscr{P} \rightarrow V$ : Compute $\left[\boldsymbol{u}_{-1}\right]:=\left[\boldsymbol{A}_{2}\right] \boldsymbol{w}_{1}$ and $\left[\boldsymbol{u}_{1}\right]:=\left[\boldsymbol{A}_{1}\right] \boldsymbol{w}_{2}$. Send $\left[\boldsymbol{u}_{\ell}\right]$ for $\ell= \pm 1$. $\left(\left[\boldsymbol{u}_{0}\right]:=[\boldsymbol{t}]\right.$ is known to the verifier. $)$
- $V \rightarrow \mathscr{P}:$ Pick $\boldsymbol{z} \leftarrow \widetilde{\chi}_{3}$ with corresponding $\boldsymbol{x}, \boldsymbol{y}$. Send $(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$.
- Both parties compute $[\widehat{A}]=x_{1}\left[\boldsymbol{A}_{1}\right]+x_{2}\left[\boldsymbol{A}_{2}\right] \in \mathbb{G}^{m \times n / 2}$ and $[\overrightarrow{\boldsymbol{t}}]=\sum_{\ell=-1}^{1} z_{\ell}\left[\boldsymbol{u}_{\ell}\right] \in \mathbb{G}$ as the new batched statement. Moreover, $\mathscr{P}$ computes $\widehat{\boldsymbol{w}}=\boldsymbol{w}_{1} y_{1}+\boldsymbol{w}_{2} y_{2}$. The protocol may then be (recursively resumed), setting $n \leftarrow n / 2$, $\boldsymbol{w} \leftarrow \widehat{\boldsymbol{w}}$, $[t] \leftarrow[\widehat{t}],[A] \leftarrow[\widehat{A}]$.
Base case. Suppose $n \leq 2$.
- $\mathscr{P} \rightarrow V$ : Send $w$.
- $V$ : Tests if $[A] \boldsymbol{w} \stackrel{?}{=}[\boldsymbol{t}]$.

See Appendix G for a sketch of the protocol. For efficiency, our base case could also start at $n=4$, as this saves one round-trip.

Lemma 3.8 (Recursive extraction). Consider the situation above. Let $\widetilde{\chi}_{3}$ be a testing distribution with $x_{i} y_{j}=z_{j-i}$ as above. ${ }^{5}$ Let $\left[\boldsymbol{u}_{\ell}\right]$, $\left[\boldsymbol{A}_{i}\right],[\boldsymbol{t}], \boldsymbol{w}_{j}$ and $[\widehat{\boldsymbol{A}}],[\widehat{\boldsymbol{t}}]$ be defined as above. Then:

- Given a non-trivial kernel element of $[\widehat{A}]$, we (efficiently) find a non-trivial kernel element of $[A]$.
- Given 3 linearly independent challenges (with accepting transcripts), i.e. an invertible matrix $Z$, one can extract (unconditionally) $a$ witness $[A] \boldsymbol{w}=[\boldsymbol{t}]$.
- Given 4 challenges in general position, ${ }^{6}$ if the witness from above does not fit w.r.t. the $\left[\boldsymbol{u}_{\ell}\right]$, i.e. if an honest prover would send different $\left[\boldsymbol{u}_{\ell}\right]$ for $\boldsymbol{w}$, then we find (additionally) a nontrivial kernel element $\boldsymbol{v}$, i.e $[A] \boldsymbol{v}=0$.
Moreover, we have short-circuit extraction: From 2 independent challenges, one can compute a candidate witness $\boldsymbol{w}^{\prime}$ for quick-extraction. If $\left[\boldsymbol{A}_{i}\right] \boldsymbol{w}_{j}^{\prime} \neq\left[\boldsymbol{u}_{\ell}\right]$ for some $\ell= \pm 1$, then we are guaranteed to find a non-trivial kernel element from 4 challenges in general position.

Note that, maybe surprisingly, extraction of a witness $\boldsymbol{w}$ with $[A] \boldsymbol{w}=[t]$ is unconditional, i.e. we have a proof of knowledge. (See

[^3]also Question 3.5.) The proof is a minor generalisation of [13, 17]. See [36] for details.

Remark 3.9. There are variants of $\mathrm{LMPA}_{\text {noZK }}$ which use other testing distributions so that only one element $\left[\boldsymbol{u}_{-1}\right]+\left[\boldsymbol{u}_{1}\right]$ is transferred. Unfortunately, these testing distributions require to run two subprotocols. All in all, this does not improve overall performance. See [36] for details.
3.4.3 Going zero-knowledge. There are many variations for going zero-knowledge. The most straightforward one is to run Protocol $\Sigma_{\text {std }}$ and replace sending $z$ by proving $\exists z:[A] z=\beta[\boldsymbol{t}]+[\boldsymbol{a}]$ via LMPA $_{\text {noZK }}$. This gives a proof of knowledge, and is quite communication efficient. But computing $[A] r$ for random $r$ is expensive. This approach is similar to [13, 17], where LMPA noZK only saves communication.

We achieve zero-knowledge more carefully. Instead of blinding the witness, we note that it is enough to blind the prover's responses. For this, a logarithmic amount of randomness suffices. This should make the prover more efficient.

Warm-up: Proving knowledge of opening of a commitment. For simplicity, we first sketch a protocol which assumes that $[A]=$ $[g] \in \mathbb{G}^{1 \times n}$, and $[g]$ is a commitment key. Thus, $[A]$ has hard kernel assumption by construction. Later, we deal with $m>1$ and adversarially chosen $[A]$, which we actually solve with a different technique. But the techniques employed in this simple example help understanding the more complex technique, and they are reused and extended in Section 4.4.

Our current problem is to prove $\exists \boldsymbol{w}:[\boldsymbol{g}] \boldsymbol{w}=[t]$ in zero-knowledge. We will employ a masked version of LMPA noZK, with judiciously chosen randomness $r$, to achieve this. In particular, we do not pick $r \leftarrow \mathbb{F}_{p}^{n}$. We pick $r$ so that only logarithmically many $r_{i}$ are nonzero. Thus, computing $[g] r=[a]$ is quite cheap (unlike in Proto$\left.\operatorname{col} \Sigma_{\mathrm{std}}\right)$. By the uniform-or-unique guideline, we want that each message $\left[\boldsymbol{u}_{ \pm 1}\right]$ looks uniformly random. By analysing the recursive structure of LMPA ${ }_{\text {noZK }}$, one sees that picking $r_{i} \leftarrow \mathbb{F}_{p}$ for $i \in \mathbb{M}_{n} \subseteq\{0, \ldots, n-1\}$ with $\mathbb{M}_{n}$ as defined below, and $r_{i}=0$ else, achieves this property. ${ }^{7}$

Definition 3.10 (Masking sets). We define the masking (randomness) sets/spaces $\mathbb{M}_{n} \subseteq\{0, \ldots, n-1\}$ (for $n=2^{d}$ ) by the formulas below. The set $\mathbb{M}_{n}$ describes the unit vectors of $\mathbb{F}_{p}^{n}$ (with zero-based indexing) which are used for random masking. We typically treat $\mathbb{M}_{n}$ as a subvector space of $\mathbb{F}_{p}^{n}$ (instead of explicitly referring to its $\left.\operatorname{span}\left\langle\boldsymbol{e}_{i} \mid i \in \mathbb{M}_{n}\right\rangle\right)$.

- $\mathbb{M}_{1}:=\{0\}$ and $\mathbb{M}_{2}:=\{0,1\}$.
- $\mathbb{M}_{2^{d}}:=\left\{\mathbb{M}_{2^{d-1}}\right\} \dot{\cup}\left\{2^{d-1}, 2^{d-1}+1\right\}$ for $d \geq 2$.

See Fig. 2 for a pictorial description.
By the structure of the masking sets, we have that (for $k=2$ ), if $\boldsymbol{r}$ is split into $\boldsymbol{r}=\binom{\boldsymbol{r}_{1}}{\boldsymbol{r}_{2}}$ as in LMPA noZK, then $\left[\boldsymbol{u}_{j-i}\right]=\left[\boldsymbol{g}_{i}\right] \boldsymbol{r}_{j}$ is uniformly distributed for $\boldsymbol{r} \leftarrow \mathbb{M}_{n}$. Moreover, $\widehat{\boldsymbol{r}}=y_{1} \boldsymbol{r}_{1}+y_{2} \boldsymbol{r}_{2}$ is distributed like a fresh $\boldsymbol{r}^{\prime} \leftarrow \mathbb{M}_{n / 2}$. This holds even when considering the joint distribution $\left(\left[\boldsymbol{u}_{-1}\right],\left[\boldsymbol{u}_{1}\right], \widehat{\boldsymbol{r}}\right)$. Thus, masking sets exhibit a useful recursive structure. There are some minor prerequisites to use the recursive structure, which we ignore for now.

[^4]Protocol 3.11. Let crs $=[g] \in \mathbb{G}^{1 \times n}$ be a uniformly random commitment key (in particular, $[g]$ has hard kernel relation under the DLOG assumption on $\mathbb{G}$.). The following is a protocol to prove $\exists \boldsymbol{w}:[t]=[\boldsymbol{g}] \boldsymbol{w}$. Let $\widetilde{\chi}_{3}$ be a testing distribution as in Protocol 3.7. Common input is $(\mathrm{crs},[t]) \in \mathbb{G}^{1 \times n} \times \mathbb{G}$. We assume $n=2^{d}$. The prover's witness is some $\boldsymbol{w} \in \mathbb{F}_{p}^{n}$.

- $\mathscr{P} \rightarrow V$ : Choose $r \leftarrow \mathbb{M}_{n}$. Compute $[a]=[\boldsymbol{g}] \boldsymbol{r}$. Send $[a]$.
- $V \rightarrow \mathscr{P}$ : Choose $\beta \leftarrow \chi^{(\beta)}$. Send $\beta$.
- $\mathscr{P} \leftrightarrow V$ : Let $z:=\beta \boldsymbol{w}+\boldsymbol{r}$ and $\left[t^{\prime}\right]:=\beta[t]+[a]$. Engage in $\mathrm{LMPA}_{\text {noZK }}$ for $\exists z:[g] z=\left[t^{\prime}\right]$.

It is clear that this protocol is correct. Short-circuit extraction follows easily as this is a composition of Protocol $\Sigma_{\text {std }}$ and LMPA noZK. Thus, only zero-knowledge remains. For this, one should note that $z=\beta \boldsymbol{w}+\boldsymbol{r}$ behaves like a linear combination throughout the protocol, because the reduced witness $\widehat{\boldsymbol{z}}$ is of the form $\beta \widehat{\boldsymbol{w}}+\widehat{\boldsymbol{r}}$. Indeed, we can view the protocol as a linear combination of protocols. Thus, to see that $\left[\boldsymbol{u}_{ \pm 1}\right]$ is uniformly distributed, we can focus our attention on $r$ and its effect alone. As explained before, due to the form of $\mathbb{M}_{n},\left(\widehat{\boldsymbol{r}},\left[\boldsymbol{u}_{-1}\right],\left[\boldsymbol{u}_{1}\right]\right)$ is uniformly distributed in $\mathbb{M}_{n / 2} \times \mathbb{G} \times \mathbb{G}$. Thus, each iteration outputs uniformly distributed $\left[\boldsymbol{u}_{ \pm 1}\right]$, and $\widehat{\boldsymbol{r}}$ distributed as $\widehat{\boldsymbol{r}} \leftarrow \mathbb{M}_{n / 2}$. For the base case, we note that by construction, $\mathbb{M}_{2}=\{0,1\}$. Thus, $r \leftarrow \mathbb{M}_{2}$ is uniformly random in $\mathbb{F}_{p}^{2}$, and hence $\beta \boldsymbol{w}+\widehat{\boldsymbol{r}}$ is uniformly random for $n \leq 2$, perfectly hiding $\boldsymbol{w}$. In particular, the messages in the base case are uniformly random too. The HVZK simulator can be built as usual, since the uniform-or-unique property is satisfied.

Difficulties arising from general $[A]$. There are two main difficulties arising from general $[A] \in \mathbb{G}^{m \times n}$. First, the higher dimension due to $m>1$ makes masking sets as described not directly applicable anymore. Second, we want to deal with adversarial [ $A$ ]. In the above sketch for zero-knowledge, we ignored a detail concerning the recursion. If it ever happens that in [g], for some $i \in \mathbb{M}_{n}$, the element $\left[g_{i}\right]$ is zero, the distribution of $\left(\widehat{\boldsymbol{r}},\left[\boldsymbol{u}_{-1}\right],\left[\boldsymbol{u}_{1}\right]\right)$ is skewed and zero-knowledge fails. An adversary can provoke this.

Resolving these problems efficiently (for the prover) is technical. See Appendix A. 2 for the construction and security claims. We remark that the naive approach to zero-knowledge (as in Protocol $3.1\left(\Sigma_{\text {std }}\right)$ ) for general $[A]$ is a simple and viable option, denoted LMPA simpleZK , if the computational overhead is acceptable. Considering the computational costs of LMPA noZK, this is often the case. Nevertheless, we demonstrate that, by applying our design guidelines, a more efficient, but more technical, conversion to zero-knowledge (with slightly larger proofs) is possible.

### 3.5 Step 3: Adding (arithmetic circuit) relations to the witness

If the witness $\boldsymbol{w}$ for $[A] \boldsymbol{w}=[\boldsymbol{t}]$ is committed to, e.g. if the first row of $[A]$ is a Pedersen commitment CRS [g], it is easily possible to make other (zero-knowledge) statements about $\boldsymbol{w}$ by composition of zero-knowledge protocols. Using Protocol QESA Copy $^{\text {from Sec- }}$ tion 4 (or [17] in special cases), it is possible to add constraints on the witness. In particular, one can use range-proofs to control $w$.

Remark 3.12. Often, $\boldsymbol{w}$ is much larger than the part which has to satisfy some constraints. It is efficiently possible to "split" and

Figure 2: Left: The (construction of the) masking randomness sets $\mathbb{M}_{4}, \mathbb{M}_{8}, \mathbb{M}_{16}$ and $\mathbb{M}_{32}$ (for $k=2$ ). The squares denote the numbers $0, \ldots, n-1$ (or the respective basis vectors (with zero-based indexing)). Right: A demonstration of the "overlap" when a recursive step is applied to $\mathbb{M}_{16}$, i.e. $\widehat{r}=y_{1} r_{1}+y_{2} r_{2}$ is computed. Note that by removing two dark squares in the overlap (i.e. the randomness being "used up" in $\left[u_{ \pm 1}\right]$ ), the sum is still is randomised as $\mathbb{M}_{8}$. This "recursive property" is essential. The indices in $\mathbb{M}_{n}$ can also be constructed recursively via string concatenation: $m_{2 n}=m_{n} \mid 110^{n-2}$ and $m_{1}=1, m_{2}=11$.
"merge" Pedersen commitments i.e. $[c]=\left[c_{1}\right]+\left[c_{2}\right]$ where $[G]=$ $\left[G_{1} \mid G_{2}\right]$ and $\left[c_{i}\right]=\left[G_{i}\right] w_{i}$. (Indeed, we use this quite often. With small changes, this is possible in zero-knowledge.) With this, one can split off the relevant portion $\boldsymbol{w}_{1}$ of $\boldsymbol{w}$ into the commitment [ $c_{1}$ ] and prove additional relations about this portion only. Splitting is generally very cheap. See Appendix C. 1 for a concrete application.

## 4 ARITHMETIC CIRCUIT SATISFIABILITY FROM QUADRATIC EQUATIONS

In this section, we describe quadratic gates, and relate them to rank 1 constraint systems (R1CS) and arithmetic circuits (AC). Then, we construct a proof of satisfiability of a set of quadratic equations via a (zero-knowledge) inner-product argument.

### 4.1 Quadratic gates

The equations our scheme is able to prove are quadratic equations, i.e. given a witness $\boldsymbol{w} \in \mathbb{F}_{p}^{n}$ and a matrix $\Gamma \in \mathbb{F}_{p}^{n \times n}$ we wish to prove

$$
\boldsymbol{w}^{\top} \boldsymbol{\Gamma} \boldsymbol{w}=0 .
$$

We choose this description of quadratic equations for simplicity and uniformity of notation. In particular, we assume without loss of generality, that the witness $\boldsymbol{w}$ has the constant 1 as first component, i.e. $w_{1}=1$. Our notation is similar to [23], which uses such notation for Groth-Sahai proofs [34]. Indeed, our arguments are essentially commit-and-prove systems [23].

Consider a general quadratic equation $\boldsymbol{x}^{\top} \boldsymbol{\Gamma} \boldsymbol{x}+\boldsymbol{a}^{\top} \boldsymbol{x}=t$, with $\boldsymbol{a}, \boldsymbol{x} \in \mathbb{F}_{p}^{n}, \Gamma \in \mathbb{F}_{p}^{n \times n}, t \in \mathbb{F}_{p}$ with statement given by the constants $(\boldsymbol{a}, \Gamma, t)$. This can be encoded via $\boldsymbol{w}=\binom{1}{\boldsymbol{x}}$ and suitably (re)defined $\Gamma$, namely $\boldsymbol{w}^{\top}\left(\begin{array}{cc}-t & 0 \\ a & \Gamma\end{array}\right) \boldsymbol{w}=0$.

It is straightforward to encode arithmetic circuits (ACs) as systems of quadratic equations. Doing this allows for ACs built from quadratic gates, i.e. gates whose input-output behaviour is described by a quadratic equation.

### 4.2 Arithmetic circuits and rank 1 constraint systems

Rank 1 constraint systems (R1CS) are systems of equations of the form $\left(\boldsymbol{w}^{\top} \boldsymbol{a}\right)\left(\boldsymbol{b}^{\top} \boldsymbol{w}\right)-\boldsymbol{c}^{\top} \boldsymbol{w}=0$, where $\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c} \in \mathbb{F}_{p}^{n}$. Evidently, these
are special cases of quadratic equations with $\Gamma=\boldsymbol{a} \boldsymbol{b}^{\top}+e_{1} \boldsymbol{c}^{\top} .{ }^{8}$ Arithmetic circuit satisfiability can be encoded in R1CS, c.f. [9].

The gates testable by one R1CS equation allow a single "multiplication". As we saw in the introduction, quadratic equations are more flexible. For example, the inner product $\boldsymbol{x}^{\top} \boldsymbol{y}$ is a single quadratic gate. To the best of our knowledge, $n$ gates are necessary to encode this in R1CS (essentially one per $x_{i} y_{i}$ multiplication). Thus, quadratic gates enable new optimisations. Indeed, all "AC to R1CS" optimisations (and more), are applicable for "AC to QE".

### 4.3 The verification strategy

Verifying that a system of quadratic gates is satisfied is easy given the witness $\boldsymbol{w}$, in our case the wire assignments of the AC , and equations $\Gamma_{\mathfrak{g}}$ (the gate g encoded as a matrix). Just check $\boldsymbol{w}^{\top} \boldsymbol{\Gamma}_{\mathfrak{g}} \boldsymbol{w}=$ 0 for all $\mathfrak{g} \in\left(\mathfrak{5}\right.$. By batching this can be sped up: Pick $\left(r_{\mathfrak{g}}\right)_{\mathfrak{g}} \leftarrow \chi_{\# \mathfrak{G}}$ from a testing distribution. Then compute $\Gamma:=\sum_{\mathfrak{g} \in(\mathfrak{F}} r_{\mathfrak{g}} \Gamma_{\mathfrak{g}}$ as the "batched statement". Finally, check if $\boldsymbol{w}^{\top} \boldsymbol{\Gamma} \boldsymbol{w}=0$.

We run this strategy in a commit-then-prove manner. First, commit to the witness $\boldsymbol{w}$. Then let the verifier pick testing randomness $\left(r_{\mathfrak{g}}\right)_{\mathfrak{g}}$ and prove that $\boldsymbol{w}^{\top} \boldsymbol{\Gamma} \boldsymbol{w}=0$ where $\boldsymbol{\Gamma}:=\sum_{\mathfrak{g} \in \mathfrak{F}} r_{\mathfrak{g}} \boldsymbol{\Gamma}_{\mathfrak{g}}$ is the "batched statement". Note that $\boldsymbol{w}^{\top} \boldsymbol{\Gamma} \boldsymbol{w}=\langle\boldsymbol{w}, \boldsymbol{\Gamma} \boldsymbol{w}\rangle$ is an inner product. Hence, we require a zero-knowledge inner-product argument.

For technical reasons, we cannot generate a commitment to $\Gamma \boldsymbol{w}$ efficiently (prior to knowing $\Gamma$ ). Therefore, the prover first commits to $\boldsymbol{w}$ as $\left[c_{\boldsymbol{x}}\right]=\operatorname{Com}_{\mathrm{ck}_{1}}(\boldsymbol{w})$. Then he obtains $\Gamma$ and commits to $\Gamma \boldsymbol{w}$ as $\left[c_{y}\right]=\mathrm{Com}_{\mathrm{ck}_{2}}(\Gamma \boldsymbol{w})$. Then the prover carries out the inner product argument. He must also prove that the commitments [ $c_{\boldsymbol{x}}$ ] and $\left[c_{\boldsymbol{y}}\right]$ open to values $\boldsymbol{x}=\boldsymbol{w}$ and $\boldsymbol{y}=\Gamma \boldsymbol{w}$ as promised. Again, we use (linear) batching to shorten the proof for $\boldsymbol{y}=\Gamma \boldsymbol{x}$. Namely, to check $y=\Gamma x$, the verifier picks random $s \leftarrow \chi_{n}$ (after $\left[c_{x}\right],\left[c_{y}\right]$ and hence $\boldsymbol{x}, \boldsymbol{y}$ are fixed) and the prover proves $0=\langle\boldsymbol{\Gamma} \boldsymbol{x}-\boldsymbol{y}, \boldsymbol{s}\rangle$.

Instead of two inner product arguments (for $\langle\boldsymbol{x}, \boldsymbol{y}\rangle=0$ and $\langle\Gamma \boldsymbol{x}-\boldsymbol{y}, \boldsymbol{s}\rangle=0$ ) we batch verify again: The verifier picks randomness $\alpha$ and the prover proves knowledge of openings $\boldsymbol{x}, \boldsymbol{y}$ such that,

$$
\begin{align*}
\left\langle\boldsymbol{x}-\alpha \boldsymbol{s}, \boldsymbol{y}+\alpha \boldsymbol{\Gamma}^{\top} \boldsymbol{s}\right\rangle & =\langle\boldsymbol{x}, \boldsymbol{y}\rangle+\alpha\left(\left\langle\boldsymbol{x}, \boldsymbol{\Gamma}^{\top} \boldsymbol{s}\right\rangle-\langle\boldsymbol{s}, \boldsymbol{y}\rangle\right)-\alpha^{2}\left\langle\boldsymbol{s}, \boldsymbol{\Gamma}^{\top} \boldsymbol{s}\right\rangle \\
& =\langle\boldsymbol{x}, \boldsymbol{y}\rangle+\alpha\langle\boldsymbol{\Gamma} \boldsymbol{x}-\boldsymbol{y}, \boldsymbol{s}\rangle-\alpha^{2}\left\langle\boldsymbol{s}, \boldsymbol{\Gamma}^{\top} \boldsymbol{s}\right\rangle \\
& \stackrel{!}{=}-\alpha^{2}\left\langle\boldsymbol{s}, \boldsymbol{\Gamma}^{\top} \boldsymbol{s}\right\rangle=: t \tag{4.1}
\end{align*}
$$

[^5]where $t$ is fixed by the random choices of the verifier. If $\boldsymbol{x}, \boldsymbol{y}, \Gamma, \boldsymbol{s}$ are fixed, the lemma of Schwartz-Zippel can be applied to the polynomial in $\alpha$. If $\alpha \leftarrow \mathcal{S}$, the probability that Eq. (4.1) holds but $\langle\boldsymbol{x}, \boldsymbol{y}\rangle \neq 0$ or $\langle\boldsymbol{\Gamma} \boldsymbol{x}-\boldsymbol{y}, \boldsymbol{s}\rangle \neq 0$ is $2 / \# \mathcal{S}$. If $\boldsymbol{s}$ is chosen from a testing distribution $\chi_{n}$ with error $\delta_{\text {snd }}\left(\chi_{n}\right)$, the probability that $\Gamma \boldsymbol{x}-\boldsymbol{y} \neq 0$ is at most $\delta_{\text {snd }}\left(\chi_{n}\right)$. Thus, this strategy is sound. To instantiate it, we need a zero-knowledge inner product argument.

### 4.4 Zero-knowledge inner product argument

Now, we show how to construct a zero-knowledge inner product argument (IPA). We first recall [13, 17], from a high level. We identify [17] as a linear combination of protocols. We achieve HVZK similar to Protocol 3.11 by masking the witness, but we also exploit redundancy (or kernel) guideline. Addition of zero-knowledge adds a single round, where one group element and one challenge are sent. For technical reasons we have a base case at $n=8$.
4.4.1 Inner product argument (IPA). First, we describe the IPA following [13, 17]. For simplicity, we ignore zero-knowledge.

Our setting is as follows: We have a CRS crs $=\left(\left[g^{\prime}\right],\left[g^{\prime \prime}\right],[Q]\right)$ for which finding a non-trivial kernel element of $\left[\boldsymbol{g}^{\prime}, \boldsymbol{g}^{\prime \prime}, Q\right] \in$ $\mathbb{G}^{2 n+1}$ is hard. In other words, these are three independent (or one large three-split) Pedersen commitment keys.

Naively, one proves knowledge of openings of $c_{\boldsymbol{w}}^{\prime}$ and $c_{\boldsymbol{w}}^{\prime \prime}$ with $\left\langle\boldsymbol{w}^{\prime}, \boldsymbol{w}^{\prime \prime}\right\rangle=t$. The idea and argument Protocol 3.11 allow to recursively shrink our statement. After one recursion step, we obtain $\left\langle\widehat{\boldsymbol{w}}^{\prime}, \widehat{\boldsymbol{w}}^{\prime \prime}\right\rangle=\widehat{t}$. The prover sends $v_{ \pm 1}=\left\langle\boldsymbol{w}_{i}^{\prime}, \boldsymbol{w}_{j}^{\prime \prime}\right\rangle($ for $j-i= \pm 1$ ), so that the verifier can compute $\widehat{t}$, analogous to $\left[u_{ \pm 1}\right]$ in Section 3.4,

To save communication, we use a linear combination of Protocol LMPA ${ }_{\text {noZK }}$ in our argument. Using the same challenge $(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$ for both runs does not work. But when swapping the challenge for, say the first instance, we see that the linear combination works. Concretely, let $\boldsymbol{x}=(1, \xi), \boldsymbol{y}=(\xi, 1)$. Then

$$
\left\langle\boldsymbol{x}^{\top} \boldsymbol{w}^{\prime}, \boldsymbol{y}^{\top} \boldsymbol{w}^{\prime \prime}\right\rangle=\xi\left\langle\boldsymbol{w}^{\prime}, \boldsymbol{w}^{\prime \prime}\right\rangle+\left\langle\boldsymbol{w}_{1}^{\prime}, \boldsymbol{w}_{2}^{\prime \prime}\right\rangle+\xi^{2}\left\langle\boldsymbol{w}_{2}^{\prime}, \boldsymbol{w}_{1}^{\prime \prime}\right\rangle
$$

Thus, analogous to $\left[\boldsymbol{u}_{0}\right]=[t]$ in $\mathrm{LMPA}_{\text {noZK }}$, the term $\left\langle\boldsymbol{w}^{\prime}, \boldsymbol{w}^{\prime \prime}\right\rangle=t$ is preserved. Therefore we run the first protocol for $w^{\prime}$ with flipped challenge ( $\boldsymbol{y}, \boldsymbol{x}$ ), and the second protocol for $\boldsymbol{w}^{\prime \prime}$ with challenge $(\boldsymbol{x}, \boldsymbol{y})$. Now, as in Protocol LMPA noZK $^{\prime}$, it suffices to send $v_{j-i}:=$ $\left\langle\boldsymbol{w}_{i}^{\prime}, \boldsymbol{w}_{2-i}^{\prime \prime}\right\rangle$ (for $i=1,2$ ).

The argument described above is a hybrid of [13] and [17]. For security, we need that "commitment merging" (see Remark 3.12), which the linear combination of protocols induces, still is binding. To obtain [17], we simply commit to $v_{\ell}$ as well (using [ $\left.Q\right]$ ), and send the combined commitment, i.e. apply again a linear combination. This "merged" commitment key is now [ $\left.\boldsymbol{g}^{\prime}, \boldsymbol{g}^{\prime \prime}, Q\right]$. Thus instead of sending two messages thrice (namely $\left[u_{ \pm 1}^{\prime}\right],\left[u_{\mp 1}^{\prime \prime}\right],\left[v_{\mp 1} Q\right]$ ), we only send the two "merged commitments" $\left[u_{ \pm 1}\right]=\left[u_{ \pm 1}^{\prime}\right]+\left[u_{\mp 1}^{\prime \prime}\right]+$ [ $v_{\mp 1} Q$ ]. Unlike [17], which uses $\boldsymbol{x}=\left(\xi^{-1}, \xi\right)$ we prefer $\boldsymbol{x}=(1, \xi)$ since exponentiation with 1 is free.

We sketch the protocol. The CRS is crs $=\left[\boldsymbol{g}^{\prime}, \boldsymbol{g}^{\prime \prime}, Q\right]$ where $\left[\boldsymbol{g}^{\prime}\right]$, $\left[g^{\prime \prime}\right] \in \mathbb{G}^{1 \times n}$ and $[Q] \in \mathbb{G}$ are random. To prove

$$
\exists w^{\prime}, w^{\prime \prime} \in \mathbb{F}_{p}^{n}:[c]=\left[g^{\prime}\right] w^{\prime}+\left[g^{\prime \prime}\right] w^{\prime \prime}+t[Q] \wedge\left\langle w^{\prime}, w^{\prime \prime}\right\rangle=t
$$

the prover computes $\left[\boldsymbol{u}_{\ell}^{\prime}\right],\left[\boldsymbol{u}_{\ell}^{\prime \prime}\right.$ as in Protocol 3.11, but with challenges flipped as described above. For $\ell= \pm 1$, the prover sends
$\left[\boldsymbol{u}_{\ell}\right]:=\left[\boldsymbol{u}_{\ell}^{\prime}\right]+\left[\boldsymbol{u}_{-\ell}^{\prime \prime}\right]+v_{-\ell}[Q]$. Both parties compute the reduced statement, and another iteration (or base case) is run.

The resulting protocol is called IPA noZK, see Appendix A. 4 for a full description. It is $\mu$-special sound (with $\mu=(2,4, \ldots, 4)$ ) for finding a witness or a non-trivial element in the kernel of $\left[\boldsymbol{g}^{\prime}, \boldsymbol{g}^{\prime \prime}, Q\right]$. And it has short-circuit extraction with $\mu^{\prime}=(1,2, \ldots, 2)$. The proof is essentially as in [13, 17].
4.4.2 Going zero-knowledge. Making the inner-product argument zero-knowledge can be done in many ways. To be competetive with Bulletproofs [17], we directly mask the witness. This is problematic, since the scalar product is non-linear. Consequently, our (initial) approach only works under some (mild) constraints.

As mentioned above, the problem with using masking randomness and proving $\left\langle\boldsymbol{w}^{\prime}+\boldsymbol{r}^{\prime}, \boldsymbol{w}^{\prime \prime}+\boldsymbol{r}^{\prime \prime}\right\rangle$ is the non-linearity: Sending only $t_{r}=\left\langle\boldsymbol{r}^{\prime}, \boldsymbol{r}^{\prime \prime}\right\rangle$ to the verifier is not enough. So we need to send also $\left\langle\boldsymbol{w}^{\prime}, \boldsymbol{r}^{\prime \prime}\right\rangle$ or $\left\langle\boldsymbol{r}^{\prime}, \boldsymbol{w}^{\prime \prime}\right\rangle$ or some other "error term" to correct the non-linearity. Then we have to show that these terms don't expose "information" about the witness. In particular, sending $\beta \boldsymbol{w}^{\prime}+\boldsymbol{r}^{\prime}$, which was possible in Section 3.3, seems impossible.

Fortunately, we already saw that the recursive argument only needs a small amount of randomness to conceal the witness. We exploit this now to show that the sketched masking almost yields zero-knowledge. Instead of sending the error terms, we pick randomness with the "kernel guideline" in mind:

$$
\begin{aligned}
& \text { - } \boldsymbol{r}^{\prime} \in \operatorname{ker}\left(\boldsymbol{w}^{\prime \prime \top}\right) \text {, i.e. }\left\langle\boldsymbol{r}^{\prime}, \boldsymbol{w}^{\prime \prime}\right\rangle=0 \\
& \text { - } \boldsymbol{r}^{\prime \prime} \in \operatorname{ker}\left(\boldsymbol{w}^{\prime \top}\right) \cap \operatorname{ker}\left(\boldsymbol{r}^{\top}\right) \text {, i.e. }\left\langle\boldsymbol{w}^{\prime}, \boldsymbol{r}^{\prime \prime}\right\rangle=0=\left\langle\boldsymbol{r}^{\prime}, \boldsymbol{r}^{\prime \prime}\right\rangle \text {. }
\end{aligned}
$$

In other words, we pick randomness which does not induce errors. Thus, the prover only has to send $\left[t_{r}\right]=\left[g^{\prime}\right] r^{\prime}+\left[g^{\prime \prime}\right] r^{\prime \prime}$ to the verifier. We first outline an almost zero-knowledge argument, using augmented masking sets $\mathbb{M}_{n}^{+}$which are defined later.

Protocol $4.1\left(\mathrm{IPA}_{\mathrm{alm}} \mathrm{ZK}\right)$. The following is an inner product argument with the same statement, witness and notation as Protocol A. 12 (IPA ${ }_{\text {noZK }}$ ).

- $\mathscr{P} \rightarrow \mathcal{V}: \operatorname{Pick} \boldsymbol{r}^{\prime} \leftarrow \operatorname{ker}\left(\boldsymbol{w}^{\prime \prime \top}\right) \cap \mathbb{M}_{n}^{+}$and $\boldsymbol{r}^{\prime \prime} \leftarrow \operatorname{ker}\left(\binom{\boldsymbol{w}^{\prime \top}}{\boldsymbol{r}^{\top \top}}\right) \cap$ $\mathbb{M}_{n}^{+}$. Compute $\left[c_{r}\right]:=\left[\boldsymbol{g}^{\prime}\right] \boldsymbol{r}^{\prime}+\left[\boldsymbol{g}^{\prime \prime}\right] \boldsymbol{r}^{\prime \prime}$. Send $\left[c_{r}\right]$.
- $V \rightarrow \mathscr{D}$ : Pick $\beta \leftarrow \chi^{(\beta)}$. Send $\beta$.
- $\mathscr{P} \leftrightarrow V$ :Run Protocol IPA noZK for $\left\langle\beta \boldsymbol{w}^{\prime}+\boldsymbol{r}^{\prime}, \beta \boldsymbol{w}^{\prime \prime}+\boldsymbol{r}^{\prime \prime}\right\rangle=$ $\beta^{2} t$ (with commitment $[c]=\beta\left[c_{w}\right]+\left[c_{r}\right]+\beta^{2} t[Q]$ ). To compute [c], the values $t$ and $\left[c_{w}\right]$ from the statement are used.

Correctness follows by inspection. Special soundness follows essentially from Lemma A. 13 and Lemma 3.2.

Corollary 4.2. Protocol 4.1 is special $\mu$-sound (with $\mu=(2,2,4$, ...,4)) for finding $a$ witness or a non-trivial element in the kernel of $\left[\boldsymbol{g}^{\prime}, \boldsymbol{g}^{\prime \prime}, Q\right]$. It has short-circuit extraction with $\mu=(2,1,2, \ldots, 2)$.

Showing zero-knowledge is more contrived. As for Protocol 3.11, we want to show that the prover's messages are uniformly random. Unfortunately, the constraints which must be satisfied now depend on the witness. Thus, an adversarially chosen witness may be a problem. Fortunately, we use IPA almZK with "randomised" witnesses, so this problem does not manifest.

Definition 4.3. Let $k$ be fixed and $n \geq 8$. Define $\mathbb{M}_{n}^{+}:=\mathbb{M}_{n} \dot{\cup}\{n-$ $2, n-1\}$. (Recall that $\mathbb{M}_{n}$ indices are zero-based and $n-2, n-1 \notin \mathbb{M}_{n}$ for $n \geq 8$.)

We introduce $\mathbb{M}_{n}^{+}$because satisfying the kernel constraints "consumes" one (resp. two) pieces of randomness in $r^{\prime}$ (resp. $\boldsymbol{r}^{\prime \prime}$ ). We compensate this in $\mathbb{M}_{n}^{+}$.

Lemma 4.4 (Informal, see [36]). If $\boldsymbol{w}^{\prime}, \boldsymbol{w}^{\prime \prime}$ are of a suitable form, then the responses in $\mathrm{IPA}_{\mathrm{alm}} \mathrm{ZK}$ are uniform-or-unique. More concretely, if $w_{n-1}^{\prime}, w_{n}^{\prime}$ are random, and $w_{n-1}^{\prime \prime}, w_{n}^{\prime \prime}$ also (not necessarily independent), then $\boldsymbol{w}$ is suitable.

### 4.5 Quadratic equation satisfiability

We can finally instantiate our sketch of an argument system for satisfiability of a system of quadratic equations from Section 4.3. It is a commit-and-prove system as follows. The prover commits to the solution $\boldsymbol{w}$. Then $\Gamma$ is fixed and $\langle\boldsymbol{w}, \Gamma \boldsymbol{w}\rangle=0$ shown to hold. The commitment scheme pads $\boldsymbol{w} \in \mathbb{F}_{p}^{n-2}$ with randomness and extends $\Gamma$ in a suitable way. Intuition for soundness is given in Section 4.3.

Protocol $4.5\left(\mathrm{QESA}_{\mathrm{ZK}}\right)$. Let $\Gamma_{i} \in \mathbb{F}_{p}^{(n-2) \times(n-2)}(i=1, \ldots, N)$ be a system of quadratic eqations. Suppose $N \geq 2 .{ }^{9}$ Let $\boldsymbol{w} \in \mathbb{F}_{p}^{n-2}$ be a solution, i.e. $\boldsymbol{w}^{\top} \boldsymbol{\Gamma}_{i} \boldsymbol{w}=0$ for all $i$. We assume that the first component $w_{1}$ of $w$ is 1 .

Let crs $=\left[\boldsymbol{g}^{\prime}, \boldsymbol{g}^{\prime \prime}, Q\right], \widetilde{\chi}_{3}, \chi^{(\beta \neq 0)}$ and $n \geq 8$ as in Protocol 4.1, and $\mathbb{M}_{n}^{+}$as in Lemma 4.4. Let $\boldsymbol{x} \leftarrow \chi_{N}$ be a testing distribution with $x_{1}=1$ and $x_{2} \neq 0$ for all $\boldsymbol{x}{ }^{10}$ Let $\boldsymbol{y} \leftarrow \chi_{n+1}$ be a testing distribution with $y_{1}=1$ always. The following is a protocol for proving

$$
\exists \boldsymbol{w} \in \mathbb{F}_{p}^{n-2}: \quad \forall i: \boldsymbol{w}^{\top} \boldsymbol{\Gamma}_{i} \boldsymbol{w}=0
$$

where crs and $\Gamma_{i}$ are common inputs and the prover's witness is $w$.

- $\mathscr{P} \rightarrow V:\left(\right.$ Step 0: Commitment.) Pick $\boldsymbol{r}^{\prime} \leftarrow \mathbb{F}_{p}^{2}$. Let the "extended" witness be $\boldsymbol{w}^{\prime}:=\binom{w}{r^{\prime}}$ and compute the commit$\operatorname{ment}\left[c_{w}^{\prime}\right]=\left[g^{\prime}\right] \boldsymbol{w}^{\prime}$. Send $\left[c_{w}^{\prime}\right]$.
- $V \rightarrow \mathscr{P}$ : (Step 1: Batch verification.) Pick and send $\boldsymbol{x} \leftarrow \chi_{N}$.
- (Batch equations): Both parties compute $\Gamma:=\sum x_{i} \Gamma_{i}$.
- (Fix $w_{1}$ to 1 ): Both parties let $\beta:=x_{2}$ and redefine $\left[g_{1}^{\prime}\right] \leftarrow$ $\beta^{-1}\left[g_{1}^{\prime}\right]$. Then $\left[c_{w}^{\prime}\right] \leftarrow\left[c_{w}^{\prime}\right]-(\beta-1)\left[g_{1}^{\prime}\right]$ (with the new $\left.\left[g_{1}^{\prime}\right]\right)$.
- $\mathscr{P} \rightarrow V$ : Let $\boldsymbol{r}^{\prime \prime}=\boldsymbol{R} \boldsymbol{r}^{\prime}$ where $\boldsymbol{R}=\left(\begin{array}{cc}0 & -1 \\ 1 & 0\end{array}\right)$ is a rotation by 90 degrees. Let $\boldsymbol{w}^{\prime \prime}=\binom{\Gamma \boldsymbol{w}}{\boldsymbol{r}^{\prime \prime}}$. Send $\left[c_{\boldsymbol{w}}^{\prime \prime}\right]=\left[\boldsymbol{g}^{\prime \prime}\right] \boldsymbol{w}^{\prime \prime}$.
- $\mathcal{V} \rightarrow \mathscr{P}$ : Pick $(1, \boldsymbol{s}, \boldsymbol{b}) \leftarrow \chi_{n+1}$, where $\boldsymbol{s} \in \mathbb{F}_{p}^{n-2}, \boldsymbol{b} \in \mathbb{F}_{p}^{2}$. Send $s^{\prime}:=\binom{s}{b}$.
- $\mathscr{P} \leftrightarrow V$ : Run Protocol IPA almZK for $\left\langle\boldsymbol{w}^{\prime}-\boldsymbol{s}^{\prime}, \boldsymbol{w}^{\prime \prime}+\Gamma^{\prime \top} \boldsymbol{s}^{\prime}\right\rangle=$ $t$ with $t=-\left\langle s, \Gamma^{\top} s\right\rangle$, and commitment $\left(\left[c_{w}^{\prime}\right]-\left[g^{\prime}\right] s^{\prime}\right)+$ $\left(\left[c_{w}^{\prime \prime}\right]+\left[\boldsymbol{g}^{\prime \prime}\right] \Gamma^{\prime \top} \boldsymbol{s}^{\prime}\right.$ ) and the modified $\left[\boldsymbol{g}^{\prime}\right]$ (and unmodified $\left.\left[\boldsymbol{g}^{\prime \prime}\right],[Q]\right)$ as commitment keys. Here $\Gamma^{\prime}=\left(\begin{array}{ll}\Gamma & 0 \\ 0 & R\end{array}\right) \in \mathbb{F}_{p}^{n \times n}$ where $R$ is as in Step 1.

See Appendix G for a sketch of this protocol.
Remark 4.6. It is not hard to see that the prover never needs to compute $[c]=\left(\left[c_{w}^{\prime}\right]-\left[g^{\prime}\right] s^{\prime}\right)+\left(\left[c_{w}^{\prime \prime}\right]+\left[g^{\prime \prime}\right] \Gamma^{\prime \top} s^{\prime}\right)$. (In general,

[^6]$\mathscr{P}$ does not need $\left[\boldsymbol{u}_{0}\right]$.) While the verifier has to check [c], using lazy evaluation and optimisations from [17], this hardly affects its runtime. All in all, dealing with $s^{\prime}$ is almost free.

We now state basic properties of QESA ${ }_{\text {ZK }}$.

## Lemma 4.7. Protocol $\mathrm{QESA}_{\mathrm{ZK}}$ has perfect correctness.

Using $\left\langle\binom{\boldsymbol{u}^{\prime}}{\boldsymbol{r}^{\prime}},\binom{\boldsymbol{u}^{\prime \prime}}{\boldsymbol{r}^{\prime \prime}}\right\rangle=\left\langle\boldsymbol{u}^{\prime}, \boldsymbol{u}^{\prime \prime}\right\rangle+\left\langle\boldsymbol{r}^{\prime}, \boldsymbol{r}^{\prime \prime}\right\rangle$ and $\langle\boldsymbol{r}, \boldsymbol{R} \boldsymbol{r}\rangle=0$ for all $r \in \mathbb{F}_{p}^{2}$, this is a straightforward check.

Lemma 4.8. Protocol QESA ${ }_{\text {ZK }}$ has $\mu$-special soundess (with $\mu=$ $(N, n+1,2,2,4, \ldots, 4))$ for extracting a witness or a non-trivial kernel element of $\left[\boldsymbol{g}^{\prime}, \boldsymbol{g}^{\prime \prime}, Q\right]$. It inherits short-circuit extraction with $\mu=(1,1,2,2,2, \ldots, 2)$.

We did away with " $\alpha$ " compared to Section 4.3 to improve soundness. Extracting a challenge $(\alpha, s)$ naively requires a $(3, n-2)$ subtree. Our construction only needs an $(n+1)$ sub-"tree".

Lemma 4.9. Protocol QESA ${ }_{\mathrm{ZK}}$ is $\varepsilon$-statistical zero-knowledge for some $\varepsilon \in O\left(2 \log _{2}(n)\right) / p$.

For the proof, we establish that the conditions of Lemma 4.4 are met except with probability $O\left(2 \log _{2}(n)\right) / p$. This follows essentially because QESA ZK $^{\text {uses }} \boldsymbol{w}^{\prime}=\binom{\boldsymbol{w}}{\boldsymbol{r}}$, where $\boldsymbol{r}$ is random (and similar for $\boldsymbol{w}^{\prime \prime}$ ). Thus, IPA almZK is statistical zero-knowledge, and consequently QESA $_{\mathrm{ZK}}$ is statistical zero-knowledge as well.

### 4.6 Combining QESA $A_{Z K}$ with other proof systems

As is, QESA ZK can be used to commit-and-prove quadratic equations. However, oftentimes, one wishes to prove statements about commitments which come from some other source. For example, Bulletproofs [17] were designed for confidential transaction, where the commitments are input to the proof system. This is not immediately feasible with QESA ${ }_{\mathrm{ZK}}$ as is, because QESA ZK $^{\text {is commit-and- }}$ prove only w.r.t. the solution of the set of quadratic equations.

Fortunately, extending QESA ${ }_{\mathrm{ZK}}$ is not hard. We consider following setting. There are commitment keys $\widetilde{\mathrm{ck}}^{(i)}$ for $i=1, \ldots, M$. Each commitment key corresponds to a subset $\mathscr{I}_{i} \subseteq\{1, \ldots, n\}$ of the components of $\left[g^{\prime}\right]$, where $\mathrm{crs}=\left(\left[g^{\prime}, \boldsymbol{g}^{\prime \prime}, Q\right]\right)$ is the commitment key of QESA ZK . That is $\widetilde{\mathrm{ck}^{(i)}} \widehat{\equiv}\left\{\left[g_{j}^{\prime}\right]\right\}_{j \in \mathscr{I}_{i}}$. Let $\mathscr{I}:=\cup_{i=1}^{M} \mathscr{g}_{i}$ be the set of all indices which are part of some $\widetilde{\mathrm{ck}}^{(i)}$. Let $M^{(i)}:=\# \mathscr{I}_{i}$ be the size of $\widetilde{\mathrm{ck}}^{(i)}$. We assume the following: Every commitment key $\widetilde{c k}^{(i)}$ uses $\left[g_{n}^{\prime}\right]$ (or $\left[g_{n-1}^{\prime}\right]$ ) as its randomness components. Moreover, $1 \notin \mathscr{g}_{i}$, because the index $1 \widehat{=}\left[g_{1}^{\prime}\right]$ is reserved for the commitment to value 1 in QESA $_{\mathrm{ZK}}$. A useful point of view is that $\widetilde{\mathrm{ck}}^{(i)}$ is a commitment under $\left[\boldsymbol{g}^{\prime}\right] \in \mathbb{G}^{n}$ to a vector $\boldsymbol{v}^{(i)} \in \mathbb{F}_{p}^{n}$ with

$$
\begin{equation*}
\forall i \notin \mathscr{I}_{i}: v_{i}=0 . \tag{4.2}
\end{equation*}
$$

We assume for simplicity that there is one commitment per key $\widetilde{\mathrm{ck}^{( }}{ }^{(i)}$. To model the case of multiple commitments [ $\left.c_{1}\right], \ldots,\left[c_{M}\right]$ per key, e.g. all commitments are under $\widetilde{\mathrm{ck}}=\widetilde{\mathrm{ck}}^{(1)}$, we simply duplicate $\widetilde{\mathrm{ck}}$, i.e. we rewrite this as $\left[\widetilde{\mathrm{c}}^{(i)}\right]=\left[c_{i}\right], \widetilde{\mathrm{ck}}^{(i)}=\widetilde{\mathrm{ck}}$.

Example 4.10. In a typical range proof, with Pedersen committed value, we would have $\widetilde{\mathrm{ck}^{(1)}} \widehat{=}\left[g_{2}^{\prime}, g_{n}^{\prime}\right]$, where $M=1$. We write $\widetilde{\mathrm{ck}}:=\widetilde{\mathrm{ck}}{ }^{(1)}$ for simplicity. This means $\mathscr{I}=\{2, n\}$.

Remark 4.11. Using the in $n$ varying $\left[g_{n}^{\prime}\right]$ in the commitment keys $\widetilde{\mathrm{ck}}^{(i)}$ is problematic and inconvenient. We want the randomness terms in QESA ${ }_{Z K}$ and our commitment to "overlap". But now, running QESA $_{Z K}$ for a smaller or larger instance, e.g. an instance of size $n / 2$ or $2 n$ is incompatible. A simple solution is to fix some (random) $\left[g_{\text {rnd } 1}^{\prime, \star}, g_{\text {rnd } 2}^{\prime, \star}\right]$ (as part of crs) and construct $\left[g^{\prime}\right]$ when starting Protocol QESA $\mathrm{ZK}_{\text {so }}$ so that $\left[g_{n-1}^{\prime}, g_{n}^{\prime}\right]=\left[g_{\text {rnd } 1}^{\prime, \star}, g_{\text {rnd } 2}^{\prime, \star}\right]$. Another solution is to permute the position of the randomness and reserve the fixed indices 2,3 for randomness (instead of $n-1, n$ ).

With this setup, we can extend QESA ZK as follows: Given commitments $\left[\widetilde{c}^{(i)}\right]$ under keys $\widetilde{\mathrm{ck}}{ }^{(i)}$, prove that the values committed in $\left[\widehat{c}^{(i)}\right]$ satisfy some set of quadratic equations. In other words, prove that the $\left[\hat{c}^{(i)}\right]$ satisfy some arithmetic circuit.

Example 4.12 (Aggregate range proof). Consider $\left[\widetilde{c}^{(j)}\right], j=1, \ldots, 10$. We wish to prove that the values $\boldsymbol{v}^{(j)}$ committed in $\left[\widetilde{c}^{(j)}\right]$ all lie in the range $\left\{0, \ldots, 2^{8}-1\right\}$.

Unsurprisingly, our solution to the problem is probabilistic verification. Our idea for general interoperability is as follows: The initial QESA ${ }_{\mathrm{ZK}}$ witness $\boldsymbol{w}$ (commitment $c_{\boldsymbol{w}}^{\prime}$ ) has all components in $\mathscr{I}$ zeroed (except for randomness $n-1, n$ ) and also contains copies of the committed $\boldsymbol{v}^{(i)}$. The actual equations, i.e. the $\Gamma_{i}$, only refer to the copies and the components $\mathscr{G}$. The verifier sends randomness $\boldsymbol{\alpha} \leftarrow \chi_{M+1}$ with $\alpha_{0}=0$, and we set $\left[c_{\boldsymbol{w}}^{\prime}\right] \leftarrow\left[c_{\boldsymbol{w}}^{\prime}\right]+\sum_{i} \alpha_{i}\left[\widetilde{c}^{(i)}\right]$, and $\boldsymbol{w}^{\prime} \leftarrow \boldsymbol{w}^{\prime}+\sum_{i} \alpha_{i} \boldsymbol{v}^{(i)}$ as new (extended) witness. Note that all (extended) equations $\boldsymbol{w}^{\prime} \Gamma_{i}^{\prime \top} \boldsymbol{w}^{\prime}$ still hold (for an honest prover). Now we add (linear) equations $\Gamma_{\text {copy }}^{(i)}$ to the statement, which we call copy-equations and which depend on the randomness $\alpha_{i}$. These equations simply assert that, if we compute $\sum_{i} \alpha_{i} \boldsymbol{v}^{(i)}$ using the committed copies in $\boldsymbol{w}$, then this equals the values committed in components $\mathscr{\mathscr { L }}$ (again excluding the randomness components $n-1$, $n)$. In other words, we assert that the purported copies of $\boldsymbol{v}^{(i)}$ in witness [ $c_{\boldsymbol{w}}^{\prime}{ }_{\text {,old }}$ ] were valid copies. This "copy-based" approach is simple and modular.

The formulaic description of Protocol QESA Copy is arguably technical. However, the example in Fig. 3 demonstrates that it is actually a simple concept. In Appendix A.5, Fig. 4, we give a more complex example. This extension of QESA ${ }_{\mathrm{ZK}}$ is again complete, special-sound, and statistical zero-knowledge. See Appendix A. 5 for more details.

## 5 IMPLEMENTATION

We implemented all protocols in C++17 using the RELIC toolkit [5] for underlying group operations. Our instantiation uses $\mathbb{G}=$ Curve25519 and thus $\mathbb{F}_{p}=\mathbb{F}_{2^{255}-19}$. For a fair comparison, we implemented Bulletproofs on the same architecture with equal care. The code is available on GitHub. ${ }^{11}$

Representing $\Gamma$. All QESA protocols make use of sparse matrices $\Gamma$. For efficient computation, a suitable representation is necessary. Decomposing $\Gamma$ into a sum $\sum_{i} \boldsymbol{a}_{i} \boldsymbol{b}_{i}^{\top}$, similar to R1CS, allows for both runtime and memory optimisations. Note that vectors $\boldsymbol{a}_{i}$ and $\boldsymbol{b}_{\boldsymbol{i}}$ are sparse themselves, allowing for even further optimisation via an appropriate data structure. For multiplications $\Gamma s$, at most

[^7]

Figure 3: An example of a copying two values from two commitments. The blocks are colour-coded as follows: White blocks contain either 0 or the value indicated. Orange blocks belong to the (value-part) of commitment indices, i.e. to $\mathscr{l}$. Green blocks denote "copied" values. Gray blocks contain an arbitrary value. Blue blocks refer to randomness parts (i.e. components $n-1, n$ ). Note that randomness is not copied, as it is not a relevant part of the committed value. It is simply accumulated in $r_{2}^{*}=\alpha_{0} r_{2}+\alpha_{1} r^{(1)}+\alpha_{2} r^{(2)}$. The actual statements (i.e. the matrices $\Gamma_{i}$ ) are statements over all variables except the orange (and blue) blocks, as these are merely "testvalues" which ensure that $w$ contains copies of (the message part of) $\boldsymbol{v}^{(i)}$, here $m^{(i)}$, as claimed.

| Parameters | Bulletproofs |  | QESARP |  | QESA ${ }_{\text {RP }}$ (short) |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\mathscr{P}$ | 1 | $\mathscr{P}$ | $V$ | $\mathscr{P}$ | $v$ |

| 252 bit $\times 32$ | 30.2 | 18.6 | 20.8 | 9.5 | 18.9 | 6.8 |
| 252 bit $\times 128$ | 121 | 74.3 | 83.5 | 37.8 | 76.1 | 27.4 |
| 252 bit $\times 512$ | 484 | 297 | 358 | 165 | 302 | 109 |

Table 3: Comparison of runtime in seconds of aggregate range proofs from [17] with this work.
$m \sum_{i} k_{i} \ell_{i}$ scalar multiplications are necessary, where $m, k_{i}, \ell_{i}$ are the number of non-zero entries in $\boldsymbol{s}, \boldsymbol{a}_{\boldsymbol{i}}, \boldsymbol{b}_{\boldsymbol{i}}$. Thus, all operations remain polynomial in the input size.

Results. We benchmarked our protocols on an Intel Core i7-6600U CPU at 2.6 GHz running Debian Stretch 4.9.168 using a single core. A point multiplication with a random 254-bit scalar takes on average 0.28 ms on this platform. Table 3 shows how our aggregate range proofs QESA $_{R P}$ compare to Bulletproofs. For QESA ${ }_{R P}$, the internal witness $\boldsymbol{w}$ contains 4 static elements: the constant 1 , the aggregate element for QESA Copy , and the 2 random elements added

| Shuffle size | 1000 |  | 10000 |  | 100000 |  |

Table 4: Evaluation of shuffle proofs via QESA Copy and $\mathrm{LMPA}_{\text {simpleZK }}$.
by QESA ${ }_{\text {Inner }}$, c.f. Appendix G. Hence, we select the range as a power of 2 minus 4 , in order to keep the CRS size from expanding to the next power of two. Our results show that QESA ${ }_{R P}$ outperforms Bulletproofs for all tested parameters. Allowing batching randomnesses to be small further improves the performance (cf. QESA ${ }_{R P}$ (short) for 140 -bit random values). ${ }^{12}$ Note that the execution times given in [17] are lower, since a highly optimised library dedicated to a single elliptic curve was used instead of a general purpose library as in this work. However, since both protocols were benchmarked on the same platform with the same underlying library, the values in Table 3 give a fair comparison.

Note that we have not applied special optimisations. Using $d e-$ layed (batch) verification, e.g. as in [17], significantly improves verifier performance. Optimised verification performance of Bulletproofs and our proof systems is probably almost identical. ${ }^{13}$ We are not aware of similar optimisations for the prover.

Table 4 gives execution times for our shuffle proofs. They are an instantiation of [6], c.f. Appendix C, and we project them to be $2-3 \times$ more computationally expensive than [6], but they are size $O(\log (N))$ instead of $O(\sqrt{N})$ for $N$ ciphertexts. Again the very high execution times compared to [6] are caused by the underlying library.

## ACKNOWLEDGMENTS

We thank the anonymous reviewers of CRYPTO '19 and CCS '19 for helpful comments, which improved the overall quality and presentation of this work. This work is supported by the German Research Association under grants PA 587/10-1 and RU 1664/3-1.

## A OMISSIONS

## A. 1 Omissions: Testing distributions

Lemma A. 1 (Schwartz-Zippel). Let $f \in \mathbb{F}_{p}\left[X_{1}, \ldots, X_{n}\right]$ be a non-zero polynomial of (total) degree $d$. Let $\chi$ be a distribution on $\mathbb{F}_{p}$ Let $p_{\infty}(\chi):=\sup _{x \in \mathbb{F}_{p}} \chi(x)$, where $\chi(x):=\mathbb{P}(x=y \mid x \leftarrow \chi)$. Then $\mathbb{P}(f(\boldsymbol{x})=0) \leq d p_{\infty}(\chi)$ for $\boldsymbol{x} \leftarrow \chi^{n}$ (i.e. $x_{i} \leftarrow \chi$ ). Moreoever, since $p_{\infty}(\psi) \leq \frac{1}{\varepsilon} p_{\infty}(\chi)$ for any subdistribution $\psi$ of weight $\varepsilon$, we get $\mathbb{P}_{\boldsymbol{x} \leftarrow \psi^{n}}(f(\boldsymbol{x})=0) \leq \frac{d p_{\infty}(\chi)}{\varepsilon}$.

The usual proof can be adapted easily.
A.1.1 Dual testing distributions. Testing distributions are essentially a stronger (and simplified) form of the general concept of probabilistic verification with efficient extraction. They allow to test if an element in $\mathbb{F}_{p}^{n}$ is 0 . By dualising, we find another concept, for which an intuitive description seems harder. Instead of a distribution on $\boldsymbol{x}^{\top} \in \mathbb{F}_{p}^{1 \times m}$ satisfying with high probability $\bigcap_{i=1}^{m} \operatorname{ker}\left(\boldsymbol{x}^{\top}\right)=$ $\{0\}$, we consider a distribution on $\boldsymbol{M} \in \mathbb{F}_{p}^{m \times m-1}$, satisfying with high probability $\bigcap_{i=1}^{m} \operatorname{im}(\boldsymbol{M})=\{0\}$, In a sense, $\boldsymbol{M}$ guarantees that for any $0 \neq z \in \mathbb{F}_{p}^{m}, z \notin \operatorname{im}(\boldsymbol{M})$ with high probability. Hence, we can use it to enforce $z=0$, instead of testing for it.

More concretely, we use this to ensure that for a Pedersen commitment $[c]=[\boldsymbol{G} \mid \boldsymbol{H}]\binom{\boldsymbol{w}}{\boldsymbol{z}}$ the adversary must have $\boldsymbol{z}=0$. We do so by constructing $[H]$ as $[H]:=[Q] M$. Intuitively, knowledge of some $\left[c^{\prime}\right]=[G \mid Q]\binom{w}{\boldsymbol{y}}$ cannot be transferred to $[G \mid H]$ because we must have $\boldsymbol{z}=\boldsymbol{M} \boldsymbol{y}$, i.e. $\boldsymbol{z} \in \operatorname{im}(\boldsymbol{M})$, which is unlikely (except for $z=0$ or if $\mathcal{A}$ breaks the binding property). Thus, we can provably "zero" a part of a commitment without an (expensive) argument. Generally, this allows to derive "fresh" commitment keys. Using this is more communication efficient than picking and sending a fresh $[H] \leftarrow \mathbb{G}^{m}$.

Morally, dual testing enforces $z=0$, while "normal" testing verifies $\boldsymbol{z}=0$.

Definition A.2. An (arbitrary) dual testing distribution $\chi_{m}^{\vee}$ is a distribution on $\mathbb{F}_{p}^{m \times(m-1)}$. The (computational) soundess error $\delta_{\text {snd }}\left(\chi_{m}^{\vee}\right)$ is defined as before, but using $\mathbb{P}\left(\cap_{i=1}^{m} \operatorname{im}\left(\boldsymbol{M}_{i}\right) \neq\{0\}\right)$.

Let $\chi_{m}$ be a testing distribution on $\mathbb{F}_{p}^{m}$ such that $x \leftarrow \chi_{m}$ always has $x_{1}=1$. Then $\chi_{m}^{\vee}$ defined as follows is a dual testing distribution: To pick $\boldsymbol{M} \leftarrow \chi_{m}^{\vee}$, pick $\boldsymbol{x}^{\top}=\left(1, \boldsymbol{x}^{\prime}\right)^{\top} \leftarrow \chi_{m}$ and let $\boldsymbol{M}:=\boldsymbol{M}_{\boldsymbol{x}}:=\binom{\boldsymbol{x}^{\prime}}{-\mathrm{id}_{m-1}}$. By construction $\operatorname{ker}\left(\boldsymbol{x}^{\top}\right)=\operatorname{im}\left(\boldsymbol{M}_{\boldsymbol{x}}\right)$, and consequently $\delta_{\text {snd }}\left(\chi^{\vee}\right)=\delta_{\text {snd }}\left(\chi_{m}\right)$.

Note that by construction, $\boldsymbol{M}_{\boldsymbol{x}}$ is the (parity) check matrix for the linear code with generator $\boldsymbol{x}$. In particular, $\boldsymbol{x}^{\top} \boldsymbol{M}_{\boldsymbol{x}}=0$. For simplicity, we only consider dual testing distributions associated to some testing distribution.

## A. 2 Omissions: LMPA ${ }_{Z K}$

We expand on sketches in Section 3.4 and give the description of our LMPA ${ }_{\mathrm{ZK}}$ construction with logarithmic computional overhead.

Difficulties arising from general [A]. There are two main difficulties arising from general $[A] \in \mathbb{G}^{m \times n}$. First, the higher dimension due to $m>1$ makes masking sets as described not directly applicable anymore. Since $\left[\boldsymbol{u}_{\ell}\right] \in \mathbb{G}^{m}$, the prover now communicates $m k$ elements, and hence we expect that $m k \log (n)$ random entries are necessary to randomise all of $\left[\boldsymbol{u}_{\ell}\right]$. Interestingly, the naive approach of using Protocol $\Sigma_{\text {std }}$ shows that $n$ random entries are sufficient. Note that $n<m k \log (n)$ is possible for large $m$. (In practice $m k \log (n) \ll n$.)

Second, we want to deal with adversarial [A]. In the above sketch for zero-knowledge, we ignored a detail concerning the recursion. If it ever happens that in $[g]$, for some $i \in \mathbb{M}_{n}$, the element $g_{i}$ is zero, the distribution of $\left(\widehat{\boldsymbol{r}},\left[\boldsymbol{u}_{-1}\right],\left[\boldsymbol{u}_{1}\right]\right)$ is skewed and zero-knowledge fails. Note that $[g]$ is reduced in each statement, so this can happen randomly. Thus, even the naive reduction is only statistically zeroknowledge. If $[A]$ is chosen adversarially, it may be so that this failure case always (or often) happens. Making the definition of $\mathbb{M}_{n}$ dynamic and depend on $[A]$ is inconvenient and hard. Our choice is therefore to act "dually" to commitment-extension. Remember that a commitment-extension adds a row to $[A]$ so that $[A]$ is "computationally injective". In contrast, we will, very roughly, add columns to $[A]$, to ensure that $[A]$ is surjective. Our concrete approach is detailed below.

Dealing with general $[A]$. Our proof system separates the masking randomness from the actual witness and is a linear combination of multiple protocol instances of $\mathrm{LMPA}_{\text {noZK }}$ : The actual protocol for $[A]=:\left[\boldsymbol{H}^{(0)}\right]$, and protocols for $\left[\boldsymbol{H}^{(i)}\right], i=1, \ldots, m$, where [ $\boldsymbol{H}^{(i)}$ ] essentially contains a Pedersen commitment key in the $i$-th row and is zero otherwise.

To keep things simple, we let $m=1$ in the following discussion. Intuitively, we want to run a "randomness-extended" protocol for $[B]=[A \mid H]\left(\begin{array}{c}\underset{r}{w}\end{array}\right)$. The intuition is that $r$ will randomise all $\left[u_{ \pm} 1\right]$ 's (because $[H]$ is not adversarial). Unfortunately, this intuition is wrong: $\left[u_{1}\right]=[H] w$ is certainly not zero-knowledge. The problem is how $\mathrm{LMPA}_{\text {noZK }}$ divides the statement. Appropriate shuffling of $[B]$ and $\binom{w}{r}$ would solve this. Instead, we work with a linear combination of LMPA noZK instances.

More precisely, we run two arguments, one for $[A] \boldsymbol{w}=\left[t^{\prime}\right]$ and one for $[H] r=\left[t^{\prime \prime}\right]$. The messages $\left[u_{-1}\right]$ and $\left[u_{1}\right]$ are the sums of the messages which individual protocols would send, e.g. $\left[u_{-1}\right]=$ $\left[\boldsymbol{A}_{2}\right] \boldsymbol{w}_{1}+\left[\mathrm{H}_{2}\right] \boldsymbol{r}_{1}$. Concretely
$\left[\begin{array}{c}u_{-1}^{\prime} \\ u_{1}^{\prime}\end{array}\right]=\left[\begin{array}{c}A_{1} \boldsymbol{w}_{2} \\ A_{2} \boldsymbol{w}_{1}\end{array}\right], \quad\left[\begin{array}{c}u_{-1}^{\prime \prime} \\ u_{1}^{\prime \prime}\end{array}\right]=\left[\begin{array}{c}\boldsymbol{H}_{1} \boldsymbol{r}_{2} \\ \boldsymbol{H}_{2} \boldsymbol{r}_{1}\end{array}\right], \quad\left[\begin{array}{c}u_{-1} \\ u_{1}\end{array}\right]=\left[\begin{array}{c}u_{-1}^{\prime} \\ u_{1}^{\prime}\end{array}\right]+\left[\begin{array}{c}u_{-1}^{\prime \prime} \\ u_{1}^{\prime \prime}\end{array}\right]$
This ensures that the $\left[u_{ \pm 1}^{\prime \prime}\right]$ are uniformly random in every round, because $\left[u_{ \pm 1}^{\prime \prime}\right]$ is. In the base case of the recursion, i.e. small $n$, the
prover proves $[A] w+[\boldsymbol{H}] \boldsymbol{r}=[t]$ in zero-knowledge, using (for concreteness) Protocol $\Sigma_{\text {std }}$.

To keep our protocol modular and comprehensible, we split it into two steps.

Protocol A.3 (LMPA ${ }_{\text {almSnd }}$ ). The following is a protocol to prove $\exists \boldsymbol{w}:\left[\boldsymbol{t}^{(0)}\right]=[A] \boldsymbol{w}$, using testing distributions $\chi_{m+1}$ resp. $\widetilde{\chi}_{2 k-1}$ (resp. $\chi^{(\beta)}$ ). with $\widetilde{\chi}_{3}, \chi^{(\beta)}$ as in Protocol LMPA noZK. Furthermore, we require that $\boldsymbol{x} \leftarrow \chi_{m+1}$ satisfies $x_{i} \neq 0$ for all $i$.

Common input is $\left([A],\left[\boldsymbol{t}^{(0)}\right]\right) \in \mathbb{G}^{m \times n} \times \mathbb{G}^{n}$ and some $\boldsymbol{h} \in \mathbb{G}^{n}$ (typically derived from the CRS when this protocol is used as a subprotocol). We assume $n=2^{\ell}>4$. Moreover, we let $\left[H^{(i)}\right] \in$ $\mathbb{G}^{m \times n}$ for $i=1, \ldots, m$, be defined as the matrix with $[\boldsymbol{h}]$ in the $i$-th row and zeroes elsewhere, i.e. $\left[\boldsymbol{H}^{(i)}\right]=\boldsymbol{e}_{i}[\boldsymbol{h}]$. We use a superscript 0 , e.g. $\left[\boldsymbol{H}^{(0)}\right]:=[A]$, for terms related to $[A]$. The prover's witness is some $\boldsymbol{w} \in \mathbb{F}_{p}^{n}$ (also written $\boldsymbol{r}^{(0)}$ ).

- $\mathscr{P} \rightarrow V$ : (Step 1: Prepare masking.) Pick $\boldsymbol{r}^{(i)} \leftarrow \mathbb{M}_{n} \leq \mathbb{F}_{p}^{n}$ and compute $\left[\boldsymbol{t}^{(i)}\right]=\left[\boldsymbol{H}^{(i)}\right] \boldsymbol{r}^{(i)}$. Send $\left[\boldsymbol{t}^{(i)}\right]$ for $i=1, \ldots, m$.
- $\mathcal{V} \rightarrow \mathscr{P}$ : (Step 2: Random linear combination.) Pick and send $x \leftarrow \chi_{m+1}$. The statement we prove is now effectively

$$
\left[\boldsymbol{A}\left|\boldsymbol{H}^{(1)}\right| \ldots \mid \boldsymbol{H}^{(m)}\right]\left(\begin{array}{c}
x_{0} \boldsymbol{w} \\
x_{1} \boldsymbol{r}^{(1)} \\
\vdots
\end{array}\right)=[\boldsymbol{t}]:=\sum_{i} x_{i}\left[\boldsymbol{t}^{(i)}\right] .
$$

For simplicity, the prover redefines $\boldsymbol{r}^{(i)}:=x_{i} \boldsymbol{r}^{(i)}$ for $i=$ $0, \ldots, m$.

- $\mathscr{P} \rightarrow V:\left(\right.$ Step 3: Begin the shrinking AoK.) Let $\left[\boldsymbol{H}^{(i)}\right]=$ $\left[\boldsymbol{H}_{1}^{(i)}, \boldsymbol{H}_{2}^{(i)}\right]$ with $\boldsymbol{H}_{j}^{(i)} \in \mathbb{G}^{m \times n / 2}$. Compute $\left[\boldsymbol{u}_{\ell}\right]=\sum_{i=0}^{m}\left[\boldsymbol{u}_{\ell}^{(i)}\right]$, where $\left[\boldsymbol{u}_{\ell}^{(i)}\right]$ is computed as usual, i.e. $\left[\boldsymbol{u}_{\ell}^{(i)}\right]=\sum_{j-i=\ell}\left[\boldsymbol{H}_{\ell}^{(i)}\right] \boldsymbol{r}_{\ell}^{(i)}$. Send $\left[\boldsymbol{u}_{\ell}\right]$ for $\ell= \pm 1$.
- $V \rightarrow \mathscr{P}:$ Pick $z \leftarrow \widetilde{\chi}_{3}$ (with associated $\left.\boldsymbol{x}, \boldsymbol{y}\right)$. Send $(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$.
- $\mathscr{P} \rightarrow \mathcal{V}:$ As in LMPA ${ }_{\text {noZK }}$, compute $\boldsymbol{w}=\boldsymbol{x}^{\top} \overrightarrow{\boldsymbol{w}}=\sum_{j} x_{j} \boldsymbol{w}_{i}$ and $\widehat{\boldsymbol{r}}^{(i)}=\boldsymbol{x}^{\top} \overrightarrow{\boldsymbol{r}}^{(i)}=\sum_{j} x_{j} \boldsymbol{r}_{j}^{(i)}$ and $[\widehat{\boldsymbol{A}}]=\boldsymbol{x}^{\top}[\overrightarrow{\boldsymbol{A}}]=\sum_{j} x_{j}\left[\boldsymbol{A}_{j}\right]$, $\left[\widehat{\boldsymbol{H}}^{(i)}\right]=\sum_{j} x_{j}\left[\boldsymbol{H}_{j}^{(i)}\right]$, and $[\boldsymbol{t}]=\boldsymbol{z}^{\top} \boldsymbol{u}=\sum_{\ell} z_{j} \boldsymbol{u}_{\ell}$, for the reduced statement (which $\mathcal{V}$ also computes).
If $n>4$, engage recursively in the AoK for this statement, i.e. goto Step 3. If $n \leq 4$, engage in (for concreteness) Proto$\operatorname{col} \Sigma_{\text {std }}$ to prove the statement.

It is easy to check that Protocol A. 3 is complete.
Lemma A.4. Protocol $\mathrm{LMPA}_{\text {almSnd }}$ has $\mu$-special soundness (with $\mu=(m+1,4, \ldots, 4,2)$ ) for finding a preimage $\overrightarrow{\boldsymbol{v}} \in\left(\mathbb{F}_{p}^{n}\right)^{m}$ (unconditionally) with $\left[\boldsymbol{A}\left|\boldsymbol{H}^{(1)}\right| \ldots \mid \boldsymbol{H}^{(m)}\right]\binom{\boldsymbol{v}_{0}}{\boldsymbol{v}_{m}}=\left[\boldsymbol{t}^{(0)}\right]$, or a non-trivial kernel element of $\left[\boldsymbol{A}\left|\boldsymbol{H}^{\prime(1)}\right| \ldots \mid \boldsymbol{H}^{\prime(m)}\right]$. Here, $\left[\boldsymbol{H}^{\prime(i)}\right]$ consists only of the non-zero components of $\left[\boldsymbol{H}^{(i)}\right]$. (It is easy to find non-trivial kernel elements if $[\boldsymbol{h}]$ has zeroes, so we exclude them) The protocol inherits short-circuit extraction with $\mu^{\prime}=(m+1,2, \ldots, 2,2)$.

Note Lemma A. 4 does not assert a witness $\boldsymbol{w} \in \mathbb{F}_{p}^{n}$ for $[A] \boldsymbol{w}=$ $\left[t^{(0)}\right]$. That will be assured in follow-up step.

Proof. We only sketch the proof. Let tree $\mu_{\mu}$ be a good $\mu$-tree of transcripts. First of all, we can extract the base subprotocol of

Step 3. Using these witnesses, we can extract the linearly combined argument essentially as in Lemma 3.8. ${ }^{14}$ Now we extract Step 2. From Step 3, we have $m+1$ preimages $\overrightarrow{\boldsymbol{v}}_{i} \in\left(\mathbb{F}_{p}^{m}\right)^{n}$ with $\left[A\left|\boldsymbol{H}^{(1)}\right| \ldots \mid \boldsymbol{H}^{(m)}\right] \overrightarrow{\boldsymbol{v}}_{i}=[\boldsymbol{T}] \boldsymbol{x}_{i}$ where $[T]=\left[\boldsymbol{t}^{(0)}, \ldots, \boldsymbol{t}^{(m)}\right]$. Arrange matrices $\boldsymbol{V}=\left(\overrightarrow{\boldsymbol{v}}_{0}, \ldots, \overrightarrow{\boldsymbol{v}}_{m}\right)$ and $\boldsymbol{X}$ as usual. ( $\boldsymbol{V}$ corresponds to $\widehat{\boldsymbol{W}}$ from Lemma 3.8.) We find $\left[\boldsymbol{A}\left|\boldsymbol{H}^{(1)}\right| \ldots \mid \boldsymbol{H}^{(m)}\right] V_{i}=[\boldsymbol{t}] \boldsymbol{X}$. Multiplying with $X^{-1}$, we find preimages for each $\left[t^{(i)}\right]$, in particular a preimage for $\left[\boldsymbol{t}^{(0)}\right]$.

To prove zero-knowledge of Protocol LMPA almSnd , we first show that the prover's messages $\left[\boldsymbol{u}_{\ell}\right]$ in the recursive steps are almost always uniformly distributed. This yields statistical HVZK via straightforward simulation.

As a preparation, note following (easy) linear algebra facts:
Lemma A.5. Consider Protocol A. 3 (LMPA ${ }_{\text {almSnd }}$ ). Suppose that (at least) all components of $[\boldsymbol{h}]$ in $\mathbb{M}_{n}$ are distributed uniformly random (and the rest may be 0). Suppose that for any $x \leftarrow \chi_{m+1}$ we have $x_{i} \neq 0$ for all $i$.

Then, in this argument system, with probability about $O\left(\log _{2}(n) k\right) / p$ the vector $\boldsymbol{U}$ consisting of messages $\left[\boldsymbol{u}_{\ell}\right]$ of all recursive rounds is uniformly random. The randomness is over $[\boldsymbol{h}]$, the challenges and the prover's randomness.

We give a short proof intuition for the case $m=1$. So we have $[A],[H] \in \mathbb{G}^{1 \times n}$. Intuitively, we need $2 \mathbb{F}_{p}$-elements of randomness in each round to mask $\left[u_{ \pm 1}\right]$. Moreover, these two terms of randomness must be split so that one is in the first half $\boldsymbol{r}_{1}$ of $\boldsymbol{r}$, and one in the second half $\boldsymbol{r}_{2}$, since $\left[u_{j-i}\right]=\left[\boldsymbol{H}_{i}\right] \boldsymbol{r}_{j}$. The masking sets $\mathbb{M}_{n}$ are built exactly as such, see Fig. 2. Moreover, to allow inductive reasoning, the masking sets are built in such a way that even when "removing" two terms of randomness (say $\boldsymbol{r}_{1,0}$ and $\boldsymbol{r}_{2,1}$ ), the sum $\boldsymbol{r}_{1}^{\prime}+\boldsymbol{r}_{2}^{\prime}$ is distributed according to $\mathbb{M}_{n / 2}$. Evidently, we need $x_{i} \neq 0$ to prevent loss of randomness by multiplication with 0 . More precisely, we want surjectivity of the "transition map", $\left(\begin{array}{cc}x_{1} \mathrm{id}_{n} & x_{2} \mathrm{id}_{n} \\ \boldsymbol{H}_{2} & 0 \\ 0 & \boldsymbol{H}_{2}\end{array}\right)\binom{\boldsymbol{r}_{1}}{r_{2}}=\left(\begin{array}{c}\widehat{r_{n}^{\prime}} \\ u_{-1}^{\prime \prime} \\ u_{1}^{\prime \prime}\end{array}\right)$ when restricted to $\mathbb{M}_{2 n} \leq \mathbb{F}_{p}^{2 n}$ in each step. See [36] for a full proof.

Lemma A.6. Protocol $\mathrm{LMPA}_{\mathrm{ZK}}$ is $\varepsilon$-statistical zero-knowledge for $\varepsilon \in O\left(2 \log _{2}(n)\right) / p$.

We sketch HVZK simulation: For a recursive step, the HVZK simulator picks $\left[\boldsymbol{u}_{\ell}\right] \leftarrow \mathbb{G}^{m}$ for $\ell \neq 0$ and computes the uniquely defined $\left[\boldsymbol{u}_{0}\right]$ which makes the verifier accept that round. For Step 1 note that $\left[\boldsymbol{t}^{(i)}\right]=\left[\boldsymbol{e}_{i} t^{(i)}\right](i \neq 0)$ and hence $\left[\boldsymbol{t}^{(0)}\right]$ and $[\boldsymbol{t}]$ (which is $\left[\boldsymbol{u}_{0}\right]$ of the last recursion) uniquely define all $\left[\boldsymbol{t}^{(i)}\right]$. Since the messages $\left[\boldsymbol{u}_{\ell}\right.$ ] are uniformly distributed in an honest execution with probability $O\left(2 \log _{2}(n) 2\right) / p$, our claim follows.

Now, we finish the protocol and ensure that extraction yields a witness $\boldsymbol{w}$ for $[A] \boldsymbol{w}=[\boldsymbol{t}]$ as we desired. For this, we use a dual testing distribution to ensure $\boldsymbol{v}_{i} \stackrel{!}{=} 0$ for $i \geq 1$ (with notation as in Lemma A.4).

Protocol A. 7 (LMPA ${ }_{\mathrm{ZK}}$ ). The following is a protocol to prove $\exists \boldsymbol{w}:[A] \boldsymbol{w}=[\boldsymbol{t}]$. We use Protocol A. $3\left(\mathrm{LMPA}_{\text {almSnd }}\right)$ as a subprotocol with the same testing distributions $\chi_{m+1}$ resp. $\widetilde{\chi}_{3}$ (resp.

[^9]$\left.\chi^{(\beta)}\right)$. By $\chi_{\operatorname{dim}\left(\mathbb{M}_{n}\right)+1}^{\vee}$, we refer to the dual testing distribution of $\chi_{\operatorname{dim}\left(\mathbb{M}_{n}\right)+1}$ as in Definition A.2. In particular, we require that the first component $x_{0}$ of $\boldsymbol{x} \leftarrow \chi_{\operatorname{dim}\left(\mathbb{M}_{n}\right)+1}$ is always 1 .

Common input is $([A],[t]) \in \mathbb{G}^{m \times n} \times \mathbb{G}^{n}$ We assume $n=2^{\ell}>4$. The prover's witness is some $\boldsymbol{w} \in \mathbb{F}_{p}^{n}$ (also written $\boldsymbol{r}^{(0)}$ ). The CRS contains randomly (independently) chosen $[\boldsymbol{q}] \leftarrow \mathbb{G}^{1 \times \operatorname{dim}\left(\mathbb{M}_{n}\right)+1}$.

- $V \rightarrow \mathscr{P}$ : (Step 0: Setup of a "new" crs.) $V$ picks and sends $M:=M_{\boldsymbol{x}} \leftarrow \chi_{\operatorname{dim}\left(\mathbb{M}_{n}\right)+1}^{\vee}$ (as described in Definition A.2).
- Both parties compute $[\widetilde{h}]:=[q] M \in \mathbb{G}^{1 \times \operatorname{dim}\left(\mathbb{M}_{n}\right)}$. They define $[h] \in \mathbb{G}^{n}$ so that the components $\mathbb{M}_{n} \subseteq\{0, \ldots, n-1\}$ of $[\boldsymbol{h}]$ correspond to $[\widetilde{\boldsymbol{h}}]$ (in order). All components of $[\boldsymbol{h}]$ not in $\mathbb{M}_{n}$ are set to 0 . See Fig. 2 for a pictorial description of (non-)zero components of [ $\boldsymbol{h}]$.
- $\mathscr{P} \leftrightarrow V$ : Engage in Protocol LMPA almSnd for $\exists \boldsymbol{w}:[A] \boldsymbol{w}=$ $[t]$ with parameters (in particular $[\boldsymbol{h}]$ ) as above.
Lemma A.8. Protocol $\mathrm{LMPA}_{\mathrm{ZK}}$ has $\mu$-special soundness (with $\mu=$ $\left.\left(\operatorname{dim}\left(\mathbb{M}_{n}\right)+1, m+1,4, \ldots, 4,2\right)\right)$ for finding $a$ witness $w \in \mathbb{F}_{p}^{n}$ with $[A] \boldsymbol{w}=[\boldsymbol{t}]$, or a non-trivial kernel element of $\left[\boldsymbol{A}\left|\boldsymbol{e}_{1}^{\top} \boldsymbol{q}\right| \ldots \mid \boldsymbol{e}_{m}^{\top} \boldsymbol{q}\right]$ (equivalently $[\boldsymbol{A} \mid \operatorname{diag}(\boldsymbol{q}, \ldots, \boldsymbol{q})]$ ). Moreover, the protocol has shortcircuit extraction with $\mu^{\prime}=(1, m+1,2, \ldots, 2,2)$.

There are reasons to suspect that $\mathrm{LMPA}_{\mathrm{ZK}}$ may have unconditional extraction, i.e. it is proof of knowledge. But we could not (dis)prove it yet. Compare to Question 3.5.

Proof. By extracting LMPA ${ }_{\text {almSnd }}$ i.e. applying Lemma A.4, we can find preimages $\overrightarrow{\boldsymbol{u}} \in\left(\mathbb{F}_{p}^{n}\right)^{m+1}$. (Also, we inherit short-circuit and unconditional extraction.) Let $[\boldsymbol{h}]$ and $\left[\boldsymbol{H}^{(i)}\right]=\boldsymbol{e}_{i}[\boldsymbol{h}]$ be as constructed in the protocols.

For simplicity, we first consider the case $m=1$ and remove all 0 columns of $[H]$. In other words, we consider $[A \mid \boldsymbol{q} M] \in \mathbb{G}^{1 \times n+\operatorname{dim}(\mathbb{M})}$.

We know (i.e. extracted) some $\boldsymbol{w} \in \mathbb{F}_{p}^{n}, \boldsymbol{v} \in \mathbb{F}_{p}^{\operatorname{dim}(\mathbb{M})}$ such that $[A] \boldsymbol{w}+[H] \boldsymbol{v}=[t]$. We have to show that $[A] \boldsymbol{w}=[t]$, or we find a non-trivial element in the kernel of $[\boldsymbol{A} \mid \boldsymbol{q}]$. In the case that $[H] \boldsymbol{v}=0, \boldsymbol{w}$ is the witness we want. So suppose that $[\boldsymbol{H}] \boldsymbol{v} \neq 0$. In that case, we guarantee short-circuit extraction. So, suppose we have $\operatorname{dim}(\mathbb{M})+1$ transcripts with "independent" challenge matrices $\boldsymbol{M}_{i}$. (Remember that this means $\bigcap_{i=0}^{\operatorname{dim}(\mathbb{M})} \operatorname{im}\left(\boldsymbol{M}_{i}\right)=\{0\}$, which is equivalent to $\boldsymbol{x}_{\boldsymbol{i}}$ being linearly independent since $\boldsymbol{M}_{\boldsymbol{i}}=\boldsymbol{M}_{\boldsymbol{x}_{i}}$. By subtracting the 0 -th witness from the $i$-th witness, we find $[A]\left(\boldsymbol{w}_{i}-\right.$ $\left.\boldsymbol{w}_{0}\right)+[\boldsymbol{q}]\left(\boldsymbol{M}_{\boldsymbol{i}} \boldsymbol{v}_{\boldsymbol{i}}-\boldsymbol{M}_{0} \boldsymbol{v}_{0}\right)$. Thus, if $\boldsymbol{M}_{\boldsymbol{i}} \boldsymbol{v}_{\boldsymbol{i}}-\boldsymbol{M}_{0} \boldsymbol{v}_{0} \neq 0$, we obtain a non-trivial kernel element. The only case where we do not obtain a non-trivial kernel element of $[\boldsymbol{A} \mid \boldsymbol{q} \boldsymbol{M}]$ is, if for all $i$ we have $\boldsymbol{M}_{i} \boldsymbol{v}_{i}=$ $\boldsymbol{M}_{0} \boldsymbol{v}_{0}=: \boldsymbol{u}$. However, this implies that $\boldsymbol{u} \in \bigcap_{i=0}^{\operatorname{dim}(\mathbb{M})} \operatorname{im}\left(\boldsymbol{M}_{i}\right)$. But, by assumption we have $\bigcap_{i=0}^{\operatorname{dim}(\mathbb{M})} \operatorname{im}\left(\boldsymbol{M}_{\boldsymbol{i}}\right)=\{0\}$. Thus, the bad case is impossible.

For general $m$, we have $\operatorname{diag}(Q, \ldots)$ and $\operatorname{diag}(\boldsymbol{M}, \ldots)$ instead of $Q$ and $\boldsymbol{M}$. We obtain $\binom{\boldsymbol{w}}{\boldsymbol{v}}$ from $\mathrm{LMPA}_{\text {almSnd }}$ with $[\boldsymbol{A} \mid \operatorname{diag}(\boldsymbol{H}, \ldots)]\binom{\boldsymbol{w}}{\boldsymbol{v}}=$ $[\boldsymbol{t}]$. Evidently, $\bigcap_{i=0}^{\operatorname{dim}(\mathbb{M})} \operatorname{im}\left(\operatorname{diag}\left(\boldsymbol{M}_{i}, \ldots, \boldsymbol{M}_{i}\right)\right)=\bigcap_{i=0}^{\operatorname{dim}(\mathbb{M})} \operatorname{im}\left(\boldsymbol{M}_{\boldsymbol{i}}\right)^{m}=$ $\{0\}$. Thus, our claim follows analogously.

Corollary A.9. Protocol $\mathrm{LMPA}_{\mathrm{ZK}}$ has $\varepsilon$-statistical HVZK with $\varepsilon \in$ $O\left(2 \log _{2}(n)\right) / p$.

Proof. This is immediate from Lemma A. 6 .

## A. 3 Omissions: LMPA $_{\text {batch }}$

We directly apply AND-compilation in the protocol. We use general testing distributions, but the reader may want to imagine the familiar setting of polynomial testing with $\boldsymbol{x}=\left(x^{0}, \ldots, x^{m}\right)$ first.

Protocol A. 10 (Protocol LMPA ${ }_{\text {batch }}$ ). The following is a protocol to prove $\exists \boldsymbol{w}:[\boldsymbol{t}]=[A] \boldsymbol{w}$. Let $\chi_{m}$ and $\chi^{(\beta)}$ be testing distributions. Common input is $([A],[t]) \in \mathbb{G}^{m \times n} \times \mathbb{G}^{m}$. The prover's witness is some $\boldsymbol{w} \in \mathbb{F}_{p}^{n}$.

- $\mathscr{P} \rightarrow \mathcal{V}$ : pick $r_{w} \leftarrow \mathbb{F}_{p}$, and compute $\left[c_{w}\right]=\left[g_{0}\right] r_{w}+$ $[\bar{g}]^{\top} \boldsymbol{w}=\operatorname{Com}\left(\boldsymbol{w} ; r_{\boldsymbol{w}}\right)$. Send $\left[c_{\boldsymbol{w}}\right]$.
- $V \rightarrow \mathscr{P}$ : pick $\boldsymbol{x} \leftarrow \chi_{m}$. Send $\boldsymbol{x}$. Let $[\widehat{A}]=\boldsymbol{x}^{\top}[A] \in \mathbb{G}^{1 \times n}$ and $[\widehat{t}]=\boldsymbol{x}^{\top}[\boldsymbol{t}] \in \mathbb{G}$ be the batched statement (for both $\mathscr{P}$ and $\mathcal{V}$ ). Let $[\boldsymbol{B}]:=\left[\begin{array}{cc}g_{0} & \bar{g} \\ 0 & \hat{A}\end{array}\right]$ and let $\exists\left(\boldsymbol{w}, r_{\boldsymbol{w}}\right):[B]\binom{r_{\boldsymbol{w}}}{\boldsymbol{w}}=\left[\begin{array}{c}c_{\boldsymbol{w}} \\ t\end{array}\right]=:[\boldsymbol{u}]$ be the new (AND-type) statement.
- $\mathscr{P} \leftrightarrow \mathfrak{V}$ : Engage in Protocol $\Sigma_{\text {std }}$ for $\exists\binom{r_{w}}{w}:[B]\binom{r_{w}}{w}=[\boldsymbol{u}]$.

In words, Protocol LMPA ${ }_{\text {batch }}$ batches $[A]$ to $[\widehat{A}]$, and carries out an AND-proof for opening the commitment $\left[c_{w}\right]$ and that the content $\boldsymbol{w}$ of $\left[c_{\boldsymbol{w}}\right]$ is preimage of $[t]$ under $[\widehat{A}]$. This is proven via a subprotocol call to Protocol $\Sigma_{\text {std }}$.

Lemma A.11. Protocol LMPA batch $^{\text {is }}$ a 5 -move HVZK-AoK for $\exists w:[t]=[A] w$ with $(m, 2)$-special soundness for finding $a$ witness or a non-trivial kernel element for $[\boldsymbol{g}]$. It has $(1,2)$ short-circuit extraction.

Proof. Completeness: It is straightforward to see that completeness holds.

Zero-knowledge: The simulator picks $\beta, \boldsymbol{x}$ according to the distributions. The simulator proceeds in two steps. First, simulate the Protocol $\Sigma_{\text {std }}$, i.e. the final three rounds. Since those are now simulated independently of $\left[c_{\boldsymbol{w}}\right]$, we pick $\left[c_{\boldsymbol{w}}\right] \leftarrow \mathbb{G}$ randomly. This gives a perfect HVZK simulation.

Extraction: Given a good ( $m, 2$ )-tree tree $\mu$, we first extract the second layer (i.e. the subprotocol $\Sigma_{\text {std }}$ ). If not all of them yield the same ( $r_{\boldsymbol{w}}, \boldsymbol{w}$ ), we found a non-trivial kernel element for $[\boldsymbol{g}]$ and are finished. To prove short-circuit extraction, we show that if this does not happen, $\boldsymbol{w}$ is a valid witness. Now, for all $\boldsymbol{x}_{i}$, we have $\left[\boldsymbol{B}_{i}\right]\binom{r_{w}}{w}=\left[\begin{array}{c}c_{w} \\ t_{i}\end{array}\right]$, where the subscript $i$ denotes the matrices of the $i$-th round. Then in particular, $\boldsymbol{x}_{i}^{\top}[A] \boldsymbol{w}=\left[\widehat{\boldsymbol{A}}_{i}\right] \boldsymbol{w}=\left[\widehat{t}_{i}\right]=\boldsymbol{x}_{i}^{\top}[\boldsymbol{t}]$. Arranging the $m$ linear equations into a vector, we find with $X=$ $\left(x_{1}, \ldots, x_{n}\right)$,

$$
X^{\top}[A] w=X^{\top}[t] \text { and hence }[A] w=[t] .
$$

Since tree ${ }_{\mu}$ is good, $\boldsymbol{X}$ is invertible. Thus $\boldsymbol{w}$ is a valid witness.

## A. 4 Omissions: IPA noZK

Protocol A. 12 ( $\mathrm{IPA}_{\text {noZK }}$ ). The following is an argument to prove $\exists \boldsymbol{w}^{\prime}, \boldsymbol{w}^{\prime \prime} \in \mathbb{F}_{p}^{n}:[c]=\left[\boldsymbol{g}^{\prime}\right] \boldsymbol{w}^{\prime}+\left[\boldsymbol{g}^{\prime \prime}\right] \boldsymbol{w}^{\prime \prime}+t[Q] \wedge\left\langle\boldsymbol{w}^{\prime}, \boldsymbol{w}^{\prime \prime}\right\rangle=t$.
Let $\widetilde{\chi}_{3}$ (and $\chi^{(\beta \neq 0)}$ ) be a testing distribution with the properties as in Protocol 3.7, i.e. we for $z \leftarrow \widetilde{\chi}_{3}$ (with $z$ indexed from -1 to 1) together with $\boldsymbol{x}, \boldsymbol{y}$ such that $z_{j-i}=x_{i} y_{j}$. Common input is
$\left.\operatorname{crs}=\left(\left[\boldsymbol{g}^{\prime}, \boldsymbol{g}^{\prime \prime}, Q\right]\right)\right) \in \mathbb{G}^{1 \times n} \times \mathbb{G}^{1 \times n} \times \mathbb{G}$ and the statement $([c], t)$ We assume $n=2^{d}$. The prover's witness is ( $\boldsymbol{w}^{\prime}, \boldsymbol{w}^{\prime \prime}$ ).

- $\mathcal{V} \rightarrow \mathscr{P}$ : (Step 0: "Fixing" $t$.) $v$ picks $\alpha \leftarrow \chi^{(\beta \neq 0)}$. Send $\alpha$. Both sides set $[Q]:=\alpha^{-1}[Q]$. Then they set $[c]:=([c]-$ $\alpha t[Q])+t[Q]{ }^{15}$
Recursive step. Suppose $n=2^{d}>1$.
- $\mathscr{P} \rightarrow \mathcal{V}$ : Compute $\left[\boldsymbol{u}_{-1}^{\prime}\right]=\left[\boldsymbol{g}_{1}^{\prime}\right] \boldsymbol{w}_{2}^{\prime},\left[\boldsymbol{u}_{1}^{\prime}\right]=\left[\boldsymbol{g}_{2}^{\prime}\right] \boldsymbol{w}_{1}^{\prime}$, where [ $\left.\boldsymbol{g}_{j}^{\prime}\right]$ and $\left[\boldsymbol{w}_{j}^{\prime}\right]$ are as usual (i.e. split $\left[\boldsymbol{g}^{\prime}\right],\left[\boldsymbol{w}^{\prime}\right]$ into 2 equalsize pieces). Compute the respective $\left[\boldsymbol{u}_{\ell}^{\prime \prime}\right]$. Let $v_{-1}:=\left\langle\boldsymbol{w}_{1}^{\prime}, \boldsymbol{w}_{2}^{\prime \prime}\right\rangle$, $v_{1}:=\left\langle\boldsymbol{w}_{2}^{\prime}, \boldsymbol{w}_{1}^{\prime \prime}\right\rangle$. Let $\left[\boldsymbol{u}_{\ell}\right]:=\left[\boldsymbol{u}_{\ell}^{\prime}\right]+\left[\boldsymbol{u}_{-\ell}^{\prime \prime}\right]+v_{-\ell}[Q]$. Send $\left[\boldsymbol{u}_{\ell}\right]$ for $\ell= \pm 1 .{ }^{16}$
- $\mathcal{V} \rightarrow \mathscr{P}$ : pick $z \leftarrow \widetilde{\chi}_{3}$ with corresponding $\boldsymbol{x}, \boldsymbol{y}$. $\operatorname{Send}(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$.
- Both parties compute $\left[\hat{\boldsymbol{g}}^{\prime}\right]=\sum_{i=1}^{2} x_{i}\left[\boldsymbol{g}_{i}^{\prime}\right] \in \mathbb{G}^{1 \times n / 2}$ and $\left[\widehat{\boldsymbol{g}}^{\prime \prime}\right]=\sum y_{i}\left[\boldsymbol{g}_{i}^{\prime \prime}\right] \in \mathbb{G}^{1 \times n / 2}$. and $[\widehat{c}]=\sum_{\ell=-1}^{1} z_{\ell}\left[\boldsymbol{u}_{\ell}\right] \in \mathbb{G}$ as new batched statement. Moreover, $\mathscr{P}$ computes $\widehat{\boldsymbol{w}}^{\prime}=$ $\sum_{i} y_{i} \overrightarrow{\boldsymbol{w}}^{\prime}$ and $\widehat{\boldsymbol{w}}^{\prime \prime}=\sum_{i} x_{i} \vec{w}^{\prime \prime}$.
Skipping Step 0 , (recursively) continue with $n \leftarrow n / 2, \boldsymbol{w}^{\prime} \leftarrow$ $\widehat{\boldsymbol{w}}^{\prime}, \boldsymbol{w}^{\prime \prime} \leftarrow \widehat{\boldsymbol{w}}^{\prime \prime},[c] \leftarrow[\widehat{c}],\left[\boldsymbol{g}^{\prime}\right] \leftarrow\left[\widehat{\boldsymbol{g}}^{\prime}\right],\left[\boldsymbol{g}^{\prime \prime}\right] \leftarrow\left[\widehat{\boldsymbol{g}}^{\prime \prime}\right]$.
Base case. Suppose $n=1$.
- $\mathscr{P} \rightarrow V$ : Send $\boldsymbol{w}^{\prime}, \boldsymbol{w}^{\prime \prime}$.
- V: Let $t:=\left\langle\boldsymbol{w}^{\prime}, \boldsymbol{w}^{\prime \prime}\right\rangle$ and test if $[c] \stackrel{?}{=}\left[\boldsymbol{g}^{\prime}\right] \boldsymbol{w}^{\prime}+\left[\boldsymbol{g}^{\prime \prime}\right] \boldsymbol{w}^{\prime \prime}+t[Q]$.

See Appendix G for a sketch of this protocol. The above argument is correct by inspection. Due to space constraints, we do not consider Step 0 a transformation on its own, compare [17, Protocol 1].

Lemma A.13. Protocol IPA noZK is $\mu$-special sound (with $\mu=(2,4$, $\ldots, 4)$ ) for finding $a$ witness or a non-trivial element in the kernel of $\left[\boldsymbol{g}^{\prime}, \boldsymbol{g}^{\prime \prime}, Q\right]$. It has short-circuit extraction with $\mu^{\prime}=(1,2, \ldots, 2)$.

The proof is essentially as in [13, 17]. See [36] for details.

## A. 5 Omissions: Details on QESA Copy

Protocol A. 14 (QESA ${ }_{\text {Copy }}$ ). Let $n \geq 8, \Gamma_{i}$, crs $=\left[\boldsymbol{g}^{\prime}, \boldsymbol{g}^{\prime \prime}, Q\right]$, $\widetilde{\chi}_{3}$ be as in Protocol QESA ${ }_{Z K}$. Let $\chi_{M+1}$ be a testing distribution where the first component is always 1, i.e. $\boldsymbol{\alpha} \leftarrow \chi_{M+1}$ has $\alpha_{0}=$ 1. ${ }^{17}$ Let $\widetilde{\mathrm{ck}}^{(i)} \widehat{\equiv} \mathscr{g}_{i}$ be commitment keys for commitments (for $i=1, \ldots, M)$, as described above. Let $\left[\widetilde{c}^{(i)}\right]$ be commitments to values $\boldsymbol{v}^{(i)}$. We identify $\boldsymbol{v}^{(i)}$ with a vector in $\mathbb{F}_{p}^{n}$ when necessary (satisfying Eq. (4.2)). Let $\boldsymbol{w} \in \mathbb{F}_{p}^{n-2}$ be a solution, i.e. $\boldsymbol{w}^{\top} \boldsymbol{\Gamma}_{i} \boldsymbol{w}=0$ for all $i$. We assume that the first component $w_{1}$ of $\boldsymbol{w}$ is 1 and

$$
\forall i \in \mathscr{I}_{i} \cap\{1, \ldots, n-2\}: w_{i}=0 .
$$

For simplicity, assume that the last component of $\boldsymbol{v}^{(i)}$ is used for commitment randomness and $\widetilde{\mathrm{ck}}_{M^{(i)}}^{(i)}=\left[g_{n}^{\prime}\right]$, hence message size is $M^{(i)}-1$. We assume there is an injective map $\tau$ with

$$
\tau\left(i, \_\right):\left\{1, \ldots, M^{(i)}-1\right\} \rightarrow\{1, \ldots, n-2\} \backslash \mathscr{\mathscr { C }} \quad \text { such that } \quad w_{\tau(i, j)}=\boldsymbol{v}_{j}^{(i)}
$$ which tells us components $\boldsymbol{v}_{j}^{(i)}$ of the committed message are copied to. This excludes the commitment randomness $\boldsymbol{v}_{M^{(i)}}^{(i)}$, which by assumption corresponds to component $n$ and maps to component

[^10]$n .{ }^{18}$ In other words, the mapping $\tau$ tells us where copied components $\boldsymbol{v}_{j}^{(i)}$ are stored in $\boldsymbol{w}$. (We ignore commitment randomness at indices $n-1, n$, as this is of no interest, ${ }^{19}$ and part of the extended witness $\boldsymbol{w}^{\prime}=\binom{w}{r^{\prime}} \in \mathbb{F}_{p}^{n}$. . Let $\mathcal{S}$ be a protocol proving knowledge of $\boldsymbol{v}^{(i)}$ for all $i{ }^{20}$ Then the following is a protocol for proving
$\exists \boldsymbol{w} \in \mathbb{F}_{p}^{n-2}, \boldsymbol{v}^{(i)} \in \mathbb{F}_{p}^{M^{(i)}} \leq \mathbb{F}_{p}^{n}$ such that
$$
\forall j: \boldsymbol{w}^{\top} \boldsymbol{\Gamma}_{j} \boldsymbol{w}=0
$$
$$
\text { and } \quad \forall i \forall j \in \mathscr{I} \cap\{1, \ldots, n-2\}: w_{\tau(i, j)}=\boldsymbol{v}_{j}^{(i)}
$$
$$
\text { and } \quad \forall i:\left[\widetilde{c}^{(i)}\right]=\widetilde{\mathrm{ck}}^{(i)} \boldsymbol{v}^{(i)} \widehat{=}\left[\boldsymbol{g}^{\prime}\right] \boldsymbol{v}^{(i)}
$$

The prover's witness consists of $\boldsymbol{w}$ and $\boldsymbol{v}^{(i)}$. The statement consists of $\left\{\Gamma_{j}\right\}_{j}$ and $\left[\widetilde{c}^{(i)}\right]$.

- $\mathscr{P} \rightarrow V$ : (Step -1 : Prove well-formedness of $\left.\left[c^{(i)}\right]\right)$ Engage in $\mathcal{S}$ to prove that $\exists \boldsymbol{v}^{(i)}:[\boldsymbol{g}] \boldsymbol{v}^{(i)}=\left[\widetilde{c}^{(i)}\right]$ and $\boldsymbol{v}^{(i)}$ satisfies Eq. (4.2). (This may be run in parallel.)
- $\mathscr{P} \rightarrow V:\left(\right.$ Step 0: Commit to $\boldsymbol{w}$.) Send $\left[c_{\boldsymbol{w}}^{\prime}\right]:=\left[\boldsymbol{g}^{\prime}\right] \boldsymbol{w}^{\prime}$ with $\boldsymbol{w}^{\prime}=\binom{\boldsymbol{w}}{\boldsymbol{r}^{\prime}}$, where $\boldsymbol{w}$ is as outlined above and $\boldsymbol{r}^{\prime} \leftarrow \mathbb{F}_{p}^{2}$.
- $V \rightarrow \mathscr{P}$ : (Step 1: Batch verification and statement adaption for QESA ZK ) Pick and send $\boldsymbol{\alpha} \leftarrow \chi_{M+1}$, where $\left(\alpha_{0}, \ldots, \alpha_{M}\right)=$ $\boldsymbol{\alpha} \in \mathbb{F}_{p}^{M+1}$ and where $\alpha_{0}=1$ always (by assumption). Both sides set $\left[c_{\boldsymbol{w}}^{\prime}\right]:=\alpha_{0}\left[c_{\boldsymbol{w}}^{\prime}\right]+\sum_{i} \alpha_{i}\left[\widetilde{c}^{(i)}\right]$. The prover sets $\boldsymbol{w}^{\prime}:=\alpha_{0} \boldsymbol{w}^{\prime}+\sum_{i} \alpha_{i} \boldsymbol{v}^{(i)} \in \mathbb{F}_{p}^{n}$. The set of equations is augmented by additional equations, given by "copy-matrices" $\Gamma_{\text {copy }}^{(k)}$ for each $k \in \mathscr{I} \cap\{1, \ldots, n-2\}$ as follows:

$$
\boldsymbol{w}^{\top} \boldsymbol{\Gamma}_{\mathrm{copy}}^{(k)} \boldsymbol{w}=0 \widehat{=} \sum_{\tau(i, k)=j \text { if } k \in \mathscr{g}_{i}} \alpha_{i} w_{\tau(i, k)}-w_{k}=0 .
$$

These equations merely formalise that computing the (random) linear combination of the (purported) copies of $\boldsymbol{v}^{(i)}$ (as part of $\boldsymbol{w}^{\prime}$ ) yield the same value as the (random) linear combination of the commitments, c.f. Figs. 3 and 4. (Note the linearity of the commitments). With these additional equations and the adapted witness, continue as in QESA ${ }_{\text {ZK }}$ (Step 1) without further changes.
See Appendix G for a sketch of this protocol.
It not hard to see that QESA ${ }_{\text {Copy }}$ is correct. For zero-knowledge, we merely note that QESA ${ }_{Z K}$ is statistical HVZK, and by a completely analogous proof, QESA Copy is statistical HVZK as well.

Lemma A.15. Suppose $\mathcal{S}$ is $v$-special sound. Then Protocol QESA Copy is $(\nu, \mu)$-special sound for extraction of a witness or a non-trivial kernel element of $\left[\boldsymbol{g}^{\prime}, \boldsymbol{g}^{\prime \prime}, Q\right]$, with $\mu=\left(M+1, N^{\prime}, n+1,2,2,4, \ldots, 4\right)$,

[^11]where $N^{\prime}$ is the number of equations plus the number of copy equations. The $\mu$-part is short-circuit extractable with $\mu^{\prime}=(1,1,1,2,2,2$, $\ldots, 2$ ).

Proof sкetch. The proof is straightforward, but the indexing is tedious. We only sketch it.

First of all, note that just like with QESA $_{\mathrm{ZK}}$, we can for each run with randomness $\boldsymbol{\alpha}$ extract a witness $\boldsymbol{w}_{\alpha}$ satisfying all $\Gamma_{i}$, including the additional copy-equations. We only need to prove that (all) $\boldsymbol{w}_{\alpha}$ have correctly copied the values $\boldsymbol{v}^{(i)}$ of commitments $\left[\widehat{c}^{(i)}\right]$. Since we assumed special soundness of the subprotocol $\mathcal{S}$, we could use it for extraction. However, we refrain from doing so, to sketch how the lemma and proof generalise to the setting, where $\mathcal{S}$ only ensures that any opening $\boldsymbol{v}^{(i)}$ satisfies Eq. (4.2). So, by soundness of $\mathcal{S}$, we can assume that for all components not in $\mathscr{I}$, we know that $\boldsymbol{w}_{\alpha}$ does not depend on $\boldsymbol{\alpha}$, i.e. is fixed. (Remember that $\alpha_{0}=1$, and [ $c_{\boldsymbol{w}}$ ] is the only commitment which is possibly non-zero in components outside $\mathscr{I}$.) In particular, the copies of $\boldsymbol{v}^{(i)}$ in $\boldsymbol{w}_{\alpha}$ are always identical, and do not depend on $\alpha$. Otherwise we find a non-trivial kernel element. We show this in the following.

First, we note that from $M+1$ linearly independent challenges $\boldsymbol{\alpha}$, we obtain (since $\left[\widetilde{c}^{(i)}\right]$ and $\left[c_{\boldsymbol{w}}^{\prime}\right]$ are fixed) openings to each commitment in the usual way. A priori, the openings $\boldsymbol{w}$ and $\boldsymbol{v}^{(i)}$ are only openings w.r.t. [ $g^{\prime}$ ], and need not respect Eq. (4.2). However, due to subprotocol $\mathcal{S}$, we see that Eq. (4.2) holds for each $i$, or the soundness of $\mathcal{S}$ is broken.

Now, we reinterpret the setting to avoid carrying around too many indices. The "copy proofs" essentially state the following: There is a subvector $\left(\boldsymbol{a}, \boldsymbol{b}_{1}, \ldots, \boldsymbol{b}_{M}\right)$ in $\boldsymbol{w}$ such that $\boldsymbol{b}_{i}$ consists of the copied values of all $\boldsymbol{v}^{(i)}$, and $\boldsymbol{a}$ should be zero. In $\boldsymbol{w}_{\alpha}$, we get $\boldsymbol{a}_{\alpha}=\boldsymbol{a}+\sum_{i=1}^{M} \alpha_{i} \boldsymbol{v}^{(i)}$. (Note that $\boldsymbol{a}$ should be zero, but we need to prove this.) By the "copy equations" from Step 1, we also have ${ }^{21}$

$$
\sum_{i=1}^{M} \alpha_{i} \boldsymbol{b}_{i}=\boldsymbol{a}_{\alpha}=\alpha_{0} \boldsymbol{a}+\sum_{i=1}^{M} \alpha_{i} \boldsymbol{v}^{(i)}
$$

Given $M+1$ linearly independent $\boldsymbol{\alpha}$, we find that $\boldsymbol{a}=0$. Thus, we find that the $\boldsymbol{v}^{(i)}$ which satisfy these equations are openings of $\left[\widetilde{c}^{(i)}\right]$. If any of this fails, we find non-trivial kernel relations. A priori, the opening $\boldsymbol{v}^{(i)}$ only respects $\mathscr{G}$, not $\mathscr{I}_{i}$, in the sense of Eq. (4.2). But another invocation of the soundness of $\mathcal{S}$ shows that they do respect $\mathscr{g}_{i}$. Thus, they are openings w.r.t. $\widetilde{c k}^{(i)}$. (Actually, to get openings we need to look at the randomness too, i.e. include components $n-1, n$. It is not hard to do this.)

Now, we have openings for the commitments, we know that $\boldsymbol{w}$ actually contains copies of these commitments, we know that $w$ has zeroed all $w_{i}$ with $i \in \mathscr{l}$, and $\boldsymbol{w}$ satisfies the all equations $\Gamma_{i}$. This is what we wanted to show.

Remark A.16. One can "optimise away" unnecessary copies. For example, if the value of a copy can be computed from other values by some quadratic function, then one can use this instead of making an explicit copy. This is the case for range proofs, where $\boldsymbol{v}=\sum_{i} 2^{i} b_{i}$ is is copied. The bit-decomposition of $\boldsymbol{v}$ is enough to recover it, so no extra copy of $\boldsymbol{v}$ is necessary. Evidently, the "copyequations" must be adapted accordingly.

[^12]There is one further optimisation: In the case of range proofs, one does not need $b_{0}$ if one proves instead that $v-\sum_{i \geq 1} 2^{i} b_{i}$ is a bit (which is a quadratic, even R1CS, equation). A priori, this is not possible with the copy approach. However, close inspection shows that when copying a single commitment, one can, instead of copying it, adapt all $\Gamma_{i}$ of the statement by multiplying all rows and columns in $\mathscr{I}$ by $\alpha_{1}^{-1}$ (except randomness indicices, which are not even part of the equations).

In the "copy-based" case, we can combine both optimisations: Given (implicit) copies of $\boldsymbol{v}^{(2)}, \ldots, \boldsymbol{v}^{(M)}$, one can compute $\boldsymbol{v}^{(1)}$ from these and the sum $\sum_{i=1}^{M} \alpha_{i} \boldsymbol{v}^{(i)}$. By adapting all $\Gamma_{i}$ with $\alpha_{1}^{-1}$ as before, we can make use of $\boldsymbol{v}^{(1)}$ implicitly, as $\alpha_{1}^{-1} \sum_{i=2}^{M} \alpha_{i} \boldsymbol{v}_{\text {copy }}^{(i)}$. Thus, we need at most $M-1$ copies.

These optimisations are especially useful if a lot of components need to be copied, i.e. if $\# \mathscr{I}$ is large w.r.t. to the rest of the witness.

Example A.17. Consider the situation of (aggregate) range proofs in [17], that is, we have a commitment key ck $:=\left[g_{2}^{\prime}, g_{n}^{\prime}\right]$ and want to prove that commitments $\left[c_{i}\right]$, for $i=1, \ldots, M$, all under this key, contain values within a some $\ell$-bit range. We would instantiate QESA ${ }_{\text {Copy }}$ as follows: As the subprotocol $\mathcal{S}$, use a batch proof of knowledge of openings of [ $c_{i}$ ] (Appendix B). This requires transmitting 1 group element and 2 scalars (and 1 challenge). Thus, the corresponding (almost) naive QESA Copy requires $\ell M+1$ variables, and hence $n=\ell M+4 .{ }^{22}$

In total, the prover transmits $2\lceil\log (\ell M+4)\rceil+5$ group elements and 4 scalars. This is almost identical to [17], where $2\lceil\log (\ell M)\rceil+4$ group elements and 5 scalars are transmitted. However, our approach is generic and not tailored to range proofs. Thus, the performance seems adequate. ${ }^{23}$

## B BATCH PROOFS OF KNOWLEDGE

By applying the "linear combination of protocols" technique, to multiple "trivial proofs of knowledge" (c.f. Fig. 2) we obtain batch verification of statements $\left([A],\left[t_{i}\right]\right), i=1, \ldots, N$, i.e. the setting of [46], in a straightforward way.

Protocol B.1. The following is a protocol to prove: $\exists \boldsymbol{w}_{i}:[A] \boldsymbol{w}_{i}=$ $\left[\boldsymbol{t}_{i}\right]$ for $i=1, \ldots, N$. Let $\chi_{N+1}$ be a testing distribution for challenges, such that $x \leftarrow \chi_{N+1}$ has $x_{N+1} \neq 0$ always. Common input is $\left([A],\left(\left[t_{i}\right]\right)_{i}\right) \in \mathbb{G}^{m \times n} \times \mathbb{G}^{n}$. The prover's witness are some $w_{i} \in \mathbb{F}_{p}^{n}$.

- $\mathscr{P} \rightarrow \mathcal{V}:$ Pick $\boldsymbol{r} \leftarrow \mathbb{F}_{p}^{n}$ and let $[\boldsymbol{a}]=[\boldsymbol{A}] \boldsymbol{r}$. Send $[\boldsymbol{a}] \in \mathbb{G}^{m}$.
- $\mathcal{V} \rightarrow \mathscr{P}$ : Pick $\boldsymbol{x} \leftarrow \chi_{N+1}$. Send $\boldsymbol{x} \in \mathbb{F}_{p}$.
- $\mathscr{P} \rightarrow V$ : Compute $z=\boldsymbol{x}^{\top}\left(\begin{array}{c}\boldsymbol{w}_{1} \\ \dddot{w}_{N} \\ \boldsymbol{r}\end{array}\right)=\sum_{i=1}^{N} x_{i} \boldsymbol{w}_{i}+x_{N+1} \boldsymbol{r}$. Send $z \in \mathbb{F}_{p}^{n}$.
- $V$ : Check $[A] z \stackrel{?}{=} \sum_{i=1}^{N} x_{i}\left[\boldsymbol{t}_{\boldsymbol{i}}\right]+x_{N+1}[\boldsymbol{a}]$, and accept/reject if true/false.

Lemma B.2. Protocol B. 1 is a HVZK-PoK for $\exists w$ : $[\boldsymbol{t}]=[A] \boldsymbol{w}$. It is perfectly complete, has perfect HVZK and is $(N+1)$-special sound.

[^13]Proof. Completeness is straightforward. Extraction uses $N+$ 1 accepting transcripts $\left([\boldsymbol{a}], \boldsymbol{x}_{j}, \boldsymbol{z}_{j}\right)$. Let $[T]:=\left[\boldsymbol{t}_{1}, \ldots, \boldsymbol{t}_{N}, \boldsymbol{a}\right]$ and $Z$, $\boldsymbol{X}$ be appropriate matrices built from the $N+1$ transcripts. Since $[A] Z=X$, we find $\left(w_{1}, \ldots, w_{N}, r\right):=Z X^{-1}$ is a valid witness. For HVZK note that $x_{N+1} \neq 0$. Hence $z$ is uniformly distributed for any honest execution. Thus, we can pick $z \leftarrow \mathbb{F}_{p}^{m}$ and let $[a]:=[A] z-[T] x$ as usual.

Using vectors of vectors and matrices of matrices, we can write the above as

$$
\begin{array}{r}
\boldsymbol{x}^{\top} \otimes \mathrm{id}\left[\begin{array}{lll}
\boldsymbol{A} & & \\
& \ddots & \\
& & A
\end{array}\right]\left[\begin{array}{c}
\boldsymbol{w}_{1} \\
\vdots \\
\boldsymbol{r}
\end{array}\right]=[A]\left[\begin{array}{c}
\boldsymbol{w}_{1} \\
\vdots \\
\boldsymbol{r}
\end{array}\right]^{\top} \boldsymbol{x}=[A]\left(\sum_{i=1}^{N} x_{i} \boldsymbol{w}_{i}+x_{N+1} \boldsymbol{r}\right) \\
\\
=\sum_{i=1}^{N} x_{i}\left[\boldsymbol{t}_{\boldsymbol{i}}\right]+x_{N+1}[\boldsymbol{a}]=\boldsymbol{x}^{\top}\left[\begin{array}{c}
\boldsymbol{t}_{1} \\
\vdots \\
\boldsymbol{a}
\end{array}\right]=\left[\begin{array}{c}
\boldsymbol{t}_{1} \\
\vdots \\
\boldsymbol{a}
\end{array}\right]^{\top} \boldsymbol{x}
\end{array}
$$

In a sense, we run $\mathrm{LMPA}_{\text {batch }}$, but exploit the structure (namely block-diagonality) to "commute" $\boldsymbol{x}$ and $\operatorname{diag}([A], \ldots,[A])$. Linear combination also yields efficient $k$-out-of- $N$ proofs, by having the verifier only partially fix the challenge. However, this must be done carefully or it is unsound, see [35].

## C AN EFFICIENT PROOF OF CORRECTNESS OF A SHUFFLE

A proof of correctness of a shuffle is a proof that two (multi-)sets of ciphertexts decrypt to the same multi-set of plaintexts. This is especially interesting in settings with rerandomisable ciphertexts, because the "shuffling party" does not need to decrypt. For electronic voting, a shuffle achieves a certain unlinkability between the originally encrypted votes, and the (in a final step) decrypted votes, while the proofs of correctness of the shuffle ensure that the voting result is unaffected.

With our tools, it is possible to prove the correctness of a shuffle in logarithmic communication for ElGamal ciphertexts in a very naive manner. Namely, we commit to a permutation matrix (as part of $\boldsymbol{w}$ ) and rerandomisation randomness for the ElGamal ciphertexts (also part of $\boldsymbol{w}$ ). Then we prove that $[A] \boldsymbol{w}=[\vec{c}]$, where $[A]$ is constructed from the old ciphertexts and the ElGamal public key, and $[\vec{c}]$ is the vector of shuffled ciphertexts. We also add a proof that (the relevant part of) $\boldsymbol{w}$ commits to a permutation matrix, as sketched in Section 3.5. This all neatly fits into our framework, giving a logarithmic size proof overall. However, there is a huge drawback: The size of the permutation matrix, hence $\boldsymbol{w}$, is $N^{2}$ for $N$ ciphertexts. Thus, the computation grows quadratically in $N$. This is unacceptable in practice.

Remark C.1. Shuffle arguments for (Pedersen) committed values were already constructed in [17], by using a sorting circuit and comparing the sorted sequences. In [4], an improved shuffle argument (for commitments) is constructed. It relies on the techniques in [6, 44]. More generally, [4] allows randomized R1CS, by using a commit-and-prove structure of Bulletproofs.

In Appendix C. 1 below, we rely essentially on the same techniques and properties as [4]. However, our setting concerns (ElGamal) encrypted values (e.g. votes), not (Pedersen) committed values. While it is likely that Bulletproofs can be suitably modified to cover this setting as well, it is not immediately obvious how.

Figure 4: This is a more complex example of the copying technique. Colour-coding is as before. Note that $\mathscr{I}_{1} \neq \mathscr{I}_{2}$. Again, all orange values $\boldsymbol{m}^{(i)} \widehat{=} \boldsymbol{v}^{(i)}$, are copied and appear as green values in $w$. Note that we can go much further than this: Green values could be implicitly given by quadratic equations, as noted in Remark A.16. The copy for a one commitment, e.g. [cc(1)] could be elided, c.f. Remark A.16.

Lastly, we note that given any log-communication proof system, theoretically "efficient" (polynomial time) and short shuffle proofs are essentially a triviality. Just prove the relevant statements (e.g. ElGamal randomisation) in a non-black-box manner. Since we have $O(\log (\operatorname{poly}(\kappa, n)))=O(\log (\kappa)+\log (n))$, communication is almost logarithmic in $n$ (and if $n \in \Omega(\kappa)$, it is logarithmic).

## C. 1 Adapting the shuffle argument of Bayer-Groth

The shuffle argument of Bayer and Groth [6] is built from two subarguments, a "product argument" and a "multi-exponentiation argument". A generic proof of security is given in [6, Theorem 5]. The former argument can be instantiated by QESA ${ }_{\mathrm{ZK}}$, or more precisely, QESA Copy . The latter argument can be instantiated by LMPA $_{\text {ZK }}$. Since our arguments have logarithmic communication and need linearly many exponentiations, so does the resulting shuffle argument. We give a more detailed instantiation below.

- CRS: $\mathrm{ck}=\left(\mathrm{ck}_{Q}, \mathrm{ck}_{L}\right)$, where $\mathrm{ck}_{Q}=\left(\left[\boldsymbol{g}^{\prime}, \boldsymbol{g}^{\prime \prime}, Q\right]\right)$ is the commitment key for QESA $_{\mathrm{ZK}}$ and $\mathrm{ck}_{L}=[\boldsymbol{h}]$ is the commitment key for LMPA $_{Z K}$ (or empty if a simple zero-knowledge LMPA version is used). Here $\left[g^{\prime}\right] \in \mathbb{F}_{p}^{n}$, where $n \geq N+2$ is a (suitably large) power of 2 . Note that our commitment keys consist of random group elements.
- Common input: Old and new ciphertexts $\left[\mathrm{ct}_{i}^{\text {old }}\right],\left[\mathrm{ct}_{i}^{\text {new }}\right] \in$ $\mathbb{G}^{2}$ for $i=\{0, \ldots, N-1\}$ and ElGamal public key $[\mathrm{pk}] \in \mathbb{G}^{2}$.
- Prover's witness: The random permutation $\boldsymbol{\pi} \in\{0, \ldots, N-$ $1\}^{N}$ and rerandomisation randomnesses $\rho_{i} \in \mathbb{F}_{p}$ such that $\left[\mathrm{ct}_{i}^{\text {new }}\right]=\left[\mathrm{ct}_{\pi_{i}}^{\text {old }}\right]+\rho_{i}[\mathrm{pk}]$. (Note that $\operatorname{Enc}\left(0 ; \rho_{i}\right)=\rho_{i}[\mathrm{pk}]$ for ElGamal.)
- $\mathscr{P} \rightarrow V$ : Compute and send the commitment $\left[c_{\pi}\right]$ to $\pi$ :

$$
\begin{aligned}
{\left[c_{\pi}\right] } & =\operatorname{Com}_{\mathrm{ck}_{Q}}\left(\pi ; 0, r_{\pi}\right) \\
& =\left[g_{1}^{\prime}\left|g_{2}^{\prime}, \ldots, g_{N+1}^{\prime}\right| g_{N+2}^{\prime}, \ldots, g_{n-2}^{\prime} \mid g_{n-1}^{\prime}, g_{n}^{\prime}\right]\left(\begin{array}{c}
\frac{0}{\frac{\pi}{0}} \\
\frac{0}{0} \\
r_{\pi}
\end{array}\right)
\end{aligned}
$$

(Remember that $\left[\boldsymbol{g}_{n-1}^{\prime}\right]$ and $\left[\boldsymbol{g}_{n}^{\prime}\right]$ are reserved for randomness in QESA ${ }_{\text {ZK }}$ commitments, and $\left[\boldsymbol{g}_{\boldsymbol{1}}\right]$ is also reserved (for the constant 1).)

- $\mathcal{V} \rightarrow \mathscr{P}: \operatorname{Send} \boldsymbol{x}=\left(x_{0}, \ldots, x_{N-1}\right) \leftarrow \chi_{N}$.
- $\mathscr{P} \rightarrow \mathcal{V}: \operatorname{Send}\left[c_{\boldsymbol{y}}\right]=\operatorname{Com}_{\mathrm{ck}_{Q}}\left(\boldsymbol{y} ; 0, r_{\boldsymbol{y}}\right)$, where $[\boldsymbol{y}]:=\boldsymbol{\pi}(\boldsymbol{x})=$ $\left(\boldsymbol{x}_{\pi_{i}}\right)_{i}=\left(x_{\pi_{0}}, \ldots, x_{\pi_{N-1}}\right)$.
- $V \rightarrow \mathscr{P}$ : Send $\zeta, z \leftarrow \mathbb{F}_{p}$.
- $\mathscr{P} \leftrightarrow \mathcal{V}$ : Prove following statements using (logarithmic communication) sub-protocols QESA ${ }_{\text {Copy }}$ and LMPA $_{Z K}$ :
- $\left[c_{\pi}\right]$ is a permutation and $\left[c_{y}\right]$ is a commitment to $\boldsymbol{\pi}(\boldsymbol{x})$ : The prover shows (in zero-knowledge) that

$$
\prod_{i=0}^{N-1}\left(\zeta \pi_{i}+y_{i}-z\right)=\prod_{i=0}^{N-1}\left(\zeta i+x_{i}-z\right)
$$

Note that $\zeta\left[c_{\boldsymbol{\pi}}\right]+\left[c_{\boldsymbol{y}}\right]$ is a commitment to $\zeta \boldsymbol{\pi}+\boldsymbol{y}$, which can be used for QESA ZK , or more precisely, QESA ${ }_{\text {Copy }}$. Also note that the right-hand side is computable from public information.

- $\left[\overrightarrow{c t}^{\text {new }}\right]$ is a rerandomised permutation of [ $\left.\overrightarrow{c t^{\text {old }}}\right]$ : The prover shows (in zero-knowledge) that

$$
\sum_{i}\left[\mathrm{ct}_{i}^{\text {old }}\right] y_{i}+[\mathrm{pk}] \sum_{i} \rho_{i} x_{i}=\sum_{i}\left[\mathrm{ct}_{i}^{\mathrm{new}}\right] x_{i} .
$$

This fits into our matrix multiplication proofs (with witness $\binom{y}{x^{\top} \rho} \in \mathbb{F}_{p}^{N+1}$ ). Concretely, the prover commits to $\sigma:=\boldsymbol{x}^{\top} \rho$ via $\left[c_{\sigma}\right]=\operatorname{Com}_{\mathrm{ck}_{Q}}\left(\binom{0}{\sigma} ; r_{\sigma}, 0\right)=\left[g_{N+2}^{\prime}, g_{n-1}^{\prime}\right]\binom{\sigma}{r_{\sigma}}$ for $r_{\sigma} \leftarrow \mathbb{F}_{p}$. He sends $c_{\sigma}$ to the verifier and engages in a LMPA ${ }_{Z K}$ protocol for

$$
\left[\begin{array}{c|c|cc}
g_{2}^{\prime}, \ldots, g_{N+1}^{\prime} & g_{N+2}^{\prime} & g_{n-1}^{\prime} & g_{n}^{\prime} \\
g_{2}^{\prime}, \ldots, g_{N+1}^{\prime} & 0 & 0 & g_{n}^{\prime} \\
0 & g_{N+2}^{\prime} & g_{n-1}^{\prime} & 0 \\
\operatorname{ct}_{0}^{\text {old }} \ldots \mathrm{ct}_{N-1}^{\text {old }} & \mathrm{pk} & 0 & 0
\end{array}\right]\left(\begin{array}{c}
\boldsymbol{y} \\
\hline \sigma \\
\hline r_{\sigma} \\
r_{\boldsymbol{y}}
\end{array}\right)=\left[\begin{array}{c}
c_{\boldsymbol{y}}+c_{\sigma} \\
c_{\boldsymbol{y}} \\
c_{\sigma} \\
\boldsymbol{u}
\end{array}\right]
$$

where $[\boldsymbol{u}]:=\sum x_{i}\left[\mathrm{ct}_{i}^{\text {new }}\right]$. The top row is added so one can run $\mathrm{LMPA}_{\text {batch }}$, reducing to a $2 \times n$ matrix. Since [ $\boldsymbol{g}^{\prime}$ ] has hard kernel relation, so has [A]. (This is a "commitmentextension", see Remark 3.4.) Also note that this LMPA proof ensures the requirements of QESA Copy on the opening of $\left[c_{y}\right]$, hence no additional subprotocol $\mathcal{S}$ is necessary in this instance.
Honest verifier zero-knowledge of this protocol follows from honest verifier zero-knowledge of the subprotocols. Soundness (and extraction) follows from soundness (and extraction) of the subprotocols. Namely, for fixed $\boldsymbol{\pi}$, randomly chosen $\boldsymbol{x}$ and arbitrary $\boldsymbol{y}$, the probability that $\prod_{i=0}^{N-1}\left(\zeta \pi_{i}+y_{i}-z\right)=\prod_{i=0}^{N-1}\left(\zeta i+x_{i}-z\right)$ holds for
$\zeta, z \leftarrow \mathbb{F}_{p}$ if $y_{i} \neq x_{\pi(i)}$ is negligible thanks to the Schwartz-Zippel lemma. ${ }^{24}$

In [6], intuition and a detailed security argument is given. Despite our minor modifications, their proof adapts seamlessly to our setting. The idea of using (permutation invariant sets of) roots of polynomials to prove that one set of roots is a permutation of another goes back to [44] and was extended to restricted permutations in [47].

A rough efficiency estimate of our scheme is 30 N exponentiations for the prover and 10 N exponentiations for the verifier. These are roughly twice the numbers of [6], when trading interaction for efficiency. However [6] has $O(\sqrt{N})$ size proofs, while we have $O(\log (N))$ size proofs.

## D WITNESS-EXTENDED EMULATION AND

## TreeFind

## D. 1 Witness-extended emulation

We define (black-box) witness-extended emulation following [13, $32,39]$. But we separate extraction and emulation, and allow emulation (or rather extraction) to fail with probability depending on the extraction error. This is somewhat inconvenient, redundant, and yields yet another definition of "of knowledge". Fortunately, the extraction (i.e. the "knowledge" parts) are equivalent to standard formulations. However, combined with emulation, the prior work we are aware of was only concerned with negligible extraction errors.

Definition D. 1 (Witness-extended emulation). Let $(\mathscr{P}, \mathcal{V})$ by an interactive argument system for $\mathscr{R}$. We say that $(\mathscr{P}, \mathcal{V})$ is an argument of knowledge with witness-extended emulation and extraction error $\delta_{\text {ext }}$ if there exists a (universal) expected polynomialtime emulator Emu. The emulator takes as input the CRS, a statement st and a rewindable deterministic ${ }^{25}$ proof-oracle $\mathscr{P}^{*}$ (state), written Emu(crs, st, $\mathscr{P}^{*}$ (state)). (As usual, we suppress crs in the following.) It outputs a pair (tr, w) of emulated transcript and purported witness. We require following properties. For every adversary given by a pair of efficient algorithms $\left(\mathcal{A}, \mathscr{P}^{*}\right)$ we have:

## - (Computational) Emulation:

$$
\begin{aligned}
& \mathbb{P}\binom{\operatorname{crs} \leftarrow \operatorname{GenCRS}\left(1^{\kappa}\right) ;(\mathrm{st}, \text { state }) \leftarrow \mathcal{A}(\mathrm{crs}) ;}{\operatorname{tr} \leftarrow\left\langle\mathscr{P}^{*}(\mathrm{state}), \mathcal{V}(\mathrm{st})\right\rangle: \mathcal{A}(\text { state }, \mathrm{tr}) \stackrel{?}{=} 1} \\
& \stackrel{c}{\approx} \mathbb{P}\binom{\mathrm{crs} \leftarrow \operatorname{GenCRS}\left(1^{\kappa}\right) ;(\mathrm{st}, \text { state }) \leftarrow \mathcal{A}(\mathrm{crs}) ;}{(\mathrm{tr}, \mathrm{w}) \leftarrow \operatorname{Emu}\left(\mathrm{st}, \mathscr{P}^{*}(\text { state })\right): \mathcal{A}(\text { state }, \mathrm{tr}) \stackrel{?}{=} 1}
\end{aligned}
$$

- Extraction: For all crs $\leftarrow \operatorname{GenCRS}\left(1^{\kappa}\right)$ and all (st, state) $\leftarrow$ $\mathcal{A}$ (crs) we have

$$
\begin{equation*}
\mathbb{P}\left(\operatorname{Emu}\left(\text { st }, \mathscr{P}^{*}(\text { state })\right) \text { fails }\right) \leq \frac{\delta_{\mathrm{ext}}}{\mathbb{P}(\underbrace{\left\langle\mathscr{P}^{*}(\text { state }), V(\mathrm{st})\right\rangle=1}_{\mathscr{P}^{*} \text { succeeds }})} \tag{D.1}
\end{equation*}
$$

[^14]By "Emu fails", we mean that the extracted witness w does not satisfy (st, w) $\in \mathcal{R}$. An equivalent formulation of the inquality is
$\mathbb{P}\left(\operatorname{Emu}\left(\right.\right.$ state, $\mathscr{P}^{*}($ state $\left.)\right)$ fails $\mid\left\langle\mathscr{P}^{*}(\right.$ state $), \mathcal{V}($ st $\left.\left.)\right\rangle=1\right) \leq \delta_{\text {ext }}$.
where we assume $V$ uses independent randomness.
If $\delta_{\text {ext }}$ is negligible, then the definition is very similar to [13, 32, 39]. However, we can deal with non-negligible $\delta_{\text {ext }}$, e.g. fixed to $2^{-80}$ independent of the security parameter, essentially having the (partial) definition of an extractor (not emulator) due to Eq. (D.1). In any case, we require the emulated transcript to be (computationally) indistinguishable from a real transcript.

Typically, the emulator proceeds in two steps, c.f. [39]. First, it uses the honest verifier's strategy to obtain a transcript. If this is not accepting, we're done. Otherwise, the emulator runs an extractor to obtain the witness (with suitable probability). In such a two-phase setting, one can amplify the probability to obtain a witness, e.g. by retrying the extraction step often enough. ${ }^{26}$ For example, if we have acceptance probability $\varepsilon \geq \delta_{\text {ext }}\left(1+\frac{1}{\text { poly }}\right)$, then by $O(\kappa \cdot \operatorname{poly}(\kappa))$-fold repetition, we achieve overwhelming extraction probability. Thus, switching to a (sufficiently large) upper bound $\delta_{\text {ext }}^{\prime} \geq \delta_{\text {ext }}$, we can obtain overwhelming extraction for this (weaker) extraction error.

We choose not to require such amplification for two reasons: First, a "one-shot" extractor with extraction error $\delta_{\text {ext }}$ is quite natural in our applications. Second, one might arguably want to call the "minimal" $\delta_{\text {ext }}$ the extraction error. Since amplification requires $\delta_{\text {ext }}^{\prime}>\delta_{\text {ext }}$, we can only approximate $\delta_{\text {ext }}$ for such extractors, see [49] for similar considerations.

The focus of this paper is not the definition of witness-extended emulation with extraction error. Hence we stop the discussion of possible variations here.
D.1.1 Relating knowledge errors. Our definition of extraction error should be viewed as "per extractor", not "per protocol" (see [49] for a similar point of view). Moreover, we chose a definition of extraction error which implies soundness, unlike Bellare and Goldreich [7], where soundness and extraction are explicitly separated. We ignore these differences here.

The (alternative) definition of knowledge error [7, Section 6] fits nicely into our setting. Indeed, from $\mathbb{P}($ Ext succeeds $) \geq 1-\frac{\delta_{\text {ext }}}{\varepsilon}$ we see that by first generating a (random) transcript, and only invoking Ext if $\mathscr{P}^{*}$ was successful, we get an extractor Ext' with

$$
\mathbb{P}\left(\mathrm{Ext}^{\prime} \text { succeeds }\right) \geq \varepsilon\left(1-\frac{\delta_{\mathrm{ext}}}{\varepsilon}\right)=\varepsilon-\delta_{\mathrm{ext}}
$$

and expected polynomial runtime. Here, we considered an extractor sastifying Eq. (D.1), not an emulator. Thus, our notion implies that of [7]. (As noted before, witness-extended emulators can be constructed as Ext ${ }^{\prime}$.)

The converse regarding extraction is also evident from this inequality. Emulation almost follows from [39]. The construction and

[^15]proof in [39] is only for negligible extraction error (and only guarantees negligible soundness error). ${ }^{27}$ However, by choosing a weaker extraction error $\delta_{\text {ext }}^{\prime} \geq \alpha \delta_{\text {ext }}$ with a sufficient gap $\alpha>1$, the proof strategy should generalise. ${ }^{28}$ Here, $\alpha$ should be constant or at least of the form $\alpha=1+\frac{1}{\text { poly }}$. Due to runtime requirements, it is not obvious whether the (stronger) extraction error $\delta_{\text {ext }}$ can be preserved by some (improved) construction.

Again, we stop the discussion here, since this is not the focus of this work.
D.1.2 Lower bounds for black-box extraction. We pose following natural question.

Question D.2. Let $\mathscr{R}$ be a witness relation and $\Pi_{\text {Arg }}$ be an argument system for $\mathscr{R}$. Suppose $\mathscr{R}$ has "short" witnesses of size $n$. In particular, $\mathcal{R}$ defines a hard language. Suppose a transcript of $\Pi_{\text {Arg }}$ has size $s_{\mathscr{P}}+s_{\mathcal{V}}$. Does a black-box extractor (or emulator) need $n / s_{\mathcal{P}}$ transcripts for extraction? (Here $s_{\mathscr{P}}$ is the size of the total communication sent by $\mathscr{P}$, and likewise $s_{l}$.)

If above assumption is true, it gives a lower-bound on the number of necessary rewinds of any efficient emulator. Indeed, it guarantees that small communication implies large black-box extraction overhead.

## D. 2 Modular extraction from $\mu$-special soundness

Witness-extended emulation for $\mu$-special sound protocols can be constructed as a two-stage process: First, run the protocol and keep the transcript (for emulation). If it is a successful transcript, find a good $\mu$-tree. Second, apply the extractor from Definition 2.14 to obtain a witness. To find a good $\mu$-tree with acceptable runtime, the straightforward "follow your nose" approach actually works, c.f. the general forking lemma in [13]. An alternative, with better guarantees but worse runtime estimates, is given in [49].

Given such a TreeFind, we get the following:
Lemma D.3. Let $\Pi_{\mathrm{Arg}}=(\mathrm{GenCRS}, \mathscr{P}, \mathcal{V})$ be a public coin interactive argument system with $\mu$-special soundness and extractor Ext. Let $\mu=\left(\mu_{1}, \ldots, \mu_{\ell}\right)$ and $\delta_{i}=\delta_{\text {snd }}\left(\chi^{(i)}\right)$ the soundness error of the $i$ th testing distribution. Suppose TreeFind is a tree-finding algorithm with expected runtime $t_{\text {TreeFind }} / \varepsilon \in O(\operatorname{poly}(\kappa)) / \varepsilon$, where $\varepsilon$ is the probability the oracle $\mathscr{P}^{*}$ (state) convinces the honest verifier. Let $\eta$ be the probability that TreeFind outputs a bad $\mu$-tree. Then $\Pi_{\text {Arg }}$ has a witness-extended emulator Emu (as described above) with expected runtime roughly $O\left(t_{V}+t_{\text {TreeFind }}+t_{\text {Ext }}\right)$ and extraction error $\eta$.
(For more precise runtime estimates, TreeFind should be modelled as a transcript oracle for Ext. Otherwise, short-circuit extraction is not useful. We chose to simplify here.)

[^16]The TreeFind algorithm of [13] outputs the first $\mu$-tree it finds, if it is good. It generates trees recursively, depth-first, always branching paths with accepting transcripts, and aborts if it rewinds more than $1 / \alpha$ times (for suitable negligible $\alpha$ ). By a union bound, the probability that such a tree is bad is at most $\eta=\sum_{i=1}^{n} \frac{\delta_{i}}{\alpha} \prod_{j=1}^{i-1} k_{j}$. Here $\delta_{i}=\sigma_{\infty}\left(\chi^{(i)}\right)$. Unfortunately, negligible $\alpha$ enforces negligible soundness errors for all $i$. Thus one cannot fix the soundness level of the testing distributions to, say $2^{-100}$.

The algorithm in [49] can be configured to do better, e.g. to attain $\eta=\sum_{i=1}^{n} \delta_{i} v^{i}$ for any choice of $v>1$. The choice $v=2$ is quite natural, but yields relatively large bounds on runtime.

We have following question/conjecture which we also leave for future work:

Question D.4. Consider $\mu$-special soundness with $\mu=\left(\mu_{1}, \ldots, \mu_{\ell}\right)$. Suppose the respective testing distributions have soundness errors $\delta_{i}=\delta_{\text {snd }}\left(\chi^{(i)}\right)$. Hence, we expect ${ }^{29}$ the "overall extraction error" $\delta_{\text {snd }}$ to be bounded by $\sum_{i} \delta_{\text {snd }}^{(i)}$. Does there exist an efficient TreeFind algorithm such that

- TreeFind has runtime roughly $\widetilde{O}(n / \varepsilon)$ where $n=\Pi_{i} \mu_{i}$ and $\varepsilon$ is the probability for the verifier to accept. (By $\widetilde{O}(f)$, we denote asymptotic behaviour up to polylogarithmic factors.)
- TreeFind returns a good tree with probability at least 1 $\delta_{\text {snd }} / \varepsilon$.
If the above is not satisfiable, how close can we get?
The algorithms from [13, 49] do not achieve this. The TreeFinder in [13] has weak soundness guarantees, but satisfies the runtime of first point. As noted above, [49] achieves the second point arbitrarily close by sacrificing runtime. Moreover, we note that [49] generalises testing distributions by working with matroids. Improving or strengthening results [49] could settle some of our questions and conjectures.

Remark D.5. We note that [49] relies on $\sigma_{\infty}(\chi)$ instead of $\delta_{\text {snd }}(\chi)$. We hope that both measures are identical, see Conjecture E.1. We also note that our definition(s) of extraction error differs slightly from those in [49].

## E TESTING DISTRIBUTIONS

In this section, we state some simple but helpful insights on testing distributions. We note that linear independence can be generalised and used instead. For example, [49] uses a generalised setting.

## E. 1 Conjectures and computational soundness errors

We first conjecturally characterise the soundness error by a different measure, namely we define

$$
\sigma_{\infty}\left(\chi_{m}\right):=\max _{H \leq \mathbb{F}_{p}^{n}} \mathbb{P}\left(\boldsymbol{x} \leftarrow \chi_{m}: \boldsymbol{x} \in H\right)
$$

where $H$ ranges over all $(n-1)$-dimensional subspaces. We have following lemma.

[^17]Conjecture E.1. Let $\chi$ be a testing distribution on $\mathbb{F}_{p}^{m}$. Then

$$
\delta_{\text {snd }}\left(\chi_{m}\right)=\sigma_{\infty}\left(\chi_{m}\right) .
$$

Partial proof. The subdistribution $\psi_{H}$ over the maximising $H$ always yields $n$ linearly dependent vectors (i.e. determinant 0 ), Moreover, $\psi_{H}$ has weight $\varepsilon=\chi_{m}(H)=\sigma\left(\chi_{m}\right)$. By definition of $\delta_{\text {snd }}$, we find $1 \leq \frac{1}{\varepsilon} \delta_{\text {snd }}\left(\chi_{m}\right)$. Therefore $\delta_{\text {snd }}\left(\chi_{m}\right) \leq \sigma_{\infty}\left(\chi_{m}\right)$.

To prove the claim, we need to show that $\sigma_{\infty}\left(\chi_{m}\right)$ is admissible as a soundness error, i.e.

$$
\mathbb{P}\left(\boldsymbol{x}_{i} \leftarrow \psi: \operatorname{det}\left(\boldsymbol{x}_{1}, \ldots, \boldsymbol{x}_{m}\right)=0\right) \leq \frac{1}{\varepsilon} \sigma_{\infty}\left(\chi_{m}\right)
$$

for all subdistributions $\psi$ (with weight $\varepsilon$ ).
Note that the lefthand side is $\mathbb{P}\left(\boldsymbol{X} \leftarrow \psi^{m}: \boldsymbol{X} \in T\right)$ where $T:=$ $\left\{\boldsymbol{X} \in \mathbb{F}_{p}^{m \times m} \mid \operatorname{det}(\boldsymbol{X})=0\right\}$. Equivalently $T=\cup_{H} H^{m}$ where $H$ ranges over all hyperplanes. For convenience, we write $\psi(M)$ := $\mathbb{P}(M \in \psi)$. Thus, we find

$$
\begin{aligned}
\mathbb{P}\left(\boldsymbol{X} \leftarrow \psi^{m}: \boldsymbol{X} \in T\right) & =\psi^{m}\left(\cup_{H} H^{m}\right) \\
& =\sum_{H_{1}} \psi^{m}\left(H_{1}^{m}\right)-\frac{1}{2!} \sum_{H_{1} \neq H_{2}} \psi^{m}\left(H_{1}^{m} \cap H_{2}^{m}\right)+\ldots \\
& =\sum_{H_{1}} \psi\left(H_{1}\right)^{m}-\frac{1}{2!} \sum_{H_{1} \neq H_{2}} \psi\left(H_{1} \cap H_{2}\right)^{m}+\ldots
\end{aligned}
$$

by application of the inclusion-exclusion principle, probabilistic independence (for $\left.\psi^{m}\left(H^{m}\right)=\psi(H)^{m}\right)$ and subspace properties (i.e. $\left.H_{1}^{m} \cap H_{2}^{m}=\left(H_{1} \cap H_{2}\right)^{m}\right)$. Here all $H_{i}$ range over all hyperplanes.

Heuristically, the higher order term should only decrease the sum. Moreover, a sum $\sum x_{i}^{m}$ under constraints $\sum x_{i}=1, x_{i} \in$ [ $0, \sigma_{\infty}(\chi)$ ] is maximised by maximising all $x_{i}$ (i.e. to $\sigma_{\infty}(\chi)$, or whatever is "left" for the last one). Thus, heuristically, we have an upper bound $N \sigma_{\infty}(\chi)$ where $N=\frac{1}{\varepsilon}$ (the "number" of $x_{i}{ }^{\prime}$ 's). This is exactly our claim.

However, the heuristic oversimplifies possible interdependencies of higher order terms (i.e. hyperplanes sharing lower-dimensional subspaces). As is, this is not a proof.

The above conjectured characterisation of the soundness error allows to prove and argue much easier. Most of the following results are stated w.r.t. to $\sigma_{\infty}(\chi)$.

The impact of the (or a) "favoured hyperplane", that is a hyperplane $H$ with $\mathbb{P}(H \in \chi)=\sigma_{\infty}(\chi)$, is evident in following example.

Example E.2. Fix some hyperplane $H \leq \mathbb{F}_{p}^{m}$. Consider the distribution $\chi$ over $\mathbb{F}_{p}^{m}$ induced by following algorithm: Pick $x_{0} \leftarrow \mathbb{F}_{p}^{m}$ and $\boldsymbol{x}_{1} \leftarrow H$ uniformly at random. Pick $b \leftarrow\{0,1\}$ uniformly at random. Output $\boldsymbol{x}_{b}$.

This has following characteristics: With probability at most $2^{-m}+$ $3 m^{2} p^{-1}$ a sample of $m$ elements is linearly dependent. ${ }^{30}$ But the soundness error, or rather $\sigma_{\infty}$, is (slightly greater than) $\frac{1}{2}$. This is because the subdensity $\psi_{H}$, which is $\chi$ conditioned on $H$, has

[^18]weight (slightly greater than) $\frac{1}{2}$ and $m$ samples are always linearly dependent.

Remark E.3. If the halfplane $H$ in Example E. 2 is chosen uniformly at random and secret, and $m$ grows in $\kappa$ fast enough, then it is probably a hard problem to differentiate the distribution from a uniformly random one. See [16], where a similar (even more structured) assumption is used constructively.

Note that for constant $m$, one can give a (very inefficient) algorithm which recovers $H$ given enough (e.g. $2 m$ ) samples. Namely, try every subset of $m-1$ indices, compute a candidate $H^{\prime}$, and check if about $m$ samples $\boldsymbol{x}_{i}$ lie in $H$. This recovers $H$ with high probability, thus distinguishing the distribution from random. (The effort to try all subsets is exponential im $m$, which by assumption is constant. Thus the overall algorithm is still polynomial in $\kappa$.)

The definition of soundness error $\delta_{\text {snd }}(\chi)$ of $\chi$ is a "perfect unconditional" notion. It assigns to the distribution in Example E. 2 a soundness error which is greater than $\frac{1}{2}$, even when $m=\operatorname{poly}(\kappa)$ grows with with the security parameter $\kappa$, and the distribution is assumed to be pseudorandom.

This motivates a relaxation of the soundness error. There are different ways to define a(n admissible) computational soundness. ${ }^{31}$ The cleanest one is by comparison to a (unconditionally) secure distribution, similar to computational entropy. Namely, we say $\delta_{\text {snd }}^{\text {comp }}(\chi)$ is a(n admissible) computational soundness error if there exists a distribution $\chi^{\prime}$ such that $\chi \underset{\sim}{c} \chi^{\prime}$ and $\delta_{\text {snd }}\left(\chi^{\prime}\right)=\delta_{\text {snd }}^{\text {comp }}$. (Recall that whenever we say "distribution" we actually mean probability ensemble or family of distributions (paramterised over $\kappa$ ).)

While this definition is elegant and resembles pseudoentropy, it has limited use: We would like to replace uniformly random samples by a PRG and give away the seed. Replacing uniform randomness with a PRG works nicely and yields a computational soundness error which is identical to the statistical one, according to the previous definition. However, giving away the seed makes no sense in that model. There is no indistinguishability involved.

Reminder. The soundness error is a combinatorial property. There is no need for pseudorandomness, as testing with powers of $x$ shows. However, since we do not know a simple example of a distribution with (small) exponents $x_{i} \in \mathcal{S}$ for general $\mathcal{S} \subseteq \mathbb{F}_{p}$, it is natural to turn to PRG's. It is also a plausible assumption, that non-pathological PRG's have a (statistical) soundness error close to the uniform choice. Otherwise, assuming Conjecture E.1, the PRG would have to have hidden favoured hyperplanes.

To define computational soundness which can encompass the setting where a PRG seed is sent (as a compressed challenge), we need a few definitions. Since this is not the focus of the paper, we will only sketch a possible choice. For this, we have to make encoding and decoding of a testing distributions test vector explicit.

A testing distribution $\chi$ over $\mathbb{F}_{p}^{m}$ with decoding decode is a distribution $\chi^{\text {enc }}$ over some set of encodings, such that $\chi:=\operatorname{decode}\left(\chi^{\mathrm{enc}}\right)$. The (encoded) challenge is $s \leftarrow \chi^{\mathrm{enc}}$, which the actual (decoded)

[^19]challenge vector is decode $(s) \in \mathbb{F}_{p}^{m}$. Note that encoding the challenge (i.e. recovering $s$ ) need not be efficient, ${ }^{32}$ e.g. if decode $=$ PRG and $\chi^{\text {enc }}$ draws uniformly from $\{0,1\}^{\kappa}$.

A subdistribution $\psi$ of a testing distribution $\chi$ over $\mathbb{F}_{p}^{m}$ (with decoding) is called efficiently samplable if there is an algorithm Rej, the rejection sampler, such that $\operatorname{decode}\left(\operatorname{Rej}\left(\chi^{\mathrm{enc}}\right)\right)$ has the distribution of $\psi$, conditioned on $\operatorname{Rej}\left(\chi^{\text {enc }}\right) \neq \perp$ (i.e. Rej not rejecting). Note that Rej is given the encoding, e.g. the seed of the PRG challenge.

By taking a brief look at the previous definition of computational soundness error, and noting that the weights of efficiently samplable subdistributions of a computationally indistinguishable distributions must be close (up to negligible error), one sees the following: To relax the notion of computational soundness, one can allow a computational soundness error of $\delta_{\text {snd }}^{\text {comp }}$ if for all efficiently samplable subdisitributions $\psi$ there exist negligible functions negl ${ }_{1}$, negl ${ }_{2}$ such that $\mathbb{P}\left(\boldsymbol{x}_{i} \leftarrow \psi: \operatorname{det}\left(x_{1}, \ldots, x_{m}\right)=0\right) \leq$ $\left(\varepsilon(\psi)+\operatorname{negl}_{1}(\kappa)\right) \delta_{\text {snd }}^{\text {comp }}+$ negl $_{2}(\kappa)$ where $\varepsilon(\psi)$ is the weight of $\psi$.

This definition is somewhat unwieldy. But, to the best of our knowledge, it is appropriate and we have no simpler notion.

Example E.4. Let PRG by a non-uniformly secure PRG. Suppose Conjecture E. 1 holds. Then PRG has statistical soundness error negligibly close to $\delta_{\text {snd }}\left(\chi_{\text {uniform }}\right)$. Otherwise, due to Conjecture E.1, there must be a favoured hyperplane $H$ (with $\sigma_{\infty}$ (PRG) non-negligibly greater than $\left.\sigma_{\infty}\left(\chi_{\text {uniform }}\right)\right)$. Encoding this hyperplane as the non-uniform advice $z_{\kappa}$, we can constructed a distinguisher with non-negligible advantage. (If $\boldsymbol{x} \in H$, say PRG. Else, return a random guess.)

Remark E.5. It is not immediately clear how to generalise Example E. 4 to other settings, such as families of PRG's or uniform security assumptions. Hence, it is rather a testament to the strength of non-uniform security assumptions. However, by using computational soundness, the idea may be salvageable.

However, any successful "adversary" Rej induces some $\psi$ with non-negligible weight and non-negligible deviation from $(\varepsilon(\psi)+$ negl $\left._{1}(\kappa)\right) \delta_{\text {snd }}^{\text {comp }}+$ negl $_{2}(\kappa)$, where we set $\delta_{\text {snd }}^{\text {comp }}($ PRG $)=\delta_{\text {snd }}\left(\chi_{\text {uniform }}\right)$. Thus, using Conjecture E. 1 in a computational setting, the nonnegligibly more likely linear dependency of $\psi$ may allow to sample a favoured hyperplane $H^{\prime}$ via $\psi$, as a preprocessing step. Then, one can use using this $H^{\prime}$, as the advice above to break the PRG. If this works, then the technique should also apply to families of PRG's (e.g. based on RSA). (This is only an unfinished sketch and not a proof.)

## E. 2 Properties of testing distributions

Remark E.6. Let $\chi_{m}$ be a testing distribution. Then the probability that $x_{i}=x_{j}$ for $\boldsymbol{x} \leftarrow \chi_{m}$ is smaller than $\delta_{\text {snd }}\left(\chi_{m}\right)$. This is due to following observation: Let $B$ be the set of all vectors with $x_{i}=x_{j}$ and let $\varepsilon$ be the probability of $B$ under $\chi_{m}$, that is, $\varepsilon$ is the weight of the subdistribution $\psi_{B}$ belonging to $B$. Note that $B$ contains no basis of $\mathbb{F}_{p}^{m}$. Thus, the soundness error of $\chi_{m}$ is bounded below by $\varepsilon$. In other words, $\varepsilon \leq \delta_{\text {snd }}\left(\chi_{m}\right)$.

[^20]Remark E. 6 above is another example demonstrating that the soundness error can be very far from probability that a $X \leftarrow \chi_{m}^{m}$ is not invertible. For random binary $n \times n$ matrices over the reals, the conjecture is that only a $(1+o(1)) n^{2} 2^{-n}$ fraction is singular. But the probability that $x_{i}=x_{j}$ is $\frac{1}{4}$ in this case. In our case, the matrices are not over the reals, but modulo $p$. This makes a difference, e.g. for $p=2$, the fraction of singular matrices is roughly $\frac{1}{2}$. But it is natural to assume that for large $p \gg n$ (e.g. an exponential gap as in our case), asymptotics which could "justify" random binary vectors modulo $p$ as testing distributions do hold. Thus, there may be distributions, where $x_{i}=x_{j}$ with high probability, but where any $n$ random vectors are independent with very high probabity. Again, this shows the importance of considering subdistributions for $\delta_{\text {snd }}$.

Remark E.7. The above argument in Remark E. 6 generalises to other relations/properties of vectors which affect invertibility. Thus, a testing distribution must be "well-spread" over a vector space to achieve high (computational) soundness. We note that relations which are computationally hard may affect the soundness heavily, while leaving computational soundness "unaffected" (up to a negligible loss).

## E. 3 Constructions of testing distributions

We consider the tensor product of testing distributions. In a sense, this construction is the unrolling of the recursive steps in our proof systems. The tensor product distribution $\chi=\chi_{1} \otimes \ldots \otimes \chi_{\ell}$ is defined by sampling $z \leftarrow \chi$ via $z=z_{1} \otimes \ldots \otimes z_{\ell}$ for $z_{i} \leftarrow \chi_{i}$. Note that $z$ is therefore always an elementary tensor.

Lemma E.8. Let $\chi=\chi_{1} \otimes \ldots \otimes \chi_{\ell}$ be the tensor product of $\ell$ testing distributions $\chi_{i}$ on $\mathbb{F}_{p}^{k_{i}}$ with $\sigma_{\infty}\left(\chi_{i}\right)$. Then $\chi$ has $\sigma_{\infty}(\chi) \leq$ $\sum_{i=1}^{\ell} \sigma_{\infty}\left(\chi_{i}\right)$. If Conjecture E. 1 holds, this translates to $\delta_{\text {snd }}(\chi) \leq$ $\sum_{i=1}^{\ell} \delta_{\text {snd }}\left(\chi_{i}\right)$.

Proof. By induction, it suffices to consider $\ell=2$. Let $\delta_{i}:=$ $\sigma_{\infty}\left(\chi_{i}\right)$. Suppose $V=\operatorname{ker}(\varphi)$ is some hyperplane with $\sigma_{\infty}(\chi)=$ $\mathbb{P}_{z \leftarrow \chi}(z \in V)$, where $\varphi: \mathbb{F}_{p}^{k_{1}} \otimes \mathbb{F}_{p}^{k_{2}} \rightarrow \mathbb{F}_{p}$ is a linear map. Recall that any element $z$ in $\operatorname{supp}(\chi)$ is an elementary tensor $\boldsymbol{x} \otimes \boldsymbol{y}$ by definition of $\chi=\chi_{1} \otimes \chi_{2}$.

Since $\varphi\left(\_\otimes \boldsymbol{y}\right)$ induces a linear map $\operatorname{Hom}\left(\mathbb{F}_{p}^{k_{1}}, \mathbb{F}_{p}\right) \cong \mathbb{F}_{p}^{k_{1}}$, we find that

$$
\mathbb{P}_{\boldsymbol{x} \leftarrow \chi_{1}}(\varphi(\boldsymbol{x} \otimes \boldsymbol{y})=0) \leq \delta_{1}
$$

for any choice of $\boldsymbol{y}$, except if $\varphi\left(\_\otimes \boldsymbol{y}\right)=0$ as a map. But $\varphi\left(\_\otimes \boldsymbol{y}\right)=$ 0 implies that $\boldsymbol{y} \in K$, where $K:=\{\boldsymbol{b} \mid \varphi(\otimes \otimes \boldsymbol{b})=0\} \leq \mathbb{F}_{p}^{k_{2}}$. which is at most a subspace of dimension $\left(k_{2}-1\right)$, (else $\varphi=0$, a contradiction). ${ }^{33}$ Thus, we get

$$
\mathbb{P}_{\boldsymbol{y} \leftarrow \chi_{2}}\left(\varphi\left(\_\otimes \boldsymbol{y}\right)=0\right)=\mathbb{P}_{\boldsymbol{y} \leftarrow \chi_{2}}(\boldsymbol{y} \in K) \leq \delta_{2} .
$$

Then we from $z=x \otimes y$ that

$$
\begin{aligned}
\mathbb{P}_{\boldsymbol{z} \leftarrow \chi}(\boldsymbol{z} \in V) & =\mathbb{P}_{\boldsymbol{x}, \boldsymbol{y}}(\varphi(\boldsymbol{x} \otimes \boldsymbol{y})=0) \\
& \leq\left(1-\mathbb{P}_{\boldsymbol{y}}(\boldsymbol{y} \in K)\right) \max _{\boldsymbol{y} \notin K} \mathbb{P}_{\boldsymbol{x}}(\varphi(\boldsymbol{x}))+\mathbb{P}_{\boldsymbol{y}}(\boldsymbol{y} \in K) \\
& \leq \delta_{1}+\delta_{2}-\delta_{1} \delta_{2} \\
& \leq \delta_{1}+\delta_{2} .
\end{aligned}
$$

[^21]Consequently, $\sigma_{\infty}(\chi) \leq \sigma_{\infty}\left(\chi_{1}\right)+\sigma_{\infty}\left(\chi_{2}\right)$. This proves our claim. We stress the importance of using $\sigma_{\infty}$, which allowed us to work directly with $\chi$ instead of subdistributions. While $\chi$ has a simple product structure, where $\boldsymbol{x}, \boldsymbol{y}$ are drawn independently, a subdistribution of $\chi$ can break this stochastic independence.

Our recursive arguments actually have a tensor structure, namely they reduce $\mathbb{F}_{p}^{n}=\left(\mathbb{F}_{p}^{k}\right)^{\ell}$ to $\left(\mathbb{F}_{p}^{k}\right)^{\ell-1}$ in one step, i.e. they apply a linear map to one of the factors of the tensor product. It is not hard to see that in Section 3.5, Protocol 3.7, one applies $\boldsymbol{x}_{1} \otimes \ldots \otimes \boldsymbol{x}_{\ell}$ to $[A]$ and $\boldsymbol{y}_{1} \otimes \ldots \otimes \boldsymbol{y}_{\ell}$ to $\boldsymbol{w}$ when all batching steps are taken together. It follows easily, that assuming quick-extraction in Lemma 3.8, this means that we can extract a witness by obtaining $n=k^{\ell}$ separate transcripts with challenges $\boldsymbol{y}_{1} \otimes \ldots \otimes \boldsymbol{y}_{\ell} \leftarrow \chi_{1} \otimes \ldots \otimes \chi_{k}$, one can invert the respective matrix $Y \in \mathbb{F}_{p}^{n \times n}$ to recover the witness. This way of extraction only needs a TreeFind algorithm of depth 1 . Therefore, simply rewinding until $n$ transcripts are found is sufficient, giving us a runtime of $\operatorname{poly}(\kappa) / \varepsilon$ (where $\varepsilon$ is the probability of convincing the verifier). Furthermore, since the adversary induces a subdistribution on the challenges, we obtain a knowledge error of $\ell \delta_{\text {snd }}\left(\chi_{k}\right)$, which is almost optimal. Indeed, the emulator has rewinding-tightness of $O(n)$, which is almost best possible assuming the bound of $O(n / \log (n))$ from Question D. 2 holds.

Even though the above is a very special situation, we take this as a hint that Question D. 4 has a positive answer. Although the strategy must be quite different in that case.

## F FURTHER REMARKS ON OUR IMPLEMENTATION

## F. 1 Arithmetic Circuits

We use QESA ${ }_{\text {ZK }}$ to proof arithmetic circuits. In contrast to existing techniques, QESA ZK is not restricted to R1CS circuits, but can also handle quadratic equations. Hence we include a preprocessing step in Python, which transforms arithmetic circuits generated by the Pinocchio compiler [45] or jsnark ${ }^{34}$ into quadratic equations.

Preprocessing. We preprocess the arithmetic circuit in order to better make use of "quadratic equation gates" (quad gates in the following). To this end, we perform a series of transformations, which in the end yield an equivalent circuit comprised almost entirely of quad gates.

The transformations follow a few simple observations. Some gates can be represented directly by (quadratic) constraints. For example, $\operatorname{xor}(X, Y)$ can be represented as $(1-X) Y+X(1-Y)=0$. We refer to these as isolated gates in the following. Other gates, such as pack with $\operatorname{pack}\left(x_{1}, \ldots, x_{k}\right)=\sum_{1}^{k} x_{i} 2^{i}=x_{0}+2\left(x_{1}+\right.$ $2\left(\ldots+2 x_{k} \ldots\right)$ ), can be decomposed into a series of arithmetic gates, hence we coin them decomposable gates. The remaining basic gates, i.e., add, sub, const-mul, and const-mul-neg, can be merged if they precede a mul gate, resulting in a quad gate computing $\sum_{i, j} w_{i} \Gamma_{i, j} w_{j}=w_{k}$. Such a quad gate $g$ can be represented by $\Gamma_{\mathfrak{g}}=\sum_{i} \boldsymbol{a}_{\mathfrak{g}, i} \boldsymbol{b}_{\mathfrak{g}, i}^{\top}-\boldsymbol{e}_{g} \boldsymbol{e}_{\mathfrak{g}}^{\top} \in \mathbb{F}_{p}^{n \times n}$, where $\boldsymbol{a}_{\mathfrak{g}, i}, \boldsymbol{b}_{\mathfrak{g}, i}$ are constants describing the gate. We find that $\boldsymbol{w}^{\top} \boldsymbol{\Gamma}_{\mathfrak{g}} \boldsymbol{w}=0$ iff $\mathfrak{g}$ is satisfied by the wire assignment $w$.

Table 5: Comparison of runtime in seconds of aggregate range proofs from [17] with the original IPA and with IPA ${ }_{\text {noZK }}$.

Based on these observations, our preprocessing applies the following steps: First, decomposable gates are replaced with other gates depending on their functionality.

Then, each wire $w$ that is either a global output wire or an input wire of an isolated gate, is prepended with a new mul gate where one input is $w$ and the other is the constant- 1 wire. Naturally, this is only applied if $w$ is not already the output of a mul gate. The insertion allows for later aggregation of preceding logic into a single quad gate.

Now, all remaining basic gates are merged into quad gates of the form $\sum_{i, j} a_{i} w_{i} \Gamma_{i, j} b_{j} w_{j}=w_{k}$. This aggressive optimisation may result in several gates with constant $w_{k}=0$. Therefore, constant zeros are propagated through the circuit, eliminating affected gates and wires. Finally the circuit is stripped of floating gates where no output is connected any more and for each remaining gate the corresponding $\Gamma_{i}$ is extracted.

Results. We evaluate QESA ${ }_{\text {ZK }}$ using the same 512-bit SHA256 circuit without padding as in [17]. The preprocessed circuit consists of 25657 wires, i.e., $w \in \mathbb{F}_{p}^{25657}$ and 25840 matrices $\Gamma_{i} \in$ $\mathbb{F}_{p}^{25657 \times 25657}$. If the $\Gamma_{i}$ would have been stored without the sparse matrix optimisation, this would require the implementation to hold $25840 \cdot 25657^{2}>2^{43} \mathbb{F}_{p}$ elements in memory just for the matrices. The sparse representation reduces this to $197465 \mathbb{F}_{p}$ elements. Since QESA ZK expects $n$ to be a power of two, we set $n=2^{15}=$ 32768 and the witness is zero-extended accordingly. As a result, the implementation took 84.2 s for $\mathscr{P}$ and 38.1 s for $\mathcal{V}$ on average.

## F. 2 Bulletproofs with IPA ${ }_{\text {noZK }}$

One of our main contributions is the improvement of the original IPA from [17]. In order to practically evaluate the impact of said improvements, we benchmarked Bulletproofs aggregate range proofs with the same parameters as in Table 3, but this time used IPA ${ }_{\text {noZK }}$ instead. Table 5 shows the results.

## G OVERVIEW OF PROTOCOLS

In the following, we give an overview of the protocols for with several choices fixed. In particular, we fix $k=2$. Otherwise, the respective setting is as in the definition of the protocols. Let $\mathcal{S} \subseteq \mathbb{F}_{p}^{\times}$. Note that $\mathcal{S}$ are always non-zero. For simplicity, we use the testing distribution $\chi^{(\beta \neq 0)}$, which draws $\alpha \leftarrow \delta$ and returns $(\alpha, 1)$. (In this case, $\chi^{(\beta \neq 0)}=\chi^{(\beta)}$.) Moreover, we write $\alpha \leftarrow \chi^{(\beta \neq 0)}$ instead. For other testing distributions $\chi_{n}$, we consider $\boldsymbol{x} \leftarrow\{1\} \times$ $\delta^{n-1}$, that is $x_{1}=1$ always and the other components are random (small) exponents in $\mathcal{S}$. These choices are compatible with the restrictions posed in some protocols. For $\widetilde{\chi}_{2 k-1}$ we use an explicit choice $(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z})$, namely $(1, \beta)=\boldsymbol{x} \leftarrow \chi^{(\beta \neq 0)}, \boldsymbol{y}=(\beta, 1)$ and $z=\left(1, \beta, \beta^{2}\right)$.

We deviate from the standard presentation of inputs as follows:

- Inputs, which must be known to both parties are common inputs.
- Inputs, which a party (generally the prover) can derive from other inputs, are removed from common inputs.
For example, the target value $t$ in $\mathrm{IPA}_{\text {almZK }}$ is not a treated as a common input, since $\mathscr{P}$ can recompute $t=\left\langle\boldsymbol{w}^{\prime}, \boldsymbol{w}^{\prime \prime}\right\rangle$ via the witness. This makes data flow (and some optimisations) more explicit, e.g. Remark 4.6. The common input in the usual sense is always given by the "reduced" common input as above and the verifier's additional input. For this point of view to be essentially equivalent to standard zero-knowledge proofs, we merely require that the statement is fixed by the (reduced) common input and $\mathscr{P}$ 's (resp. $V$ 's) additional input.

[^0]:    ${ }^{\text {a }}$ Addendum: We note that (concretely less efficient) shuffles of commitments are present in [17], and we have been informed of an improvement similar to ours, see Remark C. 1 or [4]. Our protocol works in the setting of [6] with ElGamal ciphertexts.

[^1]:    ${ }^{1}$ Vectors $\boldsymbol{x}_{1}, \ldots, \boldsymbol{x}_{N} \in \mathbb{F}_{p}^{n}$ are in general position if any subset of size $n$ is a basis.

[^2]:    ${ }^{2}$ Drawing a random $[b] \leftarrow \mathbb{H}$ needs a basis $\left[h_{i}\right]$ of $\mathbb{H}$ and sets $[b]=\sum r_{i}\left[h_{i}\right]$ for $r_{i} \leftarrow \mathbb{F}_{p}$.
    ${ }^{3}$ It may be helpful to think of the vector space $\left(\mathbb{F}_{p}^{n / 2}\right)^{2}$ as $\mathbb{F}_{p}^{n / 2} \otimes \mathbb{F}_{p}^{2}$.

[^3]:    ${ }^{4}$ It can be shown that, up to scalar multiples, these are all such testing distributions. ${ }^{5}$ Note that the soundness error $\delta_{\text {snd }}\left(\widetilde{\chi}_{3}\right)$ is an upper bound for the soundness errors of the (induced) testing distributions for $\boldsymbol{x}$ and $\boldsymbol{y}$.
    ${ }^{6}$ By Footnote 4, if $x_{2} / x_{1}$ is different for all challenges, they are in general position.

[^4]:    ${ }^{7}$ The masking sets $\mathbb{M}$ use zero-based indexing for convenience.

[^5]:    ${ }^{8}$ The name R1CS may be misleading, since $\Gamma$ can have (tensor) rank 2, i.e. the (tensor) rank of $\Gamma$ is $\leq 2$ for R1CS. Nevertheless, we follow this standard naming convention.

[^6]:    ${ }^{9}$ Otherwise, add trivial equations $\Gamma=0$.
    ${ }^{10}$ Restrictions on $\chi_{N}$ are merely to simplify protocol description and proofs.

[^7]:    ${ }^{11}$ https://github.com/emsec/QESA_ZK

[^8]:    ${ }^{12}$ To justify short exponents, concrete security estimates are needed. We are not aware of results justifying any concrete instantiations. If our conjectures in Appendix D hold, we can justify at least 80 bit security for witness size $n \leq 2^{16}$.
    ${ }^{13}$ Application of delayed batch verification with multi-exponentiation to our setting is slightly different. However, compared to the costs of the multi-exponentiation, the difference is likely not noticeable.

[^9]:    ${ }^{14}$ Indeed, after suitably permuting the columns of $\left[\boldsymbol{A}\left|\boldsymbol{H}^{(1)}\right| \ldots \mid \boldsymbol{H}^{(m)}\right]$, witness, and randomness, the exact same reasoning as in Lemma 3.8 works for the recursive step.

[^10]:    ${ }^{15}$ This changes the committed value $s$ in $[c]$ to $\alpha(s-t)+t$ under the new [Q].
    ${ }^{16}$ Note that $\left[\boldsymbol{u}_{0}\right]$ is implicitly known to $V$.
    ${ }^{17}$ The restriction $\alpha_{0}=1$ is just for convenience.

[^11]:    ${ }^{18}$ This can trivially be relaxed to allowing randomness in components $n-1$ and $n$. By construction, the commitment randomness is not copied and cannot be reconstructed or used in the statements. If different components than $n-1, n$ are used as commitment randomness, they are treated like a committed message, and (may be) copied as well.
    ${ }^{19}$ If commitment randomness is used in other indices, we treat it like the committed message, and do copy it.
    ${ }^{20}$ It suffices to prove that Eq. (4.2) holds for all $i$. If all $\mathscr{I}$ are equal, dual testing distributions can be used instead, to freshly generate all components $g_{i}$ for $i \notin \mathscr{G}$. Remember that dual testing (Definition A.2) ensures that previous commitments must be zero for all components $i \notin \mathscr{I}$ (or cannot be opened without breaking the hard kernel assumption). If not all $\mathscr{I}$ are equal, treating them as equal, i.e. "extending" the commitment keys $\widetilde{\mathrm{ck}}^{(i)}$ and proving that the copied values are zero outside $\mathscr{J}_{i}$, still allows to resort to dual testing.

[^12]:    ${ }^{21}$ If we don't have this, $\mathrm{QESA}_{\mathrm{ZK}}$ extraction would short-circuit.

[^13]:    ${ }^{22} \mathrm{We}$ either eliminate bit $b_{0}$ or instead of copying we use the "implicit" copy $\sum 2^{i} b_{i}$. Otherwise, we would need $(\ell+1) M+1$ variables. With all optimisations of Remark A.16, we could get down to $\ell M$ variables, hence $n=\ell M+3$.
    ${ }^{23}$ [17] instantiates arithmetic circuit proofs differently. While [17] can deal with commitments, these are only single-valued Pedersen commitments. It should be possible to extend [17] to our more general setting. but it is not obvious how hard it is.

[^14]:    ${ }^{24}$ In more detail: The degree of the (difference) polynomial in $z$ is at most $N$. The two polynomials are equal if and only if they have the same roots (with multiplicity). So the sets $\left\{\zeta \pi_{i}+y_{i}\right\}_{i}$ and $\left\{\zeta i+x_{i}\right\}_{i}$ must be equal. The probability that $\zeta i+y=\zeta j+x$ if $i \neq j$ is negligible (for any fixed choice of $x, y)$. Hence if the sets are equal, with overwhelming probability we find that the sets $\left\{\left(\pi_{i}, y_{i}\right)\right\}_{i}$ and $\left\{\left(j, x_{j}\right)\right\}_{i}$ are equal. In other words, $\pi$ is a permutation of the roots. With probability $1-\delta_{\text {snd }}\left(\chi_{N}\right)$ all $x_{j}$ are distinct, see Remark E.6. Hence $\pi$ is a permutation of $\{0, \ldots, N-1\}$.
    ${ }^{25}$ We refer to [8] for a comparison of deterministic and probabilistic proof-oracles.

[^15]:    ${ }^{26}$ Doing so by retrying the whole emulation must be done with care. Simply taking the "first successful run" can skew the distribution of the emulated transcript.

[^16]:    ${ }^{27}$ The proof in [39] is in the plain model, but it translates to the CRS model. Recall that our notion of extraction (error) is "unconditional". However, we consider statements such as "either st $\in \mathcal{L}$ or a hard problem was solved" and thus still incorporate hardness assumptions. This follows [13] and is convenient to use.
    ${ }^{28}$ Namely, we estimate the success probability $\varepsilon$ of the prover precise enough (depending on $\alpha$ ). Except with probability $2^{-\kappa}$, the approximation $\varepsilon^{\prime}$ is so close that $\frac{\varepsilon^{\prime}}{\delta_{\text {ext }}^{\prime}}$ is bounded by constants small enough w.r.t. $\alpha$. Thus $\frac{1}{\varepsilon^{\prime}-\delta_{\mathrm{ext}}}$ is also (polynomially) bounded. (Note the use of $\delta_{\text {ext }}^{\prime}$ and $\delta_{\text {ext }}$ here.)

[^17]:    ${ }^{29}$ We have not formally defined an extraction error for sequences of testing distributions. Indeed, a definition is non-trivial. We conjecture for some natural generalisation of testing distribution (covering such sequences) natural results hold, e.g. the sum of the soundness errors bounds the soundness error of the sequential composition of (generalised) testing distributions. The results in [49] support this (and might even partially prove it).

[^18]:    ${ }^{30}$ Split $\mathbb{P}\left(\boldsymbol{x}_{1}, \ldots, \boldsymbol{x}_{m}\right.$ lin. dep. $)$ depending on the number $k$ of picks with $b=1$. For fixed $k$ and $\left(\boldsymbol{x}_{1}, \ldots, \boldsymbol{x}_{m}\right) \leftarrow H^{k} \times\left(\mathbb{F}_{p}^{m}\right)^{m-k}$ (which is enough due to symmetry), we find $\mathbb{P}\left(\boldsymbol{x}_{1}, \ldots, \boldsymbol{x}_{m}\right.$ lin. dep. $) \leq \mathbb{P}\left(\left\{\boldsymbol{x}_{1}, \ldots, \boldsymbol{x}_{k} \in H\right\} \cup\left\{\boldsymbol{x}_{k+1}, \ldots, \boldsymbol{x}_{m} \in\right.\right.$ $\mathbb{F}_{p}^{m}$ lin. dep. $\left.\} \cup\left\{\exists k+1 \leq i \leq m: \boldsymbol{x}_{i} \in H\right\}\right)$ which is easily bounded above by $3 m^{2} p^{-1}$ for $k<m$. For $k=m$, linear dependence is guaranteed, but this only happens with probability $2^{-m}$. Thus, $2^{-m}+\sum_{k=0}^{m-1}\binom{m}{k} 2^{-m} 3 m^{2} / p \leq 2^{-m}+3 m^{2} / p$ is the desired bound.

[^19]:    ${ }^{31}$ We speak of admissible, because there may be different computational soundness errors which are satisfied, depending on the choice of negligible functions. We do not know whether there is a (uniquely) well-defined minimal one. (Unlike statistical soundness, where a unique (minimal) error is given essentially by definition, and where Conjecture E. 1 would imply very simple characterisation of it.)

[^20]:    ${ }^{32}$ This is irrelevant for the stronger "perfect" notion of soundness error. Any "encoding" is equivalent in that setting.

[^21]:    ${ }^{33} K$ is a subspace because $\varphi(\boldsymbol{x} \otimes(\boldsymbol{b}+\gamma \boldsymbol{c}))=\varphi(\boldsymbol{x} \otimes \boldsymbol{b})+\gamma \varphi(\boldsymbol{x} \otimes \boldsymbol{c})$.
