Abstract. The standard model security of the Fiat-Shamir transform has been an active research area for many years. In breakthrough results, Canetti *et al.* (STOC'19) and Peikert-Shiehian (Crypto'19) showed that, under the Learning-With-Errors (LWE) assumption, it provides soundness by applying correlation-intractable (CI) hash functions to so-called *trapdoor* Σ -protocols. In order to be compatible with CI hash functions based on standard LWE assumptions with polynomial approximation factors, all known such protocols have been obtained via parallel repetitions of a basic protocol with binary challenges. In this paper, we consider languages related to Paillier's composite residuosity assumption (DCR) for which we give the first trapdoor Σ -protocols providing soundness in one shot, via exponentially large challenge spaces. This improvement is analogous to the one enabled by Schnorr over the original Fiat-Shamir protocol in the random oracle model. Using the correlation-intractable hash function paradigm, we then obtain simulation-sound NIZK arguments showing that an element of $\mathbb{Z}_{N^2}^*$ is a composite residue, which opens the door to space-efficient applications in the standard model. As a concrete example, we build logarithmic-size ring signatures (assuming a common reference string) with the shortest signature length among schemes based on standard assumptions in the standard model. We prove security under the DCR and LWE assumptions, while keeping the signature size comparable with that of random-oracle-based schemes.

Keywords. NIZK arguments, compactness, simulation-soundness, composite residuosity, Fiat-Shamir, ring signatures, standard model.

1 Introduction

The Fiat-Shamir transform [36] is a famous technique that collapses interactive protocols into non-interactive proof systems by computing the verifier's challenges as hash values of the transcript so far. Since its introduction, it enabled a wide range of applications in the random oracle model (ROM) although it may fail to preserve soundness in general [39]. In the standard model, it was not known to be safely instantiable under standard assumptions until recently. The

beautiful work of Canetti *et al.* [12] and Peikert and Shiehian [59] changed this state-of-affairs by showing the existence of Fiat-Shamir-based non-interactive zero-knowledge (NIZK) proofs for all NP languages under the Learning-With-Errors (LWE) assumption [60]. Their results followed the methodology of *correlation intractable* (CI) hash functions [14], which can sometimes emulate the properties of random oracles in the standard model.

In short, correlation intractability for a relation R requires the infeasibility of finding x such that $(x, H_k(x)) \in R$ given a random hashing key k . This property provides soundness because, with high probability, it prevents a cheating prover’s first message from being hashed into a challenge admitting a valid response. Canetti *et al.* [15] formalized this intuition by observing that it suffices to build CI hash functions for efficiently searchable relations as long as Fiat-Shamir is applied to *trapdoor* Σ -protocols. These are like standard Σ -protocols with two differences. First, they assume a common reference string (CRS). Second, there exists an efficiently computable function `BadChallenge` that inputs a trapdoor τ_Σ together with a false statement $x \notin \mathcal{L}$ and a first prover message a in order to compute the only challenge `Chall` such that an accepting transcript (a, Chall, z) exists for some response z . If `BadChallenge` is efficiently computable, soundness can be achieved using CI hash functions for any efficiently computable relation, which covers the case of the relation R such that $(x, y) \in R$ if and only if $y = \text{BadChallenge}(\tau_\Sigma, x, a)$.

While the results of [12,59] resolve the long-standing problem of realizing NIZK proofs for all NP under standard lattice assumptions, they raise the natural open question of whether LWE-based correlation-intractable hash functions can lead to compact proofs/arguments for specific languages like subgroup membership. In this paper, we consider this problem for Paillier’s composite residuosity assumption [56] for which we obtain NIZK arguments that are roughly as short as those obtained from the Fiat-Shamir heuristic in the ROM. In particular, we aim at trapdoor Σ -protocols that ensure soundness in one shot, without going through $\Theta(\lambda)$ parallel repetitions to achieve negligible soundness error.

OUR CONTRIBUTION. We provide space-efficient NIZK arguments showing that an element is a composite residue in the group $\mathbb{Z}_{N^2}^*$, for an RSA modulus $N = pq$. In particular, we can argue that Paillier [56] or Damgård-Jurik [30] ciphertexts decrypt to 0. These arguments extend to handle multiplicative relations between Paillier ciphertexts. We achieve this by showing that several natural Σ -protocols for Paillier-related languages can be extended into trapdoor Σ -protocols with an exponentially large challenge space, which achieve negligible soundness error in a single protocol execution. To our knowledge, we thus obtain the first trapdoor Σ -protocols that guarantee soundness without parallel repetitions.

Our constructions provide multi-theorem statistical NIZK and their soundness can be proved under the Learning-With-Errors (LWE) assumption. In addition, we show how to upgrade them into unbounded simulation-sound NIZK arguments based on the LWE and DCR assumptions. In their single-theorem version, our arguments of composite residuosity are as short as their random-oracle-based counterpart obtained from the Fiat-Shamir heuristic. Their multi-

theorem and simulation-sound extensions are only longer by a small constant factor. In particular, we can turn any trapdoor Σ -protocol into an unbounded simulation-sound NIZK argument for the same language while only lengthening the transcript by the size of a Paillier ciphertext and its randomness.

As a main application, we obtain logarithmic-size ring signatures with concretely efficient signature length in the standard model. Recall that ring signatures allow a signer to sign messages while hiding in an *ad hoc* set of users called a *ring*. To this end, the signer only needs to know the public keys of all ring members and its own secret key. So far, the only known realizations in the standard model under standard assumptions [2] incur very large signatures due to the use of non-interactive witness indistinguishable proofs for NP. In contrast, we obtain fairly short signatures comprised of a small number of Paillier ciphertexts while retaining security under well-studied assumptions. For rings of $R = 2^r$ users, each signature fits within the equivalent of $15r + 7$ RSA moduli, which is only 3 times as large as in a Fiat-Shamir-like construction in the random oracle model under the DCR assumption. The unforgeability of our scheme is proved under the DCR and LWE assumptions while its anonymity holds for unbounded adversaries.

To our knowledge, our NIZK arguments for DCR-related languages give the first examples where, under standard assumptions, Fiat-Shamir-based arguments in the standard model can be almost as short as those in the random oracle model. We believe they can find many other applications than ring signatures. For example, they easily extend to prove multiplicative relations among Paillier ciphertexts, which is a common task in MPC [27] or voting protocols [30]. The trapdoor Σ -protocol of our DCR-based ring signature can also be used in other applications of compact 1-out-of- R proofs [42,41].

TECHNICAL OVERVIEW. In order to construct a NIZK argument of composite residuosity, our starting point is the observation that any encryption scheme with linearly homomorphic properties over its message *and* randomness spaces admits a trapdoor Σ -protocol for the language $\mathcal{L}^0 = \{x \mid \exists w \in \mathcal{R} : x = \mathcal{E}_{pk}(0; w)\}$ of encryptions of 0. At a high level, if the prover’s first message is an encryption $a = \mathcal{E}_{pk}(0; r)$ of 0 and the verifier sends a challenge **Chall**, the response $z = r + \text{Chall} \cdot w$ satisfies $a \cdot x^{\text{Chall}} = \mathcal{E}_{pk}(0; z)$. If $x \notin \mathcal{L}^0$, the special soundness property ensures that, for any given a , there is at most one **Chall** such that $a \cdot x^{\text{Chall}} = \mathcal{E}_{pk}(0; z)$ for some $z \in \mathcal{R}$. Moreover, the secret key sk can serve as a trapdoor τ_Σ to compute $\text{BadChallenge}(\tau_\Sigma, x, a)$ for any element a of the ciphertext space. Indeed, if **Chall** lives a polynomial-size set (say $\{0, 1\}^{\log \lambda}$), the bad challenge is efficiently computable by outputting the first **Chall** $\in \{0, 1\}^{\log \lambda}$ for which $\mathcal{D}_{sk}(a \cdot x^{\text{Chall}}) = 0$. We note that Ciampi *et al.* [24] recently showed that any Σ -protocol can be turned into a trapdoor Σ -protocol with small (i.e., binary) challenge space, which requires many repetitions to achieve negligible soundness error. The above construction thus decreases the number of parallel repetitions by a factor $O(\log \lambda)$. Paillier’s cryptosystem [56] allows applying the above technique with an exponentially large challenge space – thus achieving negligible soundness error in a single protocol run – while keeping the BadChallenge func-

tion efficiently computable. Indeed, for an RSA modulus $N = pq$, a ciphertext is of the form $x = g^m \cdot w^N \bmod N^2$, where $g \in \mathbb{Z}_{N^2}^*$ is in the public key and $w \in \mathbb{Z}_N^*$ is the randomness. If a given statement $x \in \mathbb{Z}_{N^2}^*$ is not an encryption of $m = 0$ and the prover’s first message is $a = g^{\alpha_a} \cdot r^N \bmod N^2$, the prover can only cheat for a challenge satisfying $\alpha_a + \text{Chall} \cdot m \equiv 0 \pmod{N}$ and thus the same congruence modulo p and q . Moreover, if $m \not\equiv 0 \pmod{N}$, we have either $\gcd(m, p) = 1$ or $\gcd(m, q) = 1$. Knowing the factorization of N , **BadChallenge** can thus decrypt x and a and then compute either $\text{Chall}_p = -\alpha_a \cdot m^{-1} \bmod p$ or $\text{Chall}_q = -\alpha_a \cdot m^{-1} \bmod q$. By restricting the challenge to live in $\{0, \dots, 2^\lambda - 1\}$ and choosing $p, q > 2^\lambda$, we are guaranteed that any bad challenge satisfies $\text{Chall} = \text{Chall} \bmod p = \text{Chall} \bmod q$, so that **BadChallenge** can rightfully output Chall_p (we assume w.l.o.g. that $\gcd(m, p) = 1$) if it fits in $\{0, \dots, 2^\lambda - 1\}$.

In order to obtain a multi-theorem NIZK argument of composite residuosity, we can then apply the construction of [50, Appendix B], which compiles any trapdoor Σ -protocol into a NIZK argument for the same language using a lossy encryption scheme with equivocable lossy mode. As considered [65,3], lossy encryption is a primitive where ciphertexts encrypted under lossy public keys – which are computationally indistinguishable from injective ones – statistically hide the underlying plaintexts. Moreover, the equivocation property (a.k.a. “efficient opening” [3]) makes it possible to trapdoor open any lossy ciphertext exactly as in a trapdoor commitment. It is known [44] that Paillier’s cryptosystem [56] provides these properties under the DCR assumption.

However, in the context of the signature-of-knowledge paradigm [20], we need NIZK arguments with unbounded simulation-soundness [31]. Libert *et al.* [50] showed that any trapdoor Σ -protocol can be turned into an USS argument for the same language using a generalization of the \mathcal{R} -lossy encryption primitive introduced by Boyle *et al.* [7]. In [50], they introduced two distinct equivocation properties and gave a candidate based on the LWE assumption. In order to optimize the signature length, we give an efficient equivocable \mathcal{R} -lossy encryption candidate under the DCR assumption. This task is non-trivial since injective keys have to be indistinguishable from lossy keys, even when one of the equivocation trapdoors is given. Yet, our candidate only uses the DCR assumption while [50] used fairly powerful tools (i.e., lattice trapdoors [37]) to equivocate lossy ciphertexts. Although our DCR-based realization satisfies slightly weaker properties than those of [50], we prove it sufficient to obtain simulation-soundness. It thus allows compiling trapdoor Σ -protocols into unbounded simulation-sound NIZK arguments without using lattice trapdoors.

Armed with a DCR-based construction of USS arguments, we then build a simulation-sound NIZK argument that one-out-of-many elements of $\mathbb{Z}_{N^2}^*$ is a composite residue. To this end, we provide a DCR-based variant of the Groth-Kohlweiss (GK) [42] Σ -protocol, which allows proving that one out of R commitments contains 0 with communication cost $O(\log R)$. The reason why DCR is the most promising assumption towards trapdooring [42] is that, in its original version, the GK protocol cannot easily be turned into a trapdoor Σ -protocol by applying the transformation of Ciampi *et al.* [24]. The main difficulty is

that it only yields $(r + 1)$ -special-soundness for $r = O(\log R)$, so that up to r bad challenges may exist for a false statement and a given first prover message. Even if `BadChallenge` can identify them all for a given protocol iteration, over κ repetitions, we end up with up to r^κ combinations, which are not enumerable in polynomial time for non-constant κ and r . Since even a challenge space $\{0, 1\}^{O(\log \lambda)}$ does not suffice, we cannot instantiate [42] with discrete-logarithm-based homomorphic commitments if we want to apply the LWE-based CI hash function of [59]. For this purpose, we need a variant of GK with an exponentially large challenge space and where `BadChallenge` can efficiently enumerate all bad challenges after a single protocol iteration. We achieve this by extending our trapdoor Σ -protocol showing composite residuosity, using a `BadChallenge` function that computes the roots of a degree- r (instead of a degree-1) polynomial.

Adapting [42] to Paillier-based commitments raises several difficulties if we want to apply it in the context of ring signatures. In our proofs of unforgeability and anonymity, we need the Σ -protocol to be statistically honest-verifier zero-knowledge. In the protocol of [42] and our DCR-based variant, this requires that users' public keys be computed as statistically hiding commitments to 0. A first idea is to apply Paillier, where ciphertexts $C = g^m \cdot r^N \pmod{N^2}$ are perfectly hiding commitments when g is an N -th residue (and extractable commitments when N divides the order of g). Unfortunately, as shown in [51, Section 2.6], using a statistically hiding commitment is not sufficient to ensure statistical anonymity when the adversary can introduce maliciously generated public keys in the ring. In the case of Paillier, when g is an N -th residue, so is any honestly generated commitment. The problem is that, in the anonymity game, the adversary can choose a ring containing malformed public keys that are *not* N -th residues in $\mathbb{Z}_{N^2}^*$. This affects the statistical ZK property since the simulator cannot fully randomize commitments by multiplying them with a random commitment to 0. To address this issue, we need a statistically hiding commitment which is “dense” in that commitments to 0 are uniformly distributed over $\mathbb{Z}_{N^2}^*$. In order to obtain trapdoor Σ -protocols, we also need the commitment to be dual-mode as the `BadChallenge` function should be able to efficiently extract committed messages in the perfectly binding setting. We thus use commitments (suggested in [17] for their online/offline property) of the form $C = (1 + N)^m \cdot h^y \cdot w^N \pmod{N^2}$, for randomness (y, w) , which are perfectly binding if h is an N -th residue and perfectly hiding if N divides the order of h . Moreover, the latter configuration provides dense statistically hiding commitments since commitments to 0 are uniformly distributed over $\mathbb{Z}_{N^2}^*$.

A second difficulty arises when we adapt the proof of unforgeability of the Groth-Kohlweiss ring signature, which relies on the extractability property of their Σ -protocol. They apply the forking lemma to extract an opening of a perfectly hiding commitment by replaying the adversary $O(r)$ times. In the standard model, our reduction does not have the degree of freedom of replaying the adversary with a different random oracle. Instead, we proceed with a sequence of hybrid games that exploits the dual-mode property of our DCR-based commitment and moves to a setting where the signer's identity is only computationally

hidden. In one game, the commitment is switched to its extractable mode so as to extract the committed bits $\ell_1^* \dots \ell_r^* \in \{0, 1\}^r$ of the signer’s position ℓ^* in the ring. In the next game, the reduction guesses which honestly generated public key $vk^{(i^*)}$ will be in the ring position ℓ^* and fails if this guess is incorrect. Finally, we modify the key generation oracle and replace the expected target user’s public key $vk^{(i^*)}$ by a random element of $\mathbb{Z}_{N^2}^*$ in order to force the forgery to prove a false statement. In the last game transition, the problem is that we cannot immediately rely on the DCR assumption to change the distribution of $vk^{(i^*)}$ while using the factorization of N to extract $\ell_1^* \dots \ell_r^*$. We thus involve two distinct moduli in our DCR-based adaptation of GK. The use of distinct moduli N and \bar{N} requires to adjust our Σ -protocol and force some equality to hold over the integers (and thus modulo both N and \bar{N}) between values $a, \ell \in \mathbb{Z}_{\bar{N}}$ that our **BadChallenge** function extracts from the commitments in the first prover message. We enforce this condition by imposing an unusual range restriction to some component of the response $z = a + \text{Chall} \cdot \ell \in \mathbb{Z}$: Instead of only checking an upper bound for z , the verifier also checks a lower bound to ensure that no implicit modular reduction occurs when homomorphically computing $a + \text{Chall} \cdot \ell$ over commitments sent by a malicious prover.

Using the above ideas, the proof of unforgeability requires reliable erasures. The reason is that the security proof appeals to the NIZK simulator to answer all signing queries. Hence, if the adversary corrupts some user i after a signing query involving $sk^{(i)}$, the challenger has to pretend that the random coins of user i ’s past signatures have been erased as it cannot efficiently compute randomness that explain the simulated NIZK arguments as real arguments. In a second step, we modify the scheme to get rid of the erasure assumption.

A first idea to avoid erasures is to adapt the proof of unforgeability in such a way that the NIZK simulator is only used to simulate signatures on behalf of the expected target user (whose index i^* is guessed upfront), while all other users’ signatures are faithfully generated. If the guess is correct, user i^* is never corrupted and the reduction never gets stuck when it comes to explaining the generation of signatures created by adaptively corrupted users. However, this strategy raises a major difficulty since decoding the signer’s position ℓ^* in the ring is only possible when the bits $\ell_1^* \dots \ell_r^* \in \{0, 1\}^r$ of ℓ^* are committed using extractable commitments $\{L_i^*\}_{i=1}^r$. At the same time, our security proof requires the guessed index i^* to be statistically independent of the adversary’s view until the forgery stage. In turn, this requires to simulate user i^* ’s signatures via *statistical* NIZK arguments. Indeed, computational NIZK proofs would information-theoretically leak the index i^* of the only user for which the NIZK simulator is used in signing queries. Unfortunately, perfectly binding commitments are not compatible with statistical ZK in our setting. To resolve this tension, we need a commitment which is perfectly hiding in all signing queries and extractable in the forgery. Moreover, for anonymity purposes, the perfectly hiding mode should make it possible to perfectly randomize adversarially-chosen commitments when we multiply them with commitments to 0. We instantiate this commitment using a variant (called “dense \mathcal{R} -lossy PKE” hereafter) of our DCR-based \mathcal{R} -lossy

PKE scheme. Like our original \mathcal{R} -lossy PKE system, it can be programmed to be statistically hiding in all signing queries and extractable in the forgery, but it features different properties: It does not have to be equivocal, but we need its lossy mode to be dense in $\mathbb{Z}_{N^2}^*$ (a property not met by our equivocal \mathcal{R} -lossy PKE) in order to use it in a statistically HVZK Σ -protocol.

RELATED WORK. The negative results (e.g., [39,14]) on the standard-model soundness of Fiat-Shamir did not rule out the existence of secure instantiations when specific protocols are compiled using concrete hash functions. A large body of work [64,13,45,11,22,26,52,8,47] investigated the circumstances under which CI hash functions [14] lead to secure standard model instantiations of the paradigm. Canetti *et al.* [12] showed that correlation intractability for *efficiently searchable* relations suffices to remove interaction from any trapdoor Σ -protocol. This includes their variant of [35] for the language of Hamiltonian graphs, which enables Fiat-Shamir-based proofs for all NP. They also gave candidates assuming the existence of fully homomorphic encryption (FHE) with circular security [15]. Peikert and Shiehian [59] subsequently achieved the same result under the standard LWE assumption [60].

Canetti *et al.* [15,12] gave trapdoor Σ -protocols for the languages of Hamiltonian graphs and quadratic residues in \mathbb{Z}_N^* [38]. Like the generic trapdoor Σ -protocol of [24], they proceed with parallel repetitions of a Σ -protocol with challenge space $\{0, 1\}$. CI hash functions were also used to compress protocols with multiple interaction rounds [11,22,52,47] and larger challenges. Lombardi and Vaikuntanathan [52] notably extended the CI paradigm beyond the class of protocols where the `BadChallenge` function is efficiently computable. In this case, however, evaluating the hash function in polynomial time requires a fairly strong LWE assumption to ensure correlation intractability. Brakerski *et al.* [8] considered a stronger notion of correlation intractability which allows handling relations where the `BadChallenge` function can only be approximated by a distribution over constant-degree polynomials. They thus obtained Fiat-Shamir-based NIZK arguments from standard assumptions that are not known to imply FHE.

In the following, we consider 3-message protocols where bad challenges are efficiently (and exactly) computable – and thus enable the use of polynomial-time-computable CI hash functions based on standard lattice assumptions – in an exponentially large set after a single protocol run.

Ring signatures were coined by Rivest, Shamir and Tauman [61]. They enable unconditional anonymity and involve no registration phase nor any tracing authority. Whoever has a public key can be appointed as a ring member without being asked for his consent or even being aware of it. The original motivation of ring signatures was to enable the anonymous leakage of secrets, by concealing the identity of a source (e.g., a whistleblower in a political scandal) while simultaneously providing reliability guarantees. Recently, the primitive also found applications in the context of cryptocurrencies [55].

After the work of Rivest, Shamir and Tauman [61], a number of solutions were given under specific assumptions [10,1,63,9,42,57]. Bender *et al.* [4] gave stronger definitions and constructions from general assumptions. In the standard model,

more efficient schemes were given [63,6] in groups with a bilinear map. Brakerski and Tauman [9] gave the first constructions from lattice assumptions.

In early realizations [61,10,63,6], the size of signatures was linear in the number of ring members. Dodis *et al.* [32] suggested constant-size ring signatures in the random oracle model. Chase and Lysyanskaya [20] took a similar approach while using simulation-extractable NIZK proofs in the standard model. However, it is not clear how to adapt their approach without using generic NIZK. Assuming a common reference string, constructions with sub-linear-size signatures in the standard model were given in [19,40,25]. Malavolta and Schröder [53] used SNARKs (and thus non-falsifiable assumptions) to obtain constant-size signatures. In the random oracle model, Groth and Kohlweiss [42] obtained an elegant construction with logarithmic-size ring signatures under the discrete logarithm assumption. Lattice-based analogues of [42] were given in [33,34].

The log-size signatures of [42,49,51] are obtained by applying Fiat-Shamir to Σ -protocols that are not immediately compatible with the `BadChallenge` function paradigm. In their settings, it would require to iterate a basic Σ -protocol (with small challenge space) a super-constant number of times, thus leading to a combinatorial explosion in the total number of bad challenges as each iteration would tolerate more than one bad challenge. Backes *et al.* [2] managed to eliminate the need for a CRS while retaining logarithmic signature size. However, they did not provide concrete signature sizes and, due to the use of general non-interactive witness indistinguishable proofs, their construction would most likely incur much longer signatures than ours for any realistic ring cardinality.

While our construction relies on a common reference string, it features (to our knowledge) the first logarithmic-size signatures with concretely efficient signature length *and* security under standard assumptions in the standard model.

2 Background and Definitions

For any $t \geq 2$, we denote by \mathbb{Z}_t the ring of integers with addition and multiplication modulo t . For a finite set S , $U(S)$ stands for the uniform distribution over S . If X and Y are distributions over the same domain, $\Delta(X, Y)$ denotes their statistical distance. For a distribution D , $x \sim D$ means that x is distributed according to D , while $x \leftarrow D$ denotes the explicit action of sampling x from D .

2.1 Hardness Assumptions

We first recall the Learning-With-Errors (LWE) assumption.

Definition 2.1 ([60]). *Let $m \geq n \geq 1$, $q \geq 2$ be functions of a security parameter λ and let a distribution χ over \mathbb{Z} . The LWE problem consists in distinguishing between the distributions $(\mathbf{A}, \mathbf{A}\mathbf{s} + \mathbf{e})$ and $U(\mathbb{Z}_q^{m \times n} \times \mathbb{Z}_q^m)$, where $\mathbf{A} \sim U(\mathbb{Z}_q^{m \times n})$, $\mathbf{s} \sim U(\mathbb{Z}_q^n)$ and $\mathbf{e} \sim \chi^m$.*

When χ is the discrete Gaussian distribution $D_{\mathbb{Z}^m, \alpha q}$ with standard deviation αq for some $\alpha \in (0, 1)$, this problem is as hard as worst-case instances of well-studied lattice problems. We now recall the Composite Residuosity assumption.

Definition 2.2 ([56,30]). Let integers $N = pq$ and $\zeta > 1$ for primes p, q . The ζ -**Decision Composite Residuosity** (ζ -DCR) assumption states that the distributions $\{x = w^{N^\zeta} \bmod N^{\zeta+1} \mid w \leftarrow U(\mathbb{Z}_N^*)\}$ and $\{x \mid x \leftarrow U(\mathbb{Z}_{N^{\zeta+1}}^*)\}$ are computationally indistinguishable.

It is known [30] that the ζ -DCR assumption is equivalent to 1-DCR for any $\zeta > 1$.

2.2 Correlation Intractable Hash Functions

We consider efficiently enumerable [12] relations $R \subseteq \mathcal{X} \times \mathcal{Y}$ where, for each $x \in \mathcal{X}$, there is a polynomial number of elements $y \in \mathcal{Y}$ satisfying $R(x, y) = 1$. Moreover, these are efficiently enumerable.

Definition 2.3. A relation $R \subseteq \mathcal{X} \times \mathcal{Y}$ is **enumerable** in time T if there exists a function $f_R : \mathcal{X} \rightarrow 2^{\mathcal{Y}}$ computable in time T such that, for each $x \in \mathcal{X}$, $f_R(x) = \{y_x \in \mathcal{Y} \mid (x, y_x) \in R\}$. If $\max_{x \in \mathcal{X}} |f_R(x)| \leq 1$, it is called **searchable**.

Let $\lambda \in \mathbb{N}$ a security parameter. A hash family with input length $n(\lambda)$ and output length λ is a collection $\mathcal{H} = \{h_\lambda : \{0, 1\}^{s(\lambda)} \times \{0, 1\}^{n(\lambda)} \rightarrow \{0, 1\}^\lambda\}$ of keyed functions induced by efficient algorithms (**Gen, Hash**), where **Gen**(1^λ) outputs a key $k \in \{0, 1\}^{s(\lambda)}$ and **Hash**(k, x) computes $h_\lambda(k, x) \in \{0, 1\}^\lambda$.

Definition 2.4. For a relation ensemble $\{R_\lambda \subseteq \{0, 1\}^{n(\lambda)} \times \{0, 1\}^\lambda\}$, a hash function family $\mathcal{H} = \{h_\lambda : \{0, 1\}^{s(\lambda)} \times \{0, 1\}^{n(\lambda)} \rightarrow \{0, 1\}^{m(\lambda)}\}$ is **R -correlation intractable** if, for any probabilistic polynomial time (PPT) adversary \mathcal{A} , we have $\Pr [k \leftarrow \text{Gen}(1^\lambda), x \leftarrow \mathcal{A}(k) : (x, h_\lambda(k, x)) \in R] = \text{negl}(\lambda)$.

Peikert and Shiehian [59] described a CI hash family for any searchable relation defined by functions f of bounded depth. Their construction relies on the standard LWE assumption with polynomial approximation factors. Their proof was given for efficiently searchable relations. However, it also implies correlation intractability for efficiently enumerable relations, as observed in [15,47].

2.3 Admissible Hash Functions

Admissible hash functions were introduced in [5] as a combinatorial tool for partitioning-based security proofs.

Definition 2.5 ([5]). Let $\ell(\lambda), L(\lambda) \in \mathbb{N}$ be functions of $\lambda \in \mathbb{N}$. Let an efficiently computable function $\text{AHF} : \{0, 1\}^\ell \rightarrow \{0, 1\}^L$. For each $K \in \{0, 1, \perp\}^L$, let the partitioning function $F_{\text{ADH}}(K, \cdot) : \{0, 1\}^\ell \rightarrow \{0, 1\}$ such that

$$F_{\text{ADH}}(K, X) := \begin{cases} 0 & \text{if } \forall i \in [L] \quad (\text{AHF}(X)_i = K_i) \vee (K_i = \perp) \\ 1 & \text{otherwise} \end{cases}$$

We say that AHF is an **admissible hash function** if there exists an efficient algorithm $\text{AdmSmp}(1^\lambda, Q, \delta)$ that takes as input $Q \in \text{poly}(\lambda)$ and a non-negligible $\delta(\lambda) \in (0, 1]$ and outputs a key $K \in \{0, 1, \perp\}^L$ such that, for all $X^{(1)}, \dots, X^{(Q)}, X^* \in \{0, 1\}^\ell$ such that $X^* \notin \{X^{(1)}, \dots, X^{(Q)}\}$, we have

$$\Pr_{\kappa} \left[F_{\text{ADH}}(K, X^{(1)}) = \dots = F_{\text{ADH}}(K, X^{(Q)}) = 1 \wedge F_{\text{ADH}}(K, X^*) = 0 \right] \geq \delta(Q(\lambda)) .$$

It is known that admissible hash functions exist for $\ell, L = \Theta(\lambda)$.

Theorem 2.6 ([46, Theorem 1]). *Let $(C_\ell)_{\ell \in \mathbb{N}}$ be a family of codes $C_\ell : \{0, 1\}^\ell \rightarrow \{0, 1\}^L$ with minimal distance cL for some constant $c \in (0, 1/2)$. Then, $(C_\ell)_{\ell \in \mathbb{N}}$ is a family of admissible hash functions. Furthermore, $\text{AdmSmp}(1^\lambda, Q, \delta)$ outputs a key $K \in \{0, 1, \perp\}^L$ for which $\eta = O(\log \lambda)$ components are not \perp and $\delta(Q(\lambda))$ is a non-negligible function of λ .*

2.4 Trapdoor Σ -protocols

Canetti *et al.* [15] defined a trapdoor variant of the notion of Σ -protocols [28].

Definition 2.7 (Adapted from [15]). *Let a language \mathcal{L} associated with an NP relations R . A 3-move interactive proof system $\Pi = (\text{Gen}_{\text{par}}, \text{Gen}_{\mathcal{L}}, \text{P}, \text{V})$ in the common reference string model is a Σ -protocol for \mathcal{L} if it satisfies the following:*

- **3-Move Form:** P and V both input $\text{crs} = (\text{par}, \text{crs}_{\mathcal{L}})$, with $\text{par} \leftarrow \text{Gen}_{\text{par}}(1^\lambda)$ and $\text{crs}_{\mathcal{L}} \leftarrow \text{Gen}_{\mathcal{L}}(\text{par}, \mathcal{L})$, and a statement x . They proceed as follows: (i) P inputs $w \in R(x)$, computes $(\mathbf{a}, st) \leftarrow \text{P}(\text{crs}, x, w)$ and sends \mathbf{a} to V ; (ii) V sends back a random challenge Chall ; (iii) P finally sends a response $\mathbf{z} = \text{P}(\text{crs}, x, w, \mathbf{a}, \text{Chall}, st)$ to V ; (iv) On input of $(\mathbf{a}, \text{Chall}, \mathbf{z})$, V outputs 1 or 0.
- **Completeness:** If $(x, w) \in R$ and P honestly computes (\mathbf{a}, \mathbf{z}) for a challenge Chall , then $\text{V}(\text{crs}, x, (\mathbf{a}, \text{Chall}, \mathbf{z}))$ outputs 1 with probability $1 - \text{negl}(\lambda)$.
- **Special zero-knowledge:** There is a PPT simulator ZKSim that inputs crs , $x \in \mathcal{L}$ and a challenge $\text{Chall} \in \mathcal{C}$. It outputs $(\mathbf{a}, \mathbf{z}) \leftarrow \text{ZKSim}(\text{crs}, x, \text{Chall})$ such that $(\mathbf{a}, \text{Chall}, \mathbf{z})$ is indistinguishable from a real transcript (for $w \in R(x)$) with challenge Chall .
- **$(r + 1)$ -Special soundness:** For any CRS $\text{crs} = (\text{par}, \text{crs}_{\mathcal{L}})$ obtained as $\text{par} \leftarrow \text{Gen}_{\text{par}}(1^\lambda)$, $\text{crs}_{\mathcal{L}} \leftarrow \text{Gen}_{\mathcal{L}}(\text{par}, \mathcal{L})$, any $x \notin \mathcal{L}$, and any first message \mathbf{a} sent by P , the set of challenges $\mathcal{BADC} = f(\text{crs}, x, \mathbf{a})$ for which an accepting transcript $(\text{crs}, x, \mathbf{a}, \text{Chall}, \mathbf{z})$ exists for some third message \mathbf{z} has cardinality $|\mathcal{BADC}| \leq r$. The function f is called the “bad challenge function” of Π . That is, if $x \notin \mathcal{L}$ and $\text{Chall} \notin \mathcal{BADC}$, the verifier never accepts.

Canetti *et al.* [15] define *trapdoor* Σ -protocols as Σ -protocols where the bad challenge function is efficiently computable using a trapdoor. They also define instance-dependent trapdoor Σ -protocol where the trapdoor τ_Σ should be generated as a function of some instance $x \notin \mathcal{L}$. Here, we use a definition where x need not be known in advance and the trapdoor does not depend on a specific x . However, the CRS and the trapdoor may depend on the language in our setting. The CRS $\text{crs} = (\text{par}, \text{crs}_{\mathcal{L}})$ consists of a fixed part par and a language-dependent part $\text{crs}_{\mathcal{L}}$ which is generated as a function of par and a language description \mathcal{L} .

Definition 2.8 (Adapted from [15]). *A Σ -protocol $\Pi = (\text{Gen}_{\text{par}}, \text{Gen}_{\mathcal{L}}, \text{P}, \text{V})$ with bad challenge function f for a trapdoor language \mathcal{L} is a **trapdoor Σ -protocol** if it satisfies the properties of Definition 2.7 and there exist PPT algorithms $(\text{TrapGen}, \text{BadChallenge})$ with the following properties.*

- Gen_{par} inputs $\lambda \in \mathbb{N}$ and outputs public parameters $\text{par} \leftarrow \text{Gen}_{\text{par}}(1^\lambda)$.
- $\text{Gen}_{\mathcal{L}}$ is a randomized algorithm that, on input of public parameters par , outputs the language-dependent part $\text{crs}_{\mathcal{L}} \leftarrow \text{Gen}_{\mathcal{L}}(\text{par}, \mathcal{L})$ of $\text{crs} = (\text{par}, \text{crs}_{\mathcal{L}})$.
- $\text{TrapGen}(\text{par}, \mathcal{L}, \tau_{\mathcal{L}})$ inputs public parameters par and (optionally) a trapdoor $\tau_{\mathcal{L}}$ allowing to test membership of \mathcal{L} . It outputs $\text{crs}_{\mathcal{L}}$ and a trapdoor τ_{Σ} .
- $\text{BadChallenge}(\tau_{\Sigma}, \text{crs}, x, \mathbf{a})$ takes in a trapdoor τ_{Σ} , a CRS $\text{crs} = (\text{par}, \text{crs}_{\mathcal{L}})$, an instance x , and a first prover message \mathbf{a} . It outputs a set BADC .

In addition, the following properties are required.

- **CRS indistinguishability:** For any $\text{par} \leftarrow \text{Gen}_{\text{par}}(1^\lambda)$, and any trapdoor $\tau_{\mathcal{L}}$ for the language \mathcal{L} , an honestly generated $\text{crs}_{\mathcal{L}}$ is computationally indistinguishable from a CRS produced by $\text{TrapGen}(\text{par}, \mathcal{L}, \tau_{\mathcal{L}})$. Namely, for any aux and any PPT distinguisher \mathcal{A} , we have

$$\begin{aligned} \text{Adv}_{\mathcal{A}}^{\text{indist-}\Sigma}(\lambda) &:= |\Pr[\text{crs}_{\mathcal{L}} \leftarrow \text{Gen}_{\mathcal{L}}(\text{par}, \mathcal{L}) : \mathcal{A}(\text{par}, \text{crs}_{\mathcal{L}}) = 1] \\ &\quad - \Pr[(\text{crs}_{\mathcal{L}}, \tau_{\Sigma}) \leftarrow \text{TrapGen}(\text{par}, \mathcal{L}, \tau_{\mathcal{L}}) : \mathcal{A}(\text{par}, \text{crs}_{\mathcal{L}}) = 1]| \leq \text{negl}(\lambda). \end{aligned}$$

- **Correctness:** There exists a language-specific trapdoor $\tau_{\mathcal{L}}$ such that, for any instance $x \notin \mathcal{L}$ and all pairs $(\text{crs}_{\mathcal{L}}, \tau_{\Sigma}) \leftarrow \text{TrapGen}(\text{par}, \mathcal{L}, \tau_{\mathcal{L}})$, we have $\text{BadChallenge}(\tau_{\Sigma}, \text{crs}, x, \mathbf{a}) = f(\text{crs}, x, \mathbf{a})$.

Note that the TrapGen algorithm does not take a specific statement x as input, but only a trapdoor $\tau_{\mathcal{L}}$ allowing to recognize elements of \mathcal{L} .

2.5 \mathcal{R} -Lossy Public-Key Encryption With Equivocation

In [50], Libert *et al.* considered a generalization of the notion of \mathcal{R} -lossy encryption introduced by Boyle *et al.* [7]. The primitive is a flavor of tag-based encryption [48] where the tag space \mathcal{T} is partitioned into *injective* and *lossy* tags. When ciphertexts are generated for an injective tag, the decryption algorithm recovers the plaintext. On lossy tags, ciphertexts statistically hide the plaintexts. In \mathcal{R} -lossy PKE schemes, the tag space is partitioned according to a binary relation $\mathcal{R} \subseteq \mathcal{K} \times \mathcal{T}$. The key generation algorithm inputs an initialization value $K \in \mathcal{K}$ and partitions \mathcal{T} in such a way that injective tags $t \in \mathcal{T}$ are those for which $(K, t) \in \mathcal{R}$ (i.e., all tags t for which $(K, t) \notin \mathcal{R}$ are lossy).

The definition of [50] requires the existence of a lossy key generation algorithm LKeygen that outputs public keys for which all tags t are lossy (in contrast with injective keys where the only lossy tags are those for which $(K, t) \notin \mathcal{R}$). In addition, [50] also asks that a trapdoor allows equivocating lossy ciphertexts (a property called *efficient opening* [3]) using an algorithm called Opener . The application to simulation-soundness [50] involves two opening algorithms Opener and LOpener . The former operates over injective public keys for lossy tags while the latter can equivocate ciphertexts encrypted under lossy keys for any tag.

Definition 2.9. Let $\mathcal{R} \subseteq \mathcal{K}_\lambda \times \mathcal{T}_\lambda$ be a binary relation. An equivocable \mathcal{R} -lossy PKE scheme is a 7-uple of PPT algorithms $(\text{Par-Gen}, \text{Keygen}, \text{LKeygen}, \text{Encrypt}, \text{Decrypt}, \text{Opener}, \text{LOpener})$ such that:

Parameter generation: On input of a security parameter λ , a desired tag length $L \in \text{poly}(\lambda)$ and a lower bound $B \in \text{poly}(\lambda)$ on the message length, $\text{Par-Gen}(1^\lambda, 1^L, 1^B)$ outputs public parameters Γ that specify a tag space \mathcal{T} , a space of initialization values \mathcal{K} , a public key space \mathcal{PK} , a secret key space \mathcal{SK} and a trapdoor space \mathcal{TK} .

Key generation: For an initialization value $K \in \mathcal{K}$ and public parameters Γ , algorithm $\text{Keygen}(\Gamma, K)$ outputs an injective public key $\text{pk} \in \mathcal{PK}$, a decryption key $\text{sk} \in \mathcal{SK}$ and a trapdoor key $\text{tk} \in \mathcal{TK}$. The public key specifies a ciphertext space CtSp and a randomness space R^{LPKE} .

Lossy Key generation: Given an initialization value $K \in \mathcal{K}$ and public parameters Γ , the lossy key generation algorithm $\text{LKeygen}(\Gamma, K)$ outputs a lossy public key $\text{pk} \in \mathcal{PK}$, a lossy secret key $\text{sk} \in \mathcal{SK}$ and a trapdoor key $\text{tk} \in \mathcal{TK}$.

Decryption on injective tags: For any $\Gamma \leftarrow \text{Par-Gen}(1^\lambda, 1^L, 1^B)$, any $K \in \mathcal{K}$, any tag $t \in \mathcal{T}$ such that $(K, t) \in \mathcal{R}$, and any message $\text{Msg} \in \text{MsgSp}$, we have $\Pr[\exists r \in R^{\text{LPKE}} : \text{Decrypt}(\text{sk}, t, \text{Encrypt}(\text{pk}, t, \text{Msg}, r)) \neq \text{Msg}] < \nu(\lambda)$, for some negligible function $\nu(\lambda)$, where $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{Keygen}(\Gamma, K)$ and the probability is taken over the randomness of Keygen .

Indistinguishability: For any $\Gamma \leftarrow \text{Par-Gen}(1^\lambda, 1^L, 1^B)$, the key generation algorithms LKeygen and Keygen satisfy the following:

(i) For any $K \in \mathcal{K}$, the distributions $D_{\text{inj}} = \{(\text{pk}, \text{tk}) \mid (\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{Keygen}(\Gamma, K)\}$ and $D_{\text{loss}} = \{(\text{pk}, \text{tk}) \mid (\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K)\}$ are computationally indistinguishable. For any PPT adversary \mathcal{A} , the following advantage function $\text{Adv}_{\mathcal{A}}^{\text{indist-LPKE}}(\lambda)$ is negligible:

$$|\Pr[(\text{pk}, \text{tk}) \leftarrow D_{\text{inj}} : \mathcal{A}(\text{pk}, \text{tk}) = 1] - \Pr[(\text{pk}, \text{tk}) \leftarrow D_{\text{loss}} : \mathcal{A}(\text{pk}, \text{tk}) = 1]|.$$

(ii) For any initialization values $K, K' \in \mathcal{K}$, the two distributions $\{\text{pk} \mid (\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K)\}$ and $\{\text{pk} \mid (\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K')\}$ are $2^{-\Omega(\lambda)}$ -close in terms of statistical distance.

Lossiness: For any $\Gamma \leftarrow \text{Par-Gen}(1^\lambda, 1^L, 1^B)$, any initialization value $K \in \mathcal{K}$ and tag $t \in \mathcal{T}$ such that $(K, t) \notin \mathcal{R}$, any $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{Keygen}(\Gamma, K)$, and any $\text{Msg}_0, \text{Msg}_1 \in \text{MsgSp}$, the following distributions are statistically close: $\{C \mid C \leftarrow \text{Encrypt}(\text{pk}, t, \text{Msg}_0)\} \approx_s \{C \mid C \leftarrow \text{Encrypt}(\text{pk}, t, \text{Msg}_1)\}$. For any $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K)$, the above holds for any tag t .

Equivocation under lossy tags: For any $\Gamma \leftarrow \text{Par-Gen}(1^\lambda, 1^L, 1^B)$, any $K \in \mathcal{K}$, any keys $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{Keygen}(\Gamma, K)$, let D_R the distribution, defined over R^{LPKE} , from which the random coins of Encrypt are sampled. For any message $\text{Msg} \in \text{MsgSp}$ and ciphertext C , let $D_{\text{pk}, \text{Msg}, C, t}$ denote the distribution on R^{LPKE} with support $S_{\text{pk}, \text{Msg}, C, t} = \{\bar{r} \in R^{\text{LPKE}} \mid \text{Encrypt}(\text{pk}, t, \text{Msg}, \bar{r}) = C\}$ and such that, for each $\bar{r} \in S_{\text{pk}, \text{Msg}, C, t}$, we have

$$D_{\text{pk}, \text{Msg}, C, t}(\bar{r}) = \Pr_{r' \leftarrow D_R}[r' = \bar{r} \mid \text{Encrypt}(\text{pk}, t, \text{Msg}, r') = C]. \quad (1)$$

For any random coins $r \leftarrow D_R$, any tag $t \in \mathcal{T}_\lambda$ such that $(K, t) \notin \mathcal{R}$, and any messages $\text{Msg}_0, \text{Msg}_1 \in \text{MsgSp}$, algorithm Opener takes as inputs

$\text{pk}, C = \text{Encrypt}(\text{pk}, t, \text{Msg}_0, r)$, $r \leftarrow D_R$, and tk . It outputs a sample \bar{r} from a distribution statistically close to $D_{\text{pk}, \text{Msg}_1, C, t}$.

Equivocation under lossy keys: For any $K \in \mathcal{K}$, any keys $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K)$, any randomness $r \leftarrow D_R$, any tag $t \in \mathcal{T}_\lambda$, and any messages $\text{Msg}_0, \text{Msg}_1 \in \text{MsgSp}$, algorithm LOpener inputs $C = \text{Encrypt}(\text{pk}, t, \text{Msg}_0, r)$, r , t and sk . It outputs $\bar{r} \in R^{\text{LPKE}}$ such that $C = \text{Encrypt}(\text{pk}, t, \text{Msg}_1, \bar{r})$. We require that, for any tag $t \in \mathcal{T}_\lambda$ such that $(K, t) \notin \mathcal{R}$, the distribution $\{\bar{r} \leftarrow \text{LOpener}(\text{pk}, \text{sk}, t, C, \text{Msg}_0, \text{Msg}_1, r) \mid r \leftarrow D_R\}$ is statistically close to $\{\bar{r} \leftarrow \text{Opener}(\text{pk}, \text{tk}, t, C, \text{Msg}_0, \text{Msg}_1, r) \mid r \leftarrow D_R\}$.

The above definition is slightly weaker than the one of [50] in the property of equivocation under lossy keys. Here, we do not require that the output of LOpener be statistically close to $D_{\text{pk}, \text{Msg}_1, C, t}$ as defined in (1): We only require that, on lossy keys and lossy tags, Opener and LOpener sample random coins from statistically close distributions. Our definition turns out to be sufficient for the purpose of simulation-sound arguments (as shown in Supplementary Material B) and will allow us to obtain a construction from the DCR assumption.

Definition 2.9 also differs from [50, Definition 2.10] in that the equivocation algorithms ($\text{Opener}, \text{LOpener}$) can use the original random coins $r \in R^{\text{LPKE}}$ of the encryption algorithm. Again, this relaxation will suffice in our setting.

In our ring signature system, we also use a variant of the above \mathcal{R} -lossy encryption primitive to instantiate a tag-based commitment scheme.

Definition 2.10. A dense \mathcal{R} -lossy PKE scheme is a tuple $(\text{Par-Gen}, \text{Keygen}, \text{LKeygen}, \text{Encrypt}, \text{Decrypt})$ of efficient algorithms that proceed identically to Definition 2.9, except that the lossy mode is dense and the indistinguishability property is relaxed as below. Moreover, no equivocation property is required.

Weak Indistinguishability: For any $\Gamma \leftarrow \text{Par-Gen}(1^\lambda, 1^L, 1^B)$, the key generation algorithms LKeygen and Keygen satisfy the following:

- (i) For any $K \in \mathcal{K}$, $D_{\text{inj}} = \{\text{pk} \mid (\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{Keygen}(\Gamma, K)\}$ is indistinguishable from $D_{\text{loss}} = \{\text{pk} \mid (\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K)\}$. For any PPT adversary \mathcal{A} , the advantage function $\text{Adv}_{\mathcal{A}}^{\text{weak-indist-LPKE}}(\lambda)$, defined as the distance $|\Pr[\text{pk} \leftarrow D_{\text{inj}} : \mathcal{A}(\text{pk}) = 1] - \Pr[\text{pk} \leftarrow D_{\text{loss}} : \mathcal{A}(\text{pk}) = 1]|$, is negligible as a function of the security parameter.
- (ii) For any initialization values $K, K' \in \mathcal{K}$, the two distributions $\{\text{pk} \mid (\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K)\}$ and $\{\text{pk} \mid (\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K')\}$ are $2^{-\Omega(\lambda)}$ -close in terms of statistical distance.

Density of Lossy Mode: For any $\Gamma \leftarrow \text{Par-Gen}(1^\lambda, 1^L, 1^B)$, any initialization value $K \in \mathcal{K}$, any $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K)$ and $\text{Msg} \in \text{MsgSp}$, the distribution of $\{\text{Encrypt}(\text{pk}, \text{Msg}, r) \mid r \leftarrow D_R\}$ is statistically close to $U(\text{CtSp})$.

2.6 Ring Signatures

A ring signature [61] scheme is a tuple of efficient algorithms $(\text{CRSGen}, \text{Keygen}, \text{Sign}, \text{Verify})$ with the following specifications.

CRSGen(1^λ): Generates a common reference string ρ .
Keygen(ρ): Generates a public key vk and the corresponding secret key sk .
Sign(ρ, sk, M, R): Outputs a signature Σ on the message $M \in \{0, 1\}^*$ with respect to the ring $R = \{vk_0, \dots, vk_{R-1}\}$ as long as (vk, sk) is a valid key pair produced by **Keygen**(ρ) and $vk \in R$ (otherwise, it outputs \perp).
Verify(ρ, M, Σ, R): Given a signature Σ on a message M w.r.t. the ring of public keys R , this algorithm outputs 1 if Σ is deemed valid and 0 otherwise.

Correctness requires that users can always sign any message on behalf of a ring they belong to. The standard security requirements for ring signatures are called *unforgeability* and *anonymity*. We use the strong definitions of [4,19].

The correctness requirement is formalized as follows.

Definition 2.11 (Correctness). A ring signature scheme (**CRSGen**, **Keygen**, **Sign**, **Verify**) is correct if, for any $\rho \leftarrow \text{CRSGen}(1^\lambda)$, any $(vk, sk) \leftarrow \text{Keygen}(\rho)$, any R s.t. $vk \in R$, any $M \in \{0, 1\}^*$, we have $\text{Verify}(\rho, M, \text{Sign}(\rho, sk, M, R), R) = 1$.

A ring signature is unforgeable with respect to insider corruption if it is infeasible to forge a ring signature without controlling one of the ring members.

Definition 2.12 (Unforgeability w.r.t. insider corruption). A ring signature scheme (**CRSGen**, **Keygen**, **Sign**, **Verify**) is unforgeable w.r.t. insider corruption if for any PPT adversary \mathcal{A} ,

$$\text{Adv}_{\mathcal{A}}^{\text{unforge}}(\lambda) := \Pr[\rho \leftarrow \text{CRSGen}(1^\lambda); (M^*, R^*, \Sigma^*) \leftarrow \mathcal{A}^{\text{Keygen, Sign, Corrupt}}(\rho) : \text{Verify}(\rho, M^*, \Sigma^*, R^*) = 1] \in \text{negl}(\lambda),$$

where:

- **Keygen** on the i -th query runs $(vk^{(i)}, sk^{(i)}) \leftarrow \text{Keygen}(\rho)$ and returns $vk^{(i)}$.
- **Sign**(i, M, R) returns the output of **Sign**($\rho, sk^{(i)}, M, R$) if: (i) $(vk^{(i)}, sk^{(i)})$ has been generated by **Keygen**; (ii) $vk^{(i)} \in R$. Otherwise, it returns \perp .
- **Corrupt**(i) returns $sk^{(i)}$ if $(vk^{(i)}, sk^{(i)})$ was generated by **Keygen**.
- \mathcal{A} outputs (M^*, R^*, Σ^*) such that **Sign**(\cdot, M^*, R^*) has not been queried. Moreover, R^* is non-empty and only contains public keys $vk^{(i)}$ generated by **Keygen** and such that no query **Corrupt**(i) was made.

Definition 2.13. A ring signature scheme (**CRSGen**, **Keygen**, **Sign**, **Verify**) provides statistical anonymity if, for any (possibly unbounded) adversary \mathcal{A} ,

$$\left| \Pr \left[\begin{array}{l} \rho \leftarrow \text{CRSGen}(1^\lambda); (M^*, i_0, i_1, R^*) \leftarrow \mathcal{A}^{\text{Keygen}(\cdot)}(\rho) \\ b \xleftarrow{\$} \{0, 1\}; \Sigma^* \leftarrow \text{Sign}(\rho, sk_{i_b}, M^*, R^*) \end{array} : \mathcal{A}(\Sigma^*) = b \right] - \frac{1}{2} \right| \in \text{negl}(\lambda)$$

where $vk_{i_0}, vk_{i_1} \in R^*$ and were both generated by the **Keygen** oracle.

We note that the definition of anonymity under full key exposure [4] requires that the random coins of **Keygen** be revealed to the adversary. In our setting, it does not make a difference since we assume unbounded adversaries. We also insist that we do not assume any upper bound on the size of a ring.

In particular, we consider unforgeability with respect to insider corruption and statistical anonymity.

3 \mathcal{R} -Lossy Encryption Schemes from DCR

Libert *et al.* [50] gave a method that directly compiles any trapdoor Σ -protocol for a trapdoor language into an unbounded simulation-sound NIZK argument for the *same* language. As a building block, their construction uses an LWE-based equivocable \mathcal{R} -lossy PKE scheme for the bit-matching relation.

The construction of [50] is recalled in Supplementary Material B, where we show that it applies to trapdoor Σ -protocols with $(r + 1)$ -special-soundness for $r > 1$ as long as we have a CI hash function for efficiently enumerable relations.

Definition 3.1. Let $\mathcal{K} = \{0, 1, \perp\}^L$ and $\mathcal{T} = \{0, 1\}^L$, for some $L \in \text{poly}(\lambda)$. The **bit-matching relation** $\mathcal{R}_{\text{BM}} : \mathcal{K} \times \mathcal{T} \rightarrow \{0, 1\}$ is defined as $\mathcal{R}_{\text{BM}}(K, t) = 1$ if and only if $K = K_1 \dots K_L$ and $t = t_1 \dots t_L$ satisfy $\bigwedge_{i=1}^L (K_i = \perp) \vee (K_i = t_i)$.

In [50], the authors described an \mathcal{R}_{BM} -lossy PKE under the LWE assumption. In order to instantiate their construction with a better efficiency, we now describe a more efficient \mathcal{R}_{BM} -lossy PKE scheme based on the DCR assumption.

3.1 An Equivocable \mathcal{R}_{BM} -Lossy PKE Scheme from DCR

Par-Gen $(1^\lambda, 1^L, 1^B)$: Define the spaces $\mathcal{T} = \{0, 1\}^L$, $\mathcal{K} = \{0, 1, \perp\}^L$ and the public parameters as $\Gamma = (1^\lambda, 1^B, \mathcal{K}, \mathcal{T})$.

Keygen (Γ, K) : Given public parameters Γ and an initialization value $K \in \mathcal{K}$, generate a key pair as follows.

1. Choose an RSA modulus $N = pq$ such that $p, q > 2^{l(\lambda)}$, for some polynomial $l : \mathbb{N} \rightarrow \mathbb{N}$ such that $l(\lambda) > L(\lambda)$ for any sufficiently large λ , and an integer $\zeta \in \text{poly}(\lambda)$ such that $N^\zeta > 2^B$.
2. Choose $g \leftarrow U(\mathbb{Z}_{N^{\zeta+1}}^*)$ and $\alpha_{i,0}, \alpha_{i,1} \leftarrow U(\mathbb{Z}_N^*)$ for each $i \in [L]$. Then, for each $i \in [L]$ and $b \in \{0, 1\}$, compute $v_{i,b} = g^{\delta_{b,1-\kappa_i}} \cdot \alpha_{i,b}^{N^\zeta} \bmod N^{\zeta+1}$ if $K_i \neq \perp$ and $v_{i,b} = \alpha_{i,b}^{N^\zeta} \bmod N^{\zeta+1}$ if $K_i = \perp$.

Define $R^{\text{LPKE}} = \mathbb{Z}_N^* \times \mathbb{Z}_{N^\zeta}$ and output $\text{sk} = (p, q, K)$ as well as

$$\text{pk} := \left(N, \zeta, g, \{v_{i,b}\}_{i \in [L], b \in \{0,1\}} \right), \quad \text{tk} = \left(\{\alpha_{i,b}\}_{i \in [L], b \in \{0,1\}}, K \right).$$

LKeygen (Γ, K) : is identical to **Keygen** except that step 2 generates g by choosing $g_0 \leftarrow U(\mathbb{Z}_N^*)$ and computing $g = g_0^{N^\zeta} \bmod N^{\zeta+1}$. The algorithm defines

$R^{\text{LPKE}} = \mathbb{Z}_N^* \times \mathbb{Z}_{N^\zeta}$ and outputs the lossy secret key $\text{sk} = (g_0, \text{tk})$ together with $\text{pk} := \left(N, \zeta, g, \{v_{i,b}\}_{i \in [L], b \in \{0,1\}} \right)$, $\text{tk} = \left(\{\alpha_{i,b}\}_{i \in [L], b \in \{0,1\}}, K \right)$.

Encrypt $(\text{pk}, t, \text{Msg})$: To encrypt $\text{Msg} \in \mathbb{Z}_{N^\zeta}$ for the tag $t = t_1 \dots t_L \in \{0, 1\}^L$, choose $r \leftarrow U(\mathbb{Z}_N^*)$, $s \leftarrow U(\mathbb{Z}_{N^\zeta})$ and compute

$$\text{ct} = g^{\text{Msg}} \cdot \left(\prod_{i=1}^L v_{i,t_i} \right)^s \cdot r^{N^\zeta} \bmod N^{\zeta+1} . \quad (2)$$

Decrypt(sk, t, ct): Given sk = (p, q, K) and t = t₁ ... t_L ∈ {0, 1}^L, return ⊥ if R_{BM}(K, t) = 0. Otherwise, $\prod_{i=1}^L v_{i,t_i} \equiv \left(\prod_{i=1}^L \alpha_{i,t_i}\right)^{N^\zeta} \pmod{N^{\zeta+1}}$.

1. Compute $\beta_g = \frac{(g^{\lambda(N)} \bmod N^{\zeta+1}) - 1}{N}$, where $\lambda(N) = \text{lcm}(p-1, q-1)$ and return ⊥ if $\beta_g = 0$ or $\text{gcd}(\beta_g, N^\zeta) > 1$.
2. Otherwise, compute

$$\text{Msg} = \frac{(\text{ct}^{\lambda(N)} \bmod N^{\zeta+1}) - 1}{N} \cdot \beta_g^{-1} \bmod N^\zeta,$$

where the division is computed over \mathbb{Z} , and output $\text{Msg} \in \mathbb{Z}_{N^\zeta}$.

Opener(pk, tk, t, ct, Msg₀, Msg₁, (r, s)): Given tk = ({α_{i,b}}_{i,b}, K), t ∈ {0, 1}^L, plaintexts Msg₀, Msg₁ ∈ \mathbb{Z}_{N^s} and random coins (r, s) ∈ R^{LPKE} such that ct = Encrypt(pk, t, Msg₀; (r, s)), return ⊥ if R_{BM}(K, t) = 1. Otherwise, define

$$v_t \triangleq \prod_{i=1}^L v_{i,t_i} \bmod N^{\zeta+1} = g^{d_t} \cdot \left(\prod_{i=1}^L \alpha_{i,t_i}\right)^{N^\zeta} \bmod N^{\zeta+1}, \quad (3)$$

where $d_t \in \{1, \dots, L\}$ is the number of non-⊥ entries of K such that $K_i \neq t_i$. Note that $\text{gcd}(d_t, N^\zeta) = 1$ since $p, q > L$. Then, compute and output

$$\begin{aligned} \bar{s} &= s + (d_t^{-1} \bmod N^\zeta) \cdot (\text{Msg}_0 - \text{Msg}_1) \bmod N^\zeta \\ \bar{r} &= r \cdot \prod_{i=1}^L \alpha_{i,t_i}^{s-\bar{s}} \cdot g^{(\text{Msg}_0 - \text{Msg}_1 + d_t \cdot (s-\bar{s}))/N^\zeta} \bmod N, \end{aligned} \quad (4)$$

where the division in the exponent above g can be computed over \mathbb{Z} since we have $\text{Msg}_0 + d_t \cdot s \equiv \text{Msg}_1 + d_t \cdot \bar{s} \pmod{N^\zeta}$. Note that (\bar{r}, \bar{s}) satisfy

$$\begin{aligned} g^{\text{Msg}_1} \cdot v_t^{\bar{s}} \cdot \bar{r}^{N^\zeta} &\equiv g^{\text{Msg}_1} \cdot \left(g^{d_t} \cdot \prod_{i=1}^L \alpha_{i,t_i}^{N^\zeta}\right)^{\bar{s}} \cdot \bar{r}^{N^\zeta} \\ &\equiv g^{\text{Msg}_1} \cdot \left(g^{d_t} \cdot \prod_{i=1}^L \alpha_{i,t_i}^{N^\zeta}\right)^{\bar{s}} \cdot r^{N^\zeta} \cdot \prod_{i=1}^L \alpha_{i,t_i}^{(s-\bar{s}) \cdot N^\zeta} \cdot g^{(\text{Msg}_0 - \text{Msg}_1 + d_t \cdot (s-\bar{s}))} \\ &\equiv g^{\text{Msg}_0} \cdot \left(g^{d_t} \cdot \prod_{i=1}^L \alpha_{i,t_i}^{N^\zeta}\right)^s \cdot r^{N^\zeta} \equiv g^{\text{Msg}_0} \cdot v_t^s \cdot r^{N^\zeta} \pmod{N^{\zeta+1}} \end{aligned}$$

LOpener(pk, sk, t, ct, Msg₀, Msg₁, (r, s)): Given sk = (g₀, tk = ({α_{i,b}}_{i,b}, K)), an arbitrary tag t ∈ {0, 1}^L, plaintexts Msg₀, Msg₁ ∈ \mathbb{Z}_{N^ζ} and randomness (r, s) ∈ R^{LPKE} such that ct = Encrypt(pk, t, Msg₀; (r, s)), let $d_t \in \{0, \dots, L\}$ the number of non-⊥ entries such that $K_i \neq t_i$. If $d_t \neq 0$, compute \bar{s} as per (4). Otherwise, choose $\bar{s} \leftarrow U(\mathbb{Z}_{N^\zeta})$. In both cases, output the pair (\bar{r}, \bar{s}) , where $\bar{r} = r \cdot \prod_{i=1}^L \alpha_{i,t_i}^{s-\bar{s}} \cdot g_0^{\text{Msg}_0 - \text{Msg}_1 + d_t \cdot (s-\bar{s})} \bmod N$.

Theorem 3.2. *The above scheme is an equivocable \mathcal{R}_{BM} -lossy PKE scheme under the DCR assumption.*

Proof. We show that the scheme satisfies the required properties.

DECRYPTION UNDER INJECTIVE TAGS. Let a tag $t \in \{0, 1\}^L$ and an initialization value $K \in \{0, 1, \perp\}^L$ such that $\mathcal{R}_{\text{BM}}(K, t) = 1$ and let a message $\text{Msg} \in \mathbb{Z}_{N^\zeta}$. Consider a triple $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{KeyGen}(\Gamma, K)$ where $\text{sk} = (p, q, K)$, $\text{tk} = (\{\alpha_{i,b}\}_{i,b}, K)$ and $\text{pk} = (N, \zeta, g, \{v_{i,b}\}_{i \in [L], b \in \{0,1\}})$. The encryption algorithm outputs a ciphertext

$$\text{ct} = g^{\text{Msg}} \cdot \left(\prod_{i=1}^L v_{i,t_i} \right)^s \cdot r^{N^\zeta} \equiv g^{\text{Msg}} \cdot \left(\prod_{i=1}^L \alpha_{i,t_i}^s \cdot r \right)^{N^\zeta} \pmod{N^{\zeta+1}}, \quad (5)$$

for some $r \in \mathbb{Z}_N^*$ and $s \in \mathbb{Z}_{N^\zeta}$, where the second equality comes from the fact that $\mathcal{R}_{\text{BM}}(K, t) = 1$ (i.e., $t_i = K_i$ whenever $K_i \neq \perp$). Since $g \sim U(\mathbb{Z}_{N^{\zeta+1}}^*)$, its order is a multiple of N^ζ with overwhelming probability $\varphi(N^\zeta)/N^\zeta = \varphi(N)/N$. Since $\lambda(N^{\zeta+1}) = N^\zeta \lambda(N)$, we thus know that $g^{\lambda(N)} \pmod{N^{\zeta+1}}$ has order N^ζ with probability $\varphi(N)/N$, in which case it has a representation of the form $g^{\lambda(N)} \equiv 1 + \beta_g N \pmod{N^{\zeta+1}}$ for some $\beta_g \in \mathbb{Z}_{N^\zeta}$ such that $\gcd(\beta_g, N^\zeta) = 1$. From (5), we find that

$$\text{ct}^{\lambda(N)} \equiv (1 + \beta_g N)^{\text{Msg}} \equiv (1 + (\beta_g \cdot \text{Msg} \pmod{N^\zeta}) \cdot N) \pmod{N^{\zeta+1}}, \quad (6)$$

which shows that Decrypt outputs $\text{Msg} \in \mathbb{Z}_{N^\zeta}$ at step 2.

INDISTINGUISHABILITY. We have two properties to verify.

- (i) When we consider the distributions of pairs (pk, tk) produced by Keygen and LKeygen, the only difference is the way to sample g . In the injective case, g is sampled from $U(\mathbb{Z}_{N^{\zeta+1}}^*)$ while, in the lossy case, g is sampled as $g = g_0^{N^\zeta} \pmod{N^{\zeta+1}}$, with $g_0 \leftarrow U(\mathbb{Z}_N^*)$. The DCR assumption states that these two distributions are indistinguishable and the same holds for the two distributions of pairs (pk, tk) .
- (ii) We claim that the distributions $\{\text{pk} \mid (\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K_b)\}_{b=0,1}$ are perfectly indistinguishable for any initialization values $K_0, K_1 \in \{0, 1, \perp\}^L$ since $g = g_0^{N^\zeta} \pmod{N^{\zeta+1}}$ is an N^ζ -th residue. Indeed, for any fixed element $g_0 \in \mathbb{Z}_N^*$, the distributions

$$\{(N, v_{i,b} = g_0^{N^\zeta} \cdot \alpha_{i,b}^{N^\zeta} \pmod{N^{\zeta+1}} \mid \alpha_{i,b} \leftarrow U(\mathbb{Z}_N^*)\}$$

and $\{(N, v_{i,b} = \alpha_{i,b}^{N^\zeta} \pmod{N^{\zeta+1}} \mid \alpha_{i,b} \leftarrow U(\mathbb{Z}_N^*)\}$ are identical.

LOSSINESS UNDER LOSSY TAGS. Let an arbitrary $K \in \mathcal{K}$ and an injective key

$$\begin{aligned} (\text{pk} = (N, \zeta, g, \{v_{i,b}\}_{i \in [L], b \in \{0,1\}}), \\ \text{sk} = (p, q, K), \text{tk} = (\{\alpha_{i,b}\}_{i,b}, K)) \leftarrow \text{Keygen}(\Gamma, K), \end{aligned}$$

where $v_{i,b} = g^{\delta_{b,1-\kappa_i}} \cdot \alpha_{i,b}^{N^\zeta} \bmod N^{\zeta+1}$. Under a tag t such that $\mathcal{R}_{\text{BM}}(K, t) = 0$, we have

$$v_t \triangleq \prod_{i=1}^L v_{i,t_i} \bmod N^{\zeta+1} = g^{d_t} \cdot \left(\prod_{i=1}^L \alpha_{i,t_i} \right)^{N^\zeta} \bmod N^{\zeta+1},$$

where $d_t \in \{1, \dots, L\}$ is the number of non- \perp positions where K disagrees with $t \in \{0, 1\}^L$. Any ciphertext ct obtained by sampling $s \leftarrow U(\mathbb{Z}_{N^\zeta})$, $r \leftarrow U(\mathbb{Z}_N^*)$ and computing

$$\text{ct} = g^{\text{Msg}} \cdot v_t^s \cdot r^{N^\zeta} \bmod N^{\zeta+1} = g^{\text{Msg}+d_t \cdot s} \cdot \left(\prod_{i=1}^L \alpha_{i,t_i}^s \cdot r \right)^{N^\zeta} \bmod N^{\zeta+1}, \quad (7)$$

perfectly hides $\text{Msg} \in \mathbb{Z}_{N^\zeta}$ since $\gcd(d_t, N^\zeta) = 1$.

EQUIVOCATION UNDER LOSSY TAGS. We know that, for any $K \in \mathcal{K}$, any injective keys $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{Keygen}(\Gamma, K)$ any message $\text{Msg} \in \mathbb{Z}_{N^\zeta}$ and any tag t such that $\mathcal{R}_{\text{BM}}(K, t) = 0$, the distribution $\{\text{ct} = \text{Encrypt}(\text{pk}, t, \text{Msg}; (r, s)) \mid (r, s) \leftarrow U(R^{\text{LPKE}})\}$ is nothing but the uniform distribution $U(\mathbb{Z}_{N^{\zeta+1}}^*)$ by (7).

From (7), we also observe that a lossy ciphertext ct uniquely determines the value $\text{Msg} + d_t \cdot s \bmod N^\zeta$ obtained by running $\text{Decrypt}(\text{sk}, t, \text{ct})$. Hence, for any pair $(\text{ct}, \text{Msg}) \in \mathbb{Z}_{N^{\zeta+1}}^* \times \mathbb{Z}_{N^\zeta}$, there exists only one $s \in \mathbb{Z}_{N^\zeta}$ such that $\text{Decrypt}(\text{sk}, t, \text{ct}) = \text{Msg} + d_t \cdot s \bmod N^\zeta$. In turn, $(\text{ct}, \text{Msg}, s)$ uniquely determine $r_{\text{ct}} = (\text{ct} \cdot g^{-(\text{Msg}+d_t \cdot s)})^{1/N^\zeta} \bmod N$ and thus $r = r_{\text{ct}} \cdot \prod_{i=1}^L \alpha_{i,t_i}^{-s} \bmod N$, which yields the only pair $(r, s) \in R^{\text{LPKE}}$ such that $\text{ct} = \text{Encrypt}(\text{pk}, t, \text{Msg}; (r, s))$. On an injective public key and a lossy tag t , for any $\text{Msg} \in \mathbb{Z}_{N^\zeta}$, the support $S_{\text{pk}, \text{Msg}, \text{ct}, t}$ is thus a singleton. This shows that, for any messages $\text{Msg}_0, \text{Msg}_1 \in \mathbb{Z}_{N^\zeta}$ and randomness $(r, s) \in R^{\text{LPKE}}$, Opener thus computes the only pair $(\bar{s}, \bar{r}) \in \mathbb{Z}_{N^\zeta} \times \mathbb{Z}_N^*$ such that $\text{Encrypt}(\text{pk}, t, \text{Msg}_0; (r, s)) = \text{Encrypt}(\text{pk}, t, \text{Msg}_1; (\bar{r}, \bar{s}))$.

EQUIVOCATION UNDER LOSSY KEYS. We now consider the case of lossy keys $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K)$, where $g = g_0^{N^\zeta} \bmod N^{\zeta+1}$. For any $\text{Msg} \in \mathbb{Z}_{N^\zeta}$ and arbitrary tags t , ciphertexts have the distribution

$$\left\{ \text{ct} = (g_0^{(\text{Msg}+d_t \cdot s)} \cdot \prod_{i=1}^L \alpha_{i,t_i}^s \cdot r)^{N^\zeta} \bmod N^{\zeta+1} \mid s \leftarrow U(\mathbb{Z}_{N^\zeta}^*), r \leftarrow U(\mathbb{Z}_N^*) \right\},$$

which is identical to $\{r^{N^\zeta} \bmod N^{\zeta+1} \mid r \leftarrow U(\mathbb{Z}_N^*)\}$. In contrast with injective keys, for a given N^ζ -th residue $\text{ct} \in \mathbb{Z}_{N^{\zeta+1}}^*$, the support $S_{\text{pk}, \text{Msg}, \text{ct}, t}$ is no longer a singleton (even for lossy tags). However, for any lossy tag t and any ciphertext $\text{ct} = \text{Encrypt}(\text{pk}, t, \text{Msg}_0; (r, s))$, $\text{Opener}(\text{pk}, \text{tk}, t, \text{ct}, \text{Msg}_0, \text{Msg}_1, (r, s))$ and $\text{LOpener}(\text{pk}, \text{sk}, t, \text{ct}, \text{Msg}_0, \text{Msg}_1, (r, s))$ output the same pair $(\bar{r}, \bar{s}) \in \mathbb{Z}_N^* \times \mathbb{Z}_{N^\zeta}$. Indeed, whenever $\mathcal{R}_{\text{BM}}(K, t) = 0$ (and thus $d_t \neq 0$), LOpener computes

$$\bar{s} = s + (d_t^{-1} \bmod N^\zeta) \cdot (\text{Msg}_0 - \text{Msg}_1) \bmod N^\zeta,$$

exactly like `Opener`. Moreover, for any $\text{ct} = g^{\text{Msg}_0} \cdot v_t^s \cdot r^{N^\zeta} \bmod N^{\zeta+1}$ and any pair $(\text{Msg}_1, \bar{s}) \in \mathbb{Z}_{N^\zeta} \times \mathbb{Z}_{N^\zeta}$,

$$\begin{aligned} \bar{r} &= (\text{ct} \cdot g^{-\text{Msg}_1} \cdot v_t^{-\bar{s}})^{1/N^\zeta} \bmod N \\ &= \left(g^{\text{Msg}_0 - \text{Msg}_1 + d_t \cdot (s - \bar{s})} \cdot \left(\prod_{i=1}^L \alpha_{i, t'_i}^{s - \bar{s}} \right)^{N^\zeta} \cdot r^{N^\zeta} \right)^{1/N^\zeta} \bmod N \\ &= g^{(\text{Msg}_0 - \text{Msg}_1 + d_t \cdot (s - \bar{s})) / N^\zeta} \cdot \prod_{i=1}^L \alpha_{i, t'_i}^{s - \bar{s}} \cdot r \bmod N \end{aligned} \quad (8)$$

$$= g_0^{\text{Msg}_0 - \text{Msg}_1 + d_t \cdot (s - \bar{s})} \cdot \prod_{i=1}^L \alpha_{i, t'_i}^{s - \bar{s}} \cdot r \bmod N \quad (9)$$

is the unique $\bar{r} \in \mathbb{Z}_N^*$ (which `Opener` and `LOpener` compute as per (8) and (9), respectively) such that $\text{ct} = g^{\text{Msg}_1} \cdot v_t^{\bar{s}} \cdot \bar{r}^{N^\zeta} \bmod N^{\zeta+1}$. \square

By plugging the above system in the construction in Supplementary Material [B](#), we obtain USS arguments from the DCR and `LWE` assumptions. A difference with [50] is that `LWE` is only used in the correlation intractable hash function and lattice trapdoors are not needed anywhere.

3.2 A Dense \mathcal{R}_{BM} -Lossy PKE Scheme from DCR

In order to construct a ring signature without relying on erasures, we will also use a “downgraded” version of the scheme in Section 3.1, where we do not need equivocation properties. However, we will rely on the property that its lossy mode induces dense commitments that are uniformly distributed in $\mathbb{Z}_{N^{\zeta+1}}^*$. The scheme of Section 3.1 does not have this density property as its lossy mode induces commitments that live in the subgroup of N^ζ -th residues.

Par-Gen($1^\lambda, 1^L, 1^B$): Define the spaces $\mathcal{T} = \{0, 1\}^L$, $\mathcal{K} = \{0, 1, \perp\}^L$ and the public parameters as $\Gamma = (1^\lambda, 1^B, \mathcal{K}, \mathcal{T})$.

Keygen(Γ, K): Given public parameters Γ and an initialization value $K \in \mathcal{K}$, generate a key pair as follows.

1. Choose an RSA modulus $N = pq$ such that $p, q > 2^{l(\lambda)}$, for some polynomial $l : \mathbb{N} \rightarrow \mathbb{N}$ such that $l(\lambda) > L(\lambda) - \lambda$ for any sufficiently large λ , and an integer $\zeta \in \text{poly}(\lambda)$ such that $N^\zeta > 2^B$.
2. Choose $\alpha_{i,0}, \alpha_{i,1} \leftarrow U(\mathbb{Z}_N^*)$ for each $i \in [L]$. Then, for each $i \in [L]$ and $b \in \{0, 1\}$, compute $v_{i,b} = (1 + N)^{\delta_{b,1} - \kappa_i} \cdot \alpha_{i,b}^{N^\zeta} \bmod N^{\zeta+1}$ if $K_i \neq \perp$ and $v_{i,b} = \alpha_{i,b}^{N^\zeta} \bmod N^{\zeta+1}$ if $K_i = \perp$.

Define $R^{\text{LPKE}} = \mathbb{Z}_N^* \times \mathbb{Z}_{N^\zeta}$ and output the secret key $\text{sk} = (p, q, K)$ together with $\text{pk} := (N, \zeta, \{v_{i,b}\}_{i \in [L], b \in \{0,1\}})$ and $\text{tk} = \perp$.

LKeygen(Γ, K): proceeds identically to **Keygen** with the difference that step 2 chooses $\{v_{i,b}\}_{i,b}$ at random. For each $i \in [L]$, $b \in \{0,1\}$, the algorithm chooses $v_{i,b} \leftarrow U(\mathbb{Z}_{N^{\zeta+1}}^*)$. It defines $R^{\text{LPKE}} = \mathbb{Z}_N^* \times \mathbb{Z}_{N^\zeta}$ and outputs $\text{sk} = \perp$ as well as $\text{pk} := \left(N, \zeta, \{v_{i,b}\}_{i \in [L], b \in \{0,1\}} \right)$, and $\text{tk} = \perp$.

Encrypt(pk, t, Msg): To encrypt $\text{Msg} \in \mathbb{Z}_{N^\zeta}$ for the tag $t = t_1 \dots t_L \in \{0,1\}^L$, choose random coins $r \leftarrow U(\mathbb{Z}_N^*)$, $s \leftarrow U(\mathbb{Z}_{N^\zeta})$ and compute the ciphertext

$$\text{ct} = (1 + N)^{\text{Msg}} \cdot \left(\prod_{i=1}^L v_{i,t_i} \right)^s \cdot r^{N^\zeta} \bmod N^{\zeta+1}.$$

Decrypt(sk, t, ct): Given the secret key $\text{sk} = (p, q, K)$ and the tag $t \in \{0,1\}^L$, return \perp if $R_{\text{BM}}(K, t) = 0$. Otherwise, compute

$$\text{Msg} = \frac{(\text{ct}^{\lambda(N)} \bmod N^{\zeta+1}) - 1}{N} \bmod N^\zeta,$$

where the division is computed over \mathbb{Z} , and output $\text{Msg} \in \mathbb{Z}_{N^\zeta}$.

Theorem 3.3. *The above system is a dense \mathcal{R}_{BM} -lossy PKE scheme under the DCR assumption. Moreover, the lossy mode is dense in $\mathbb{Z}_{N^{\zeta+1}}^*$.*

Proof. The property of decryption under injective keys can be shown exactly as in the proof of Theorem 3.2. The only difference is that $g = 1 + N$, so that its order is N^ζ with probability 1 and we have $\beta_g = 1$ in equation (6).

The proof of lossiness under lossy tags carries over in the same way. From (7), we observe that $s \sim U(\mathbb{Z}_{N^\zeta})$ perfectly hides Msg in the right-hand-side member of $\text{ct} = (1 + N)^{\text{Msg}} \cdot v_t^s \cdot r^{N^\zeta} \bmod N^{\zeta+1}$ when $d_t \neq 0$.

The first weak indistinguishability property follows directly from the semantic security of Damgård-Jurik and thus the DCR assumption. Namely, under the DCR assumption, $(1 + N)^{\delta_{b,1-K_i}} \cdot \alpha_{i,b}^{N^\zeta} \bmod N^{\zeta+1}$ is computationally indistinguishable from a random element of $\mathbb{Z}_{N^\zeta}^*$, regardless of $\delta_{b,1-K_i} \in \{0,1\}$. The second weak indistinguishability property is trivially satisfied since, in public keys generated by **LKeygen**, $\{v_{i,b}\}_{i,b}$ are generated independently of K .

Finally, for lossy keys $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K)$, the distribution of ciphertexts is

$$\left\{ \text{ct} = (1 + N)^{\text{Msg}} \cdot \left(\prod_{i=1}^L v_{i,t_i} \right)^s \cdot r^{N^\zeta} \bmod N^{\zeta+1} \mid s \leftarrow U(\mathbb{Z}_{N^\zeta}), r \leftarrow U(\mathbb{Z}_N^*) \right\},$$

which is nothing but the uniform $U(\mathbb{Z}_{N^{\zeta+1}}^*)$ unless there exists $t_1 \dots t_L \in \{0,1\}^L$ such that the order of $\prod_{i=1}^L v_{i,t_i}$ is not a multiple of N^ζ . This occurs with probability $\leq 2^L \cdot (1 - \varphi(N)/N)$, which is negligible as long as $\min(p, q) \geq 2^{L+1-\lambda}$. \square

4 Trapdoor Σ -Protocols for DCR-Related Languages

Ciampi *et al.* [24] showed that any Σ -protocol with binary challenges can be turned into a trapdoor Σ -protocol by having the prover encrypt the two possible responses and send them along with its first message. While elegant, this approach requires $\Theta(\lambda)$ repetitions to achieve negligible soundness error. In this section, we give communication-efficient protocols requiring no repetitions.

4.1 Trapdoor Σ -Protocol Showing Composite Residuosity

We first observe (as detailed in Supplementary Material C.1) that any encryption scheme which is additively homomorphic over its message and randomness spaces has a direct trapdoor Σ -protocol proving that a ciphertext encrypts 0. This construction supports polynomial-size challenge spaces and thus requires $\Theta(\lambda/\log \lambda)$ repetitions to ensure soundness. In the case of Paillier [56] and Damgård-Jurik [30] systems, we give similar trapdoor Σ -protocol with an *exponentially large* challenge space. In Damgård-Jurik, for an integer $\zeta > 1$ and an RSA modulus $N = pq$, proving that a ciphertext encrypts 0 is equivalent to proving that an element of $\mathbb{Z}_{N^{\zeta+1}}^*$ is an N^ζ -th residue. Paillier [56] is a special case with $\zeta = 1$.

The trapdoor Σ -protocol below can be seen as an extension (based on standard Σ -protocols from [43,30]) with a large challenge space of the trapdoor Σ -protocol given in [15, Section 6.2] for the Quadratic Residuosity language. However, the challenge space is now $\{0, \dots, 2^\lambda - 1\}$, so that we obtain (to our knowledge) the first trapdoor Σ -protocol with exponentially large challenges.

Let an RSA modulus $N = pq$ and an integer $\zeta > 1$. We give a trapdoor Σ -protocol for $\mathcal{L}^{\text{DCR}} := \{x \in \mathbb{Z}_{N^{\zeta+1}}^* \mid \exists w \in \mathbb{Z}_N^* : x = w^{N^\zeta} \pmod{N^{\zeta+1}}\}$. In order for **BadChallenge** to identify bad challenges for any $x \notin \mathcal{L}^{\text{DCR}}$, one difficulty is the case of instances $x \in \mathbb{Z}_{N^{\zeta+1}}^*$ that decrypt to $\alpha_x \in \mathbb{Z}_{N^\zeta}$ such that $\gcd(\alpha_x, N^\zeta) > 1$ since we cannot identify a unique bad challenge by inverting α_x in \mathbb{Z}_{N^ζ} . A closer analysis shows that, even in this case, the bad challenge is efficiently computable.

Gen_{par}(1^λ): Given the security parameter λ , define $\text{par} = \{\lambda\}$.

Gen_L($\text{par}, \mathcal{L}^{\text{DCR}}$): Given public parameters par and the description of a language \mathcal{L}^{DCR} , consisting of an RSA modulus $N = pq$ with p and q prime satisfying $p, q > 2^{l(\lambda)}$, for some polynomial $l : \mathbb{N} \rightarrow \mathbb{N}$ such that $l(\lambda) > \lambda$, define the language-dependent $\text{crs}_L = \{N\}$. The global CRS is $\text{crs} = (\{\lambda\}, \text{crs}_L)$.

TrapGen($\text{par}, \mathcal{L}^{\text{DCR}}, \tau_L$): Given the same inputs as **Gen_L** and a membership-testing trapdoor $\tau_L = (p, q)$, output $\text{crs} = (\{\lambda\}, \text{crs}_L = \{N\})$ and the trapdoor $\tau_\Sigma = (p, q)$.

P(crs, x, w) \leftrightarrow **V**(crs, x): Given a crs , a statement $x = w^{N^\zeta} \pmod{N^{\zeta+1}}$, P (who has the witness $w \in \mathbb{Z}_N^*$) and V interact as follows:

1. P chooses a random $r \leftarrow U(\mathbb{Z}_N^*)$ and sends $a = r^{N^\zeta} \pmod{N^{\zeta+1}}$ to V .
2. V sends a random challenge $\text{Chall} \leftarrow U(\{0, \dots, 2^\lambda - 1\})$ to P .
3. P computes the response $z = r \cdot w^{\text{Chall}} \pmod{N}$ and sends it to V .
4. V returns 1 if $a \cdot x^{\text{Chall}} \equiv z^{N^\zeta} \pmod{N^{\zeta+1}}$ and 0 otherwise.

BadChallenge(par, τ_Σ , crs, x, a) : Given $\tau_\Sigma = (p, q)$, decrypt x and a to obtain $\alpha_x = \mathcal{D}_{\tau_\Sigma}(x) \in \mathbb{Z}_{N^\zeta}$, $\alpha_a = \mathcal{D}_{\tau_\Sigma}(a) \in \mathbb{Z}_{N^\zeta}$. If $\alpha_x = 0$, return $\text{Chall} = \perp$. Otherwise, let $d_x = \gcd(\alpha_x, N^\zeta)$.

- a. If $1 < d_x < N^\zeta$, return \perp if d_x does not divide $N^\zeta - \alpha_a$.
- b. Otherwise, the congruence $\alpha_a + \text{Chall} \cdot \alpha_x \equiv 0 \pmod{\frac{N^\zeta}{d_x}}$ has a unique solution $\text{Chall}' = -\alpha_x^{-1} \cdot \alpha_a \in \mathbb{Z}_{N^\zeta/d_x}$ since $\gcd(\alpha_x, N^\zeta/d_x) = 1$. If $\text{Chall}' \in \mathbb{Z}_{N^\zeta/d_x} \setminus \{0, \dots, 2^\lambda - 1\}$, return \perp . Else, return $\text{Chall} = \text{Chall}'$.

Lemma 4.1 now shows that the above construction is a trapdoor Σ -protocol with large challenge space. By applying [59], this implies relatively short NIZK arguments (i.e., without using parallel repetitions to achieve negligible soundness error) for the language \mathcal{L}^{DCR} assuming that the LWE assumption holds.

Lemma 4.1. *The above protocol is a trapdoor Σ -protocol for the language \mathcal{L}^{DCR} .*

Proof. The CRS indistinguishability property is straightforward. We now construct a simulator for the special ZK property, which is identical to [30, Lemma 2] but we give it for completeness. Given crs, a statement $x \in \mathcal{L}^{\text{DCR}}$ and a challenge $\text{Chall} \in \{0, \dots, 2^\lambda - 1\}$, the simulator first samples $z \leftarrow U(\mathbb{Z}_N^*)$, computes $a = z^{N^\zeta} \cdot x^{-\text{Chall}} \pmod{N^{\zeta+1}}$ and outputs (a, z) . Since $x \in \mathcal{L}^{\text{DCR}}$, the simulated transcript (a, Chall, z) produced by the simulator is identical to that of a real conversation when the challenge is Chall . This follows from the fact that: (i) For any $x \in \mathcal{L}^{\text{DCR}}$, $\{a = z^{N^\zeta} \cdot x^{-\text{Chall}} \pmod{N^{\zeta+1}} \in \mathbb{Z}_{N^{\zeta+1}}^* \mid z \leftarrow U(\mathbb{Z}_N^*)\}$ is the uniform distribution over the subgroup of N^ζ -th residues in $\mathbb{Z}_{N^{\zeta+1}}^*$; (ii) $a \in \mathbb{Z}_{N^{\zeta+1}}^*$ and $r = a^{1/N^\zeta} \pmod{N}$ are uniquely determined by x , Chall and z in the simulation while $z = (a \cdot x^{\text{Chall}})^{1/N^\zeta} \pmod{N}$ is uniquely determined by r , x and Chall in the real protocol. For a given challenge Chall , we thus obtain the same distribution of (a, Chall, z) by first sampling $r \leftarrow U(\mathbb{Z}_N^*)$ before defining z as a function of r and Chall as when we first sample $z \leftarrow U(\mathbb{Z}_N^*)$ before defining r as a function of z and Chall .

Soundness follows from standard arguments used in [30, Lemma 2]. By combining two accepting transcripts (a, Chall, z) and (a, Chall', z') for the same first message $a \in \mathbb{Z}_{N^{\zeta+1}}^*$, we obtain $x^{\text{Chall}' - \text{Chall}} = (z' \cdot z^{-1})^{N^\zeta} \pmod{N^{\zeta+1}}$. Since $p, q > 2^\lambda$, we have $\gcd(\text{Chall}' - \text{Chall}, N^\zeta) = 1$, which implies that $x \in \mathcal{L}^{\text{DCR}}$.

Finally, we have to show that **BadChallenge** provides the correct result. If $\alpha_a = \mathcal{D}(a) = 0$, the product $a \cdot x^{\text{Chall}}$ cannot be an encryption of 0 if $\text{Chall} \neq 0$ since $\alpha_x \neq 0$. Then, the only possible bad challenge is $\text{Chall} = 0$. If $\alpha_a \neq 0$ and $\alpha_x = \mathcal{D}(x)$ is invertible in \mathbb{Z}_{N^ζ} , having $a \cdot x^{\text{Chall}}$ be an encryption of 0 implies that $\alpha_a + \text{Chall} \cdot \alpha_x \equiv 0 \pmod{N^\zeta}$, so that $\text{Chall} = -\alpha_a \cdot \alpha_x^{-1} \pmod{N^\zeta}$ is uniquely determined.

We are left with the case where $d_x = \gcd(\alpha_x, N^\zeta) > 1$, so that α_x is non-invertible. Note that d_x lives in the set

$$\{p^i q^j \mid 0 \leq i < \zeta, 0 \leq j < \zeta\} \cup \{p^i q^\zeta \mid 0 \leq i < \zeta\} \cup \{p^\zeta q^j \mid 0 \leq j < \zeta\}$$

and we know that the congruence $\alpha_x \cdot \text{Chall} \equiv -\alpha_a \pmod{N^\zeta}$ has solutions if and only if d_x divides $N^\zeta - \alpha_a$. Moreover, in this case, there are exactly d_x solutions, which are given by

$$\left\{ \text{Chall}_i = \text{Chall}_0 + i \cdot \frac{N^\zeta}{d_x} \pmod{N^\zeta} \mid i \in \{0, \dots, d_x - 1\} \right\},$$

where Chall_0 is an arbitrary solution. However, since $N^\zeta/d_x > \min(p, q) > 2^\lambda$, at most one of these solutions can fit in $\{0, \dots, 2^\lambda - 1\}$. This solution is efficiently obtained at step 2 of `BadChallenge` when it exists. We conclude that `BadChallenge` always outputs the only challenge $\text{Chall} \in \{0, \dots, 2^\lambda - 1\}$ for which a valid response exists. \square

This trapdoor Σ -protocol can be extended to prove other statements about encrypted values. In Supplementary Material C.3, we extend it into a NIZK argument showing multiplicative relations between Paillier encryptions. In Supplementary Material C.2, we show that it implies more efficient extractable instance-dependent trapdoor commitments [24].

4.2 Trapdoor Σ -Protocol Showing that a Paillier Ciphertext/Commitment Contains 0 or 1

We give a trapdoor Σ -protocol allowing to prove that a (lossy) Paillier ciphertext encrypts 0 or 1. This protocol is a DCR-based adaptation of a Σ -protocol proposed in [18,42] for Elgamal-like encryption schemes. The original protocol of [18,42] assumes additively homomorphic properties in the plaintext and randomness spaces. Here, we adapt it to the DCR setting where the randomness space is a multiplicative group. We also describe a `BadChallenge` function to obtain a trapdoor Σ -protocol with a large challenge space.

We need a DCR-based dual-mode commitment scheme where the hiding mode is dense, meaning that any element of $\mathbb{Z}_{N^2}^*$ is in the range of the commitment algorithm. We thus use commitments of the form $C = (1+N)^{\text{Msg}} \cdot h^y \cdot w^N \pmod{N^2}$, where the distribution of h determines if the commitment is perfectly hiding or perfectly binding. If h is an N -th residue (resp. $h \sim U(\mathbb{Z}_{N^2}^*)$), it is perfectly binding (resp. perfectly hiding). Moreover, the density property of the hiding mode will be crucial to prove the special ZK property of the Σ -protocol.

Let an RSA modulus $N = pq$ and let a random element $h \in \mathbb{Z}_{N^2}^*$. We give a trapdoor Σ -protocol for the following language, which is parametrized by h :

$$\begin{aligned} \mathcal{L}^{0-1}(h) = \{ & C \in \mathbb{Z}_{N^2}^* \mid \exists b \in \{0, 1\}, (y, w) \in \mathbb{Z}_N \times \mathbb{Z}_N^* : \\ & C = (1 + N)^b \cdot h^y \cdot w^N \pmod{N^2} \}. \end{aligned}$$

We include h as a language parameter because we allow the CRS to depend on N , but not on h . We note that, if N divides the order of h , the language $\mathcal{L}^{0-1}(h)$ is trivial since all elements of $\mathbb{Z}_{N^2}^*$ can be explained as a commitment to a bit. However, the language becomes non-trivial when h is an N -th residue since $C = (1 + N)^b h^y w^N \pmod{N^2}$ is then a perfectly binding commitment to b .

While a trapdoor Σ -protocol for $\mathcal{L}^{0-1}(h)$ can be obtained from [28], the one below is useful to show that one out of many ciphertexts encrypts 0 [42].

Gen_{par}(1^λ) : Given the security parameter λ , define $\text{par} = \{\lambda\}$.

Gen_L($\text{par}, \mathcal{L}^{0-1}$) : Given public parameters par and the description of a language \mathcal{L}^{0-1} , consisting of an RSA modulus $N = pq$ with p and q prime satisfying $p, q > 2^{l(\lambda)}$, for some polynomial $l : \mathbb{N} \rightarrow \mathbb{N}$ such that $l(\lambda) > 2\lambda$, define the language-dependent $\text{crs}_{\mathcal{L}} = \{N\}$. The global CRS is $\text{crs} = (\{\lambda\}, \text{crs}_{\mathcal{L}})$.

TrapGen($\text{par}, \mathcal{L}^{0-1}, \tau_{\mathcal{L}}$) : Given par , a language description \mathcal{L}^{0-1} that specifies an RSA modulus $N = pq$, and the membership-testing trapdoor $\tau_{\mathcal{L}} = (p, q)$, output $\text{crs} = (\{\lambda\}, \text{crs}_{\mathcal{L}})$ as in **Gen_L** and the trapdoor $\tau_{\Sigma} = (p, q)$.

P($\text{crs}, \mathbf{x}, \mathbf{w}$) \leftrightarrow **V**(crs, \mathbf{x}) : Given crs , a statement $\mathbf{x} = "C \in \mathcal{L}^{0-1}(h)"$, for some $h \in \mathbb{Z}_{N^2}^*$, P (who has $\mathbf{w} = (b, y, w)$) and V interact as follows:

1. P chooses $a \leftarrow U(\{2^\lambda, \dots, 2^{2\lambda} - 1\})$, $d, e \leftarrow U(\mathbb{Z}_N)$, $u, v \leftarrow U(\mathbb{Z}_N^*)$ and sends V the following:

$$A_1 = (1 + N)^a h^d u^N \bmod N^2, \quad A_2 = (1 + N)^{-a \cdot b} h^e v^N \bmod N^2.$$

2. V sends a random challenge $\text{Chall} \leftarrow U(\{0, \dots, 2^\lambda - 1\})$.
3. P sends V the response $(z, z_d, z_e, z_u, z_v) \in \mathbb{Z} \times (\mathbb{Z}_N)^2 \times (\mathbb{Z}_N^*)^2$, where

$$\begin{aligned} z &= a + \text{Chall} \cdot b, & z_1 &= d + \text{Chall} \cdot y, & z_2 &= e + (z - \text{Chall}) \cdot y, \\ z_d &= z_1 \bmod N, & z_u &= u \cdot w^{\text{Chall}} \cdot h^{\lfloor z_1/N \rfloor} \bmod N, \\ z_e &= z_2 \bmod N, & z_v &= v \cdot w^{z - \text{Chall}} \cdot h^{\lfloor z_2/N \rfloor} \bmod N. \end{aligned}$$

4. V returns 1 if and only if $2^\lambda \leq z < 2^{2\lambda+1}$ and

$$\begin{aligned} A_1 &= C^{-\text{Chall}} \cdot (1 + N)^z \cdot h^{z_d} \cdot z_u^N \bmod N^2, & (10) \\ A_2 &= C^{\text{Chall} - z} \cdot h^{z_e} \cdot z_v^N \bmod N^2. \end{aligned}$$

BadChallenge($\text{par}, \tau_{\Sigma}, \text{crs}, \mathbf{x}, \mathbf{a}$) : Given a statement $\mathbf{x} = "C \in \mathcal{L}^{0-1}(h)"$, a trapdoor $\tau_{\Sigma} = (p, q)$ and $\mathbf{a} = (A_1, A_2) \in (\mathbb{Z}_{N^2}^*)^2$, return \perp if h is not an N -th residue. Otherwise, decrypt C and (A_1, A_2) to obtain $b = \mathcal{D}_{\tau_{\Sigma}}(C) \in \mathbb{Z}_N$ and $a_i = \mathcal{D}_{\tau_{\Sigma}}(A_i) \in \mathbb{Z}_N$ for each $i \in \{1, 2\}$. If \mathbf{x} is false, we have $b \notin \{0, 1\}$. Consider the following linear system with the unknowns $(\text{Chall}, z) \in \mathbb{Z}_N^2$:

$$\begin{aligned} z - b \cdot \text{Chall} &\equiv a_1 \pmod{N}, \\ b \cdot (\text{Chall} - z) &\equiv a_2 \pmod{N}. \end{aligned} \tag{11}$$

1. If $b(b-1) \equiv 0 \pmod{N}$, assume that $b \equiv 0 \pmod{p}$ and $b \equiv 1 \pmod{q}$. Compute $z' = a_1 \bmod p$ and $\text{Chall}' = z' - a_1 \bmod q$. Then, return \perp if $\text{Chall}' - z' \not\equiv a_2 \pmod{q}$ or $a_2 \not\equiv 0 \pmod{p}$.
2. If $b(b-1) \not\equiv 0 \pmod{N}$, define $d_b = \gcd(b(b-1), N)$, so that we have $\gcd(b(b-1), N/d_b) = 1$. Any solution of (11) also satisfies the system

$$\begin{aligned} z - b \cdot \text{Chall} &\equiv a_1 \pmod{N/d_b} \\ b \cdot z - b \cdot \text{Chall} &\equiv -a_2 \pmod{N/d_b}, \end{aligned}$$

which has a unique solution $(\text{Chall}', z') \in (\mathbb{Z}_{N/d_b})^2$.

In both cases, if $2^\lambda \leq z' < 2^{2\lambda+1}$ and $0 \leq \text{Chall}' < 2^\lambda$, return $\text{Chall} = \text{Chall}'$. Otherwise, return \perp .

Any honest protocol execution always returns a valid transcript since we have $2^\lambda \leq a + b \cdot \text{Chall} \leq 2^{2\lambda} + 2^\lambda - 2 < 2^{2\lambda+1}$ and

$$\begin{aligned}
& (1 + N)^z \cdot h^{z_d} \cdot z_u^N \\
& \equiv (1 + N)^{a+\text{Chall}\cdot b} \cdot u^N \cdot w^{N\cdot\text{Chall}} \cdot h^{z_d} \cdot h^{(d+\text{Chall}\cdot y) - (d+\text{Chall}\cdot y \bmod N)} \\
& \equiv (1 + N)^{a+\text{Chall}\cdot b} \cdot u^N \cdot w^{N\cdot\text{Chall}} \cdot h^{d+\text{Chall}\cdot y} \\
& \equiv (1 + N)^a \cdot u^N \cdot h^d \cdot ((1 + N)^b \cdot w^N \cdot h^y)^{\text{Chall}} \equiv A_1 \cdot C^{\text{Chall}} \pmod{N^2} \\
C^{\text{Chall}-z} \cdot h^{z_e} \cdot z_v^N & \equiv ((1 + N)^b \cdot w^N \cdot h^y)^{\text{Chall}-z} \cdot v^N \cdot w^{(z-\text{Chall})N} \cdot h^{e+(z-\text{Chall})\cdot y} \\
& \equiv (1 + N)^{b(\text{Chall}-z)} \cdot v^N \cdot h^e \equiv (1 + N)^{b(-a+(1-b)\cdot\text{Chall})} \cdot v^N \cdot h^e \\
& \equiv (1 + N)^{-ab} \cdot v^N \cdot h^e \equiv A_2 \pmod{N^2}
\end{aligned}$$

The correctness of **BadChallenge** follows from the fact that $0 \leq \text{Chall} < 2^\lambda$ (so that $\text{Chall} = \text{Chall} \bmod p = \text{Chall} \bmod q$) and the observation that the verifier never accepts when $z \geq \min(p, q)$. This ensures that a valid response exists for at most one $z \in \mathbb{Z}$ such that $z = z \bmod p = z \bmod q$.

Remark 4.2. When h is a composite residue, the condition $b \in \{0, 1\}$ implies that, over \mathbb{Z} , we have either $z = a + b \cdot \text{Chall}$ or $z = a + b \cdot \text{Chall} - N$, where $a = \mathcal{D}_{\tau_\Sigma}(A_1)$ and $b = \mathcal{D}_{\tau_\Sigma}(C)$ (recall that (10) implies $z = a + b \cdot \text{Chall} \bmod N$). The latter case can only occur if $b = 1$ and $N - 2^\lambda \leq a \leq N - 1$. However, this would imply $\text{Chall} - 2^\lambda \leq a + \text{Chall} - N \leq \text{Chall} - 1$, which is not compatible with the lower bound of the verification test $2^\lambda \leq z < 2^{2\lambda+1}$. As a result, the equation $z = a + b \cdot \text{Chall}$ holds over \mathbb{Z} , and not only modulo N . While this property is not necessary to ensure the soundness of the above Σ -protocol, it will be crucial for the **BadChallenge** function of the trapdoor Σ -protocol in Section 4.3.⁶ In order to ensure perfect completeness, the prover chooses a in a somewhat unusual interval that does not start with 0. However, we still have statistical completeness and statistical HVZK if a is sampled from $U(\{0, \dots, 2^{2\lambda} - 1\})$.

4.3 Trapdoor Σ -Protocol Showing that One Out of Many Ciphertexts/Commitments Contains 0

We now present a DCR-based variant of the Σ -protocol of Groth and Kohlweiss [42], which allows proving that one commitment out of $R = 2^r$ contains 0.

Their Σ -protocol relies on a protocol, like the one of Section 4.2, showing that a committed b is a bit using a response of the form $z = a + b \cdot \text{Chall}$. To prove that some commitment $C_\ell \in \{C_i\}_{i=0}^{R-1}$ opens to 0 without revealing the index $\ell \in \{0, \dots, R-1\}$, the bits $\ell_1 \dots \ell_r \in \{0, 1\}^r$ of ℓ are committed and, for each of them, the prover provides evidence that $\ell_j \in \{0, 1\}$. The response

⁶ In contrast, the upper bound for z is crucial here in the first step of **BadChallenge**.

$z_j = a_j + \ell_j \text{Chall}$ is seen as a degree-1 polynomial in Chall and used to define polynomials $f_{j,1}[X] = a_j + \ell_j X$ and $f_{f,0}[X] = X - f_j$, which in turn define

$$P_i[X] = \prod_{j=1}^r f_{j,i_j}[X] = \delta_{i,\ell} \cdot X^r + \sum_{k=0}^{r-1} p_{i,k} \cdot X^k \quad \forall i \in \{0, \dots, R-1\},$$

where $P_i[X]$ has degree r if $i = \ell$ and degree $\leq r-1$ otherwise. In order to prove that one of the $\{P_i[X]\}_{i=0}^{R-1}$ has degree r , Groth and Kohlweiss homomorphically compute $\prod_{i=0}^{R-1} C_i^{P_i(\text{Chall})}$ and multiply it with $\prod_{k=0}^{r-1} C_{d_k}^{-\text{Chall}^k}$, for auxiliary commitments $\{C_{d_k} = \prod_{i=0}^{R-1} C_i^{p_{i,k}}\}_{k=0}^{r-1}$, in order to cancel out the terms of degree 0 to $r-1$ in the exponent. Then, they prove that the product $\prod_{i=0}^{R-1} C_i^{P_i(\text{Chall})} \cdot \prod_{k=0}^{r-1} C_{d_k}^{-\text{Chall}^k}$ is indeed a commitment to 0.

Let $N = pq$ and $\bar{N} = \bar{p}\bar{q}$ denote two RSA moduli. Let also $h \in \mathbb{Z}_{N^2}^*$ and $\bar{h} \in \mathbb{Z}_{\bar{N}^2}^*$. We give a trapdoor Σ -protocol for the language

$$\begin{aligned} \mathcal{L}_\Sigma^{1-R}(h, \bar{h}) := & \{((C_0, \dots, C_{R-1}), (L_1, \dots, L_r)) \in (\mathbb{Z}_{N^2}^*)^R \times (\mathbb{Z}_{\bar{N}^2}^*)^r \mid \\ & \exists y \in \mathbb{Z}_N, w \in \mathbb{Z}_N^*, \exists_{j=1}^r (\ell_j, s_j, t_j) \in \{0, 1\} \times \mathbb{Z}_{\bar{N}} \times \mathbb{Z}_{\bar{N}}^* : \\ & \bigwedge_{j=1}^r L_j = (1 + \bar{N})^{\ell_j} \bar{h}^{s_j} t_j^{\bar{N}} \pmod{\bar{N}^2} \wedge C_\ell = h^y w^N \pmod{N^2}\} \end{aligned} \quad (12)$$

where $R = 2^r$ and $\ell = \sum_{j=1}^r \ell_j \cdot 2^{j-1}$. In (12), $h \in \mathbb{Z}_{N^2}^*$ and $\bar{h} \in \mathbb{Z}_{\bar{N}^2}^*$ are used as language parameters since we allow the CRS to depend on N and \bar{N} , but not on h nor \bar{h} . The reason is that, in our construction of Section 5, we need to generate the CRS before \bar{h} is chosen.

We note that $\mathcal{L}_\Sigma^{1-R}(h, \bar{h})$ is a trivial language (i.e., it is $(\mathbb{Z}_{N^2}^*)^R \times (\mathbb{Z}_{\bar{N}^2}^*)^r$) when N and \bar{N} divide the order of h and \bar{h} , respectively. However, the security proof of our ring signature will switch to a setting where h and \bar{h} are composite residues, which turns $C_\ell = h^y \cdot w^N \pmod{N^2}$ into a perfectly binding commitment to 0 (since $C = (1 + N)^{\text{Msg}} \cdot h^y \cdot w^N \pmod{N^2}$ uniquely determines the underlying $\text{Msg} \in \mathbb{Z}_N$) and L_j into a perfectly binding commitment to ℓ_j .

We now give a Paillier-based adaptation $\Pi_\Sigma^{1-R} = (\text{Gen}_{\text{par}}, \text{Gen}_{\mathcal{L}}, \text{P}, \text{V})$ of the Σ -protocol described in [42]. The construction goes as follows.

- Gen_{par}**(1^λ): Given the security parameter λ , define $\text{par} = \{\lambda\}$.
- Gen_L**($\text{par}, \mathcal{L}_\Sigma^{1-R}$): Given par and the description of a language \mathcal{L}_Σ^{1-R} , consisting of RSA moduli $N = pq$, $\bar{N} = \bar{p}\bar{q}$ with primes p, q, \bar{p}, \bar{q} satisfying $p, q, \bar{p}, \bar{q} > 2^{l(\lambda)}$, where $l: \mathbb{N} \rightarrow \mathbb{N}$ is a polynomial such that $l(\lambda) > 2\lambda$, define the language-dependent $\text{crs}_{\mathcal{L}} = \{N, \bar{N}\}$ and the global CRS $\text{crs} = (\{\lambda\}, \text{crs}_{\mathcal{L}})$.
- TrapGen**($\text{par}, \mathcal{L}_\Sigma^{1-R}, \tau_{\mathcal{L}}$): Given par , the description of a language \mathcal{L}_Σ^{1-R} and a language trapdoor $\tau_{\mathcal{L}}$, it proceeds identically to **Gen_L** except that it also outputs the trapdoor $\tau_\Sigma = (p, q, \bar{p}, \bar{q})$.
- P**($\text{crs}, \mathbf{x}, \mathbf{w}$) \leftrightarrow **V**(crs, x): P has the witness $\mathbf{w} = (y, w, \{(\ell_j, s_j, t_j)\}_{j=1}^r)$ to the statement $\mathbf{x} = ((C_0, \dots, C_{R-1}), (L_1, \dots, L_r)) \in \mathcal{L}_\Sigma^{1-R}(h, \bar{h})$ and interacts with the verifier V in the following way:

1. For each $j \in [r]$, P chooses $\bar{a}_j \leftarrow U(\{2^\lambda, \dots, 2^{2\lambda} - 1\})$, $\bar{d}_j, \bar{e}_j \leftarrow U(\mathbb{Z}_{\bar{N}})$, $\bar{u}_j, \bar{v}_j \leftarrow U(\mathbb{Z}_{\bar{N}}^*)$ and computes

$$\begin{cases} \bar{A}_j = (1 + \bar{N})^{\bar{a}_j} \cdot \bar{h}^{\bar{d}_j} \cdot \bar{u}_j^{\bar{N}} \bmod \bar{N}^2, \\ \bar{B}_j = (1 + \bar{N})^{-\bar{a}_j \cdot \bar{\ell}_j} \cdot \bar{h}^{\bar{e}_j} \cdot \bar{v}_j^{\bar{N}} \bmod \bar{N}^2. \end{cases} \quad (13)$$

It then defines degree-1 polynomials $F_{j,1}[X] = \bar{a}_j + \bar{\ell}_j X \in \mathbb{Z}_N[X]$, $F_{j,0}[X] = X - F_{j,1}[X] \in \mathbb{Z}_N[X]$. For each index $i \in \{0, \dots, R-1\}$ of binary expansion $i_1 \dots i_r \in \{0, 1\}^r$, it computes the polynomial

$$P_i[X] = \prod_{j=1}^r F_{j,i_j}[X] = \delta_{i,\ell} \cdot X^r + \sum_{k=0}^{r-1} p_{i,k} \cdot X^k \in \mathbb{Z}_N[X], \quad (14)$$

which has degree $\leq r-1$ if $i \neq \ell$ and degree r if $i = \ell$. Then, using the coefficients $p_{i,0}, \dots, p_{i,r-1} \in \mathbb{Z}_N$ of (14), P computes commitments

$$C_{d_k} = \prod_{i=0}^{R-1} C_i^{p_{i,k}} \cdot h^{\mu_k} \cdot \rho_k^N \bmod N^2 \quad 0 \leq k \leq r-1, \quad (15)$$

where $\mu_0, \dots, \mu_{r-1} \leftarrow U(\mathbb{Z}_N)$, $\rho_0, \dots, \rho_{r-1} \leftarrow U(\mathbb{Z}_N^*)$. Finally, P sends V the message $\mathbf{a} = (\{\bar{A}_j, \bar{B}_j\}_{j=1}^r, \{C_{d_k}\}_{k=0}^{r-1})$.

2. V sends a random challenge $\text{Chall} \leftarrow U(\{0, \dots, 2^\lambda - 1\})$.
3. P sends the response $(z_y, z_w, \{\bar{z}_j, \bar{z}_{d,j}, \bar{z}_{e,j}, \bar{z}_{u,j}, \bar{z}_{v,j}\}_{j=1}^r)$, where

$$\begin{cases} \bar{z}_{d,j} = \bar{d}_j + \text{Chall} \cdot s_j \bmod \bar{N} & \bar{z}_j = \bar{a}_j + \text{Chall} \cdot \bar{\ell}_j \\ \bar{z}_{e,j} = \bar{e}_j + (\bar{a}_j + \text{Chall} \cdot (\bar{\ell}_j - 1)) \cdot s_j \bmod \bar{N} \\ \bar{z}_{u,j} = \bar{u}_j \cdot \bar{t}_j^{\text{Chall}} \cdot \bar{h}^{\lfloor (\bar{d}_j + \text{Chall} \cdot s_j) / \bar{N} \rfloor} \bmod \bar{N} \\ \bar{z}_{v,j} = \bar{v}_j \cdot \bar{t}_j^{\bar{a}_j + \text{Chall} \cdot (\bar{\ell}_j - 1)} \cdot \bar{h}^{\lfloor (\bar{e}_j + (\bar{a}_j + \text{Chall} \cdot (\bar{\ell}_j - 1)) \cdot s_j) / \bar{N} \rfloor} \bmod \bar{N} \end{cases} \quad (16)$$

and, letting $P'[X] = y \cdot X^r - \sum_{k=1}^{r-1} \mu_k \cdot X^k \in \mathbb{Z}[X]$,

$$\begin{aligned} z_y &= y \cdot \text{Chall}^r - \sum_{k=0}^{r-1} \mu_k \cdot \text{Chall}^k \bmod N = P'(\text{Chall}) \bmod N, \\ z_w &= w^{\text{Chall}^r} \prod_{k=0}^{r-1} \rho_k^{-\text{Chall}^k} \prod_{i=0}^{R-1} C_i^{-\lfloor P_i(\text{Chall}) / N \rfloor} \cdot h^{\lfloor P'(\text{Chall}) / N \rfloor} \bmod N, \end{aligned} \quad (17)$$

where $P_i(\text{Chall})$ and $P'(\text{Chall})$ are evaluated over \mathbb{Z} in the exponent.

4. V defines $f_{j,1} = \bar{z}_j$ and $f_{j,0} = \text{Chall} - \bar{z}_j \bmod N$ for each $j \in [r]$. Then, it accepts if and only if $2^\lambda \leq \bar{z}_j < 2^{2\lambda+1}$ for all $j \in [r]$,

$$\forall j \in [r] : \begin{cases} \bar{A}_j = L_j^{-\text{Chall}} \cdot (1 + \bar{N})^{\bar{z}_j} \cdot \bar{h}^{\bar{z}_{d,j}} \cdot \bar{z}_{u,j}^{\bar{N}} \bmod \bar{N}^2 \\ \bar{B}_j = L_j^{\text{Chall} - \bar{z}_j} \cdot \bar{h}^{\bar{z}_{e,j}} \cdot \bar{z}_{v,j}^{\bar{N}} \bmod \bar{N}^2 \end{cases} \quad (18)$$

and, parsing each $i \in \{0, \dots, R-1\}$ into bits $i_1 \dots i_r \in \{0, 1\}^r$,

$$\prod_{k=0}^{r-1} C_{d_k}^{-\text{Chall}^k} \cdot \prod_{i=0}^{R-1} C_i^{(\prod_{j=1}^r f_{j,i_j} \bmod N)} \equiv h^{z_y} \cdot z_w^N \pmod{N^2}. \quad (19)$$

BadChallenge($\text{par}, \tau_\Sigma, \text{crs}, \mathbf{x}, \mathbf{a}$): On input of a trapdoor $\tau_\Sigma = (p, q, \bar{p}, \bar{q})$, a statement $\mathbf{x} = ((C_0, \dots, C_{R-1}), (L_1, \dots, L_r)) \in \mathcal{L}_V^{1-R}(h, \bar{h})$ and a first prover message $\mathbf{a} = (\{\bar{A}_j, \bar{B}_j\}_{j=1}^r, \{C_{d_k}\}_{k=0}^{r-1})$, return \perp if h is not an N -th residue in $\mathbb{Z}_{N^2}^*$ or \bar{h} is not an \bar{N} -th residue in $\mathbb{Z}_{\bar{N}^2}^*$. Otherwise, compute $\ell_j = \mathcal{D}_{\tau_\Sigma}(L_j) \in \mathbb{Z}_{\bar{N}}$ and decrypt \mathbf{a} so as to obtain $\bar{a}_j = \mathcal{D}_{\tau_\Sigma}(\bar{A}_j) \in \mathbb{Z}_{\bar{N}}$, $\bar{b}_j = \mathcal{D}_{\tau_\Sigma}(\bar{B}_j) \in \mathbb{Z}_{\bar{N}}$, for each $j \in [r]$, and $c_{d_k} = \mathcal{D}_{\tau_\Sigma}(C_{d_k}) \in \mathbb{Z}_N$ for each k . Let also $c_i = \mathcal{D}_{\tau_\Sigma}(C_i) \in \mathbb{Z}_N$ for each $i = 0$ to $R-1$. Since \mathbf{x} is false, we have either: (i) $\ell_j \notin \{0, 1\}$, for some $j \in [r]$; or (ii) $\forall j \in [r] : \ell_j \in \{0, 1\}$ but $c_\ell \neq 0 \bmod N$, where $\ell = \sum_{j=1}^r \ell_j \cdot 2^{j-1}$. We consider two cases:

1. If there exists $j \in [r]$ such that $\ell_j \notin \{0, 1\}$, then run the **BadChallenge**⁰⁻¹ function of Sec. 4.2 on input of elements $(\text{par}, (\bar{p}, \bar{q}), \{\bar{N}\}, L_j, (\bar{A}_j, \bar{B}_j))$ and return whatever it outputs.
2. Otherwise, we have $\ell_j \in \{0, 1\}$ for all $j \in [r]$. Define degree-1 polynomials $F_{j,1}[X] = \bar{a}_j + \ell_j X$, $F_{j,0}[X] = X - F_{j,1}[X] \in \mathbb{Z}_N[X]$ and compute $\{P_i[X]\}_{i=0}^{R-1}$ as per (14). For each $i \in \{0, \dots, R-1\}$, parse the polynomial $P_i[X] \in \mathbb{Z}_N[X]$ as $P_i[X] = \delta_{i,\ell} \cdot X^r + \sum_{k=0}^{r-1} p_{i,k} \cdot X^k$ for some $p_{i,0}, \dots, p_{i,r-1} \in \mathbb{Z}_N$. Define the polynomial

$$Q[X] \triangleq c_\ell \cdot X^r + \sum_{k=0}^{r-1} \left(\left(\sum_{i=0}^{R-1} c_i \cdot p_{i,k} \right) - c_{d_k} \right) \cdot X^k \in \mathbb{Z}_N[X],$$

which has degree r since $c_\ell \neq 0 \bmod N$. Define $Q_p[X] \triangleq Q[X] \bmod p$ and $Q_q[X] \triangleq Q[X] \bmod q$ over $\mathbb{Z}_p[X]$ and $\mathbb{Z}_q[X]$, respectively. Since at least one of them has degree r , we assume w.l.o.g. that $\deg(Q_p[X]) = r$. Then, compute the roots⁷ $\text{Chall}_{p,1}, \dots, \text{Chall}_{p,r}$ of $Q_p[X]$ over $\mathbb{Z}_p[X]$ in lexicographical order (if it has less than r roots, the non-existing roots are replaced by $\text{Chall}_{p,i} = \perp$). For each $i \in [r]$, do the following:

- a. If $\text{Chall}_{p,i} \notin \{0, \dots, 2^\lambda - 1\}$, set $\text{Chall}_i = \perp$.
- b. If $\text{Chall}_{p,i} \in \{0, \dots, 2^\lambda - 1\}$ and $Q_q(\text{Chall}_{p,i}) \equiv 0 \pmod{q}$, then set $\text{Chall}_i = \text{Chall}_{p,i}$. Otherwise, set $\text{Chall}_i = \perp$.

CORRECTNESS. To see that honestly generated proofs are always accepted by the verifier, we first note that $2^\lambda \leq \bar{a}_j \leq \bar{z}_j = \bar{a}_j + \text{Chall} \cdot \ell_j \leq 2^{2\lambda} + 2^\lambda < 2^{2\lambda+1}$, for all $j \in [r]$, and that the equations (18) are satisfied for the same reasons as

⁷ This can be efficiently achieved using the Cantor-Zassenhaus algorithm [16], which is a probabilistic algorithm with small failure probability. The CI hash function of [59] is compatible with **BadChallenge** functions failing with negligible probability.

in Section 4.2. As for equation (19), we observe that, if the witnesses $y \in \mathbb{Z}_N$ and $w \in \mathbb{Z}_N^*$ satisfy $C_\ell = h^y \cdot w^N \pmod{N^2}$, we have

$$\begin{aligned}
& h^{z_y} \cdot z_w^N \cdot \prod_{i=0}^{R-1} C_i^{-\left(\prod_{j=1}^r f_{j,i_j} \pmod{N}\right)} \equiv h^{z_y} \cdot z_w^N \cdot \prod_{i=0}^{R-1} C_i^{-P_i(\text{Chall}) \pmod{N}} \\
& \equiv h^{z_y} \cdot w^{\text{Chall}^r \cdot N} \cdot \prod_{k=0}^{r-1} \rho_k^{-\text{Chall}^k \cdot N} \cdot \prod_{i=0}^{R-1} C_i^{-P_i(\text{Chall}) + (P_i(\text{Chall}) \pmod{N})} \\
& \qquad \qquad \qquad \cdot h^{P'(\text{Chall}) - z_y} \cdot \prod_{i=0}^{R-1} C_i^{-P_i(\text{Chall}) \pmod{N}} \\
& \equiv h^{P'(\text{Chall})} \cdot w^{\text{Chall}^r \cdot N} \cdot \prod_{k=0}^{r-1} \rho_k^{-\text{Chall}^k \cdot N} \cdot \prod_{i=0}^{R-1} C_i^{-P_i(\text{Chall})} \\
& \equiv h^{\text{Chall}^r \cdot y} \cdot w^{\text{Chall}^r \cdot N} \cdot \prod_{k=0}^{r-1} (h^{-\text{Chall}^k \mu_k} \cdot \rho_k^{-\text{Chall}^k \cdot N}) \\
& \qquad \qquad \qquad \cdot \prod_{i=0}^{R-1} C_i^{-\delta_{i,\ell} \cdot \text{Chall}^r - \sum_{k=0}^{r-1} p_{i,k} \cdot \text{Chall}^k} \\
& \equiv (h^y \cdot w^N)^{\text{Chall}^r} \cdot \prod_{k=0}^{r-1} (h^{\mu_k} \cdot \rho_k^N)^{-\text{Chall}^k} \cdot C_\ell^{-\text{Chall}^r} \cdot \prod_{i=0}^{R-1} C_i^{-\sum_{k=0}^{r-1} p_{i,k} \cdot \text{Chall}^k} \\
& \equiv \prod_{k=0}^{r-1} (h^{\mu_k} \cdot \rho_k^N)^{-\text{Chall}^k} \cdot \prod_{k=0}^{r-1} \prod_{i=0}^{R-1} C_i^{-p_{i,k} \cdot \text{Chall}^k} \\
& \equiv \prod_{k=0}^{r-1} C_{d_k}^{-\text{Chall}^k} \pmod{N^2}.
\end{aligned}$$

Lemma 4.3. *The above construction is a trapdoor Σ -protocol for \mathcal{L}_V^{1-R} .*

Proof. Lemma 4.4 shows that, on a CRS generated by $\text{Gen}_{\mathcal{L}}$, the Σ -protocol is statistically special honest-verifier zero-knowledge when the orders of $h \in \mathbb{Z}_{N^2}^*$ and $\bar{h} \in \mathbb{Z}_{\bar{N}^2}^*$ are multiples of N and \bar{N} , respectively.

When h and \bar{h} are composite residues (thus making the commitments perfectly binding), we show that **BadChallenge** correctly identifies all the possible bad challenges for any first message sent by the prover. We only consider the case where $\ell_j \in \{0, 1\}$ since, otherwise, we can simply rely on the correctness of **BadChallenge**⁰⁻¹. At step 2, the polynomials $\{P_i[X]\}_{i=0}^{R-1}$ that **BadChallenge** computes from $\{\ell_j, \bar{a}_j\}_{j=1}^r$ are of the form $P_i[X] = \delta_{i,\ell} \cdot X^r + \sum_{k=0}^{r-1} p_{i,k} \cdot X^k \in \mathbb{Z}_N[X]$, by construction. By the verification equations (18), any valid challenge-response pair $(\text{Chall}, (z_y, z_w, \{\bar{z}_j, \bar{z}_{d,j}, \bar{z}_{e,j}, \bar{z}_{u,j}, \bar{z}_{v,j}\}_{j=1}^r))$ must involve elements $\{\bar{z}_j\}_{j=1}^r$ that satisfy the conditions $\bar{z}_j = \bar{a}_j + \text{Chall} \cdot \ell_j$ over the integers, and not only modulo \bar{N} , due to the lower bound on \bar{z}_j and since ℓ_j is a bit (see Remark 4.2). Hence, the polynomials $\{F_{j,1}[X]\}_{j=1}^r$ computed at step 2 of **BadChallenge** satisfy

$\bar{z}_j = F_{j,1}(\text{Chall}) = F_{j,1}(\text{Chall}) \bmod N$. Moreover, from equation (19), we have

$$\begin{aligned} h^{z_u} \cdot z_w^N &\equiv \prod_{k=0}^{r-1} C_{d_k}^{-\text{Chall}^k} \cdot \prod_{i=0}^{R-1} C_i^{P_i(\text{Chall}) \bmod N} \\ &\equiv \prod_{k=0}^{r-1} C_{d_k}^{-\text{Chall}^k} \cdot \prod_{i=0}^{R-1} C_i^{(\delta_{i,\ell} \cdot \text{Chall}^r + \sum_{k=0}^{r-1} p_{i,k} \cdot \text{Chall}^k \bmod N)} \pmod{N^2}. \end{aligned} \quad (20)$$

By decrypting all members of (20), we see that a bad challenge must be a root of $Q[X]$ over \mathbb{Z}_N since $\mathcal{D}_{\tau_\Sigma}(h) = 0$. Since a bad challenge Chall satisfies

$$Q(\text{Chall}) = c_\ell \cdot \text{Chall}^r + \sum_{k=0}^{r-1} \left(\left(\sum_{i=0}^{R-1} c_i \cdot p_{i,k} \right) - c_{d_k} \right) \cdot \text{Chall}^k \equiv 0 \pmod{N},$$

it also satisfies $Q(\text{Chall}) \equiv 0 \pmod{p}$ and $Q(\text{Chall}) \equiv 0 \pmod{q}$. Given that $\gcd(c_\ell, N) \in \{1, p, q\}$ and $\gcd(c_\ell, N/\gcd(c_\ell, N)) = 1$, we have either $c_\ell \not\equiv 0 \pmod{p}$ or $c_\ell \not\equiv 0 \pmod{q}$, meaning that at least one the polynomials $Q_p[X]$ and $Q_q[X]$ is a non-zero degree- r polynomial over a prime field. Since $p, q > 2^\lambda$, we know that any $\text{Chall} \in \{0, \dots, 2^\lambda - 1\}$ fits in both \mathbb{Z}_p and \mathbb{Z}_q . The condition $Q(\text{Chall}) \equiv 0 \pmod{N}$ then implies that a bad challenge $\text{Chall} \in \{0, \dots, 2^\lambda - 1\}$ necessarily satisfies $Q_p(\text{Chall}) = 0 \bmod p$ and $Q_q(\text{Chall}) = 0 \bmod q$. This shows that BadChallenge always identifies all the bad challenges at step 2. \square

Following [42] and standard Σ -protocols over the integers, the above Σ -Protocol $\Pi_V^{1-R} = (\text{Gen}_{\text{par}}, \text{Gen}_{\mathcal{L}}, \text{P}, \text{V})$ is statistically special honest-verifier zero-knowledge. Although the adversary can choose Paillier commitments $\{C_i\}_{i=0}^{R-1}$ of its own (which may be N -th residues or not), we can rely on the fact that h has a component of order N to perfectly randomize commitments $\{C_{d_k}\}_{k=0}^{r-1}$ over the full group $\mathbb{Z}_{N^2}^*$ even if some of the $\{C_i\}_{i=0}^{R-1}$ are maliciously generated.

Lemma 4.4. *For any language $\mathcal{L}_V^{1-R}(h, \bar{h})$ such that N divides the order of $h \in \mathbb{Z}_{N^2}^*$ and \bar{N} divides the order of $\bar{h} \in \mathbb{Z}_{\bar{N}^2}^*$, $\Pi_V^{1-R}(h, \bar{h})$ is statistically special honest-verifier zero-knowledge.*

Proof. Let crs be a CRS generated by $\text{Gen}_{\mathcal{L}}$. By the hypothesis on their order, $h \in \mathbb{Z}_{N^2}^*$ and $\bar{h} \in \mathbb{Z}_{\bar{N}^2}^*$ can be written as $h = (1+N)^\alpha \cdot \beta^N$ and $\bar{h} = (1+\bar{N})^\alpha \cdot \bar{\beta}^{\bar{N}}$, for some $\alpha \in \mathbb{Z}_N^*$, $\bar{\alpha} \in \mathbb{Z}_{\bar{N}}^*$. We can thus assume that the commitments are perfectly hiding. To prove the claim, we describe a simulator ZKSim which, on input $(\text{crs}, \mathbf{x}, \text{Chall})$, where $\mathbf{x} \in \mathcal{L}_V^{1-R}(h, \bar{h})$ and $\text{Chall} \in \{0, \dots, 2^\lambda - 1\}$, builds a transcript $(\mathbf{a}, \text{Chall}, \mathbf{z})$ by computing a pair (\mathbf{a}, \mathbf{z}) as follows.

1. Given $((C_0, \dots, C_{R-1}), (L_1, \dots, L_r))$, for each $j \in [r]$, pick uniformly random $\bar{z}_j \leftarrow U(\{2^\lambda, \dots, 2^{2^\lambda} - 1\})$, $\bar{z}_{d,j}, \bar{z}_{e,j} \leftarrow U(\mathbb{Z}_{\bar{N}})$ and $\bar{z}_{u,j}, \bar{z}_{v,j} \leftarrow U(\mathbb{Z}_{\bar{N}}^*)$. Then, compute

$$\forall j \in [r]: \begin{cases} \bar{A}_j = L_j^{-\text{Chall}} \cdot (1 + \bar{N})^{\bar{z}_j} \cdot \bar{h}^{\bar{z}_{d,j}} \cdot \bar{z}_{u,j}^{\bar{N}} \pmod{\bar{N}^2} \\ \bar{B}_j = L_j^{\text{Chall} - \bar{z}_j} \cdot \bar{h}^{\bar{z}_{e,j}} \cdot \bar{z}_{v,j}^{\bar{N}} \pmod{\bar{N}^2} \end{cases} \quad (21)$$

2. Select $z_y \leftarrow U(\mathbb{Z}_N)$ and $z_w \leftarrow U(\mathbb{Z}_N^*)$ as well as $C_{d_k} \leftarrow U(\mathbb{Z}_{N^2}^*)$, for each $k \in \{1, \dots, r-1\}$. Then, define $f_{j,1} = \bar{z}_j$ and $f_{j,0} = \text{Chall} - \bar{z}_j \pmod N$ for each $j \in [r]$ and compute

$$C_{d_0} = h^{z_y} \cdot z_w^N \cdot \prod_{k=1}^{r-1} C_{d_k}^{\text{Chall}^k} \cdot \prod_{i=0}^{R-1} C_i^{-\left(\prod_{j=1}^r f_{j,i_j} \pmod N\right)} \pmod{N^2}, \quad (22)$$

where $i_1 \dots i_r \in \{0, 1\}^r$ is the binary expansion of $i \in \mathbb{Z}_R$.

3. Return the first-message $\mathbf{a} = (\{\bar{A}_j, \bar{B}_j\}_{j=1}^r, \{C_{d_k}\}_{k=0}^{r-1})$ and the response $\mathbf{z} = (z_y, z_w, \{\bar{z}_j, \bar{z}_{d,j}, \bar{z}_{e,j}, \bar{z}_{u,j}, \bar{z}_{v,j}\}_{j=1}^r)$.

Now, let $(\mathbf{x}, \mathbf{w}, \text{Chall})$ be the output of an unbounded adversary $\mathcal{A}(\text{crs})$ such that $(\mathbf{x}, \mathbf{w}) \in \mathcal{R}_V^{1-R}(h, \bar{h})$. We analyze both distributions of $(\mathbf{a}, \text{Chall}, \mathbf{z})$, where either $(\mathbf{a}, \mathbf{z}) \leftarrow \text{ZKSim}(\text{crs}, x, \text{Chall})$ is simulated or $(\mathbf{a}, st) \leftarrow P(\text{crs}, \mathbf{x}, \mathbf{w})$ and $\mathbf{z} \leftarrow P(\text{crs}, st, \text{Chall})$ come from the real execution of the protocol. Note that both transcripts are valid in that case.

First, since \bar{N} divides the order of \bar{h} in $\mathbb{Z}_{N^2}^*$, the triples $(\bar{A}_j, \bar{z}_{d,j}, \bar{z}_{u,j})$ and $(\bar{B}_j, \bar{z}_{e,j}, \bar{z}_{v,j})$ are all identically distributed for each $j \in [r]$. Indeed, in both cases, equations (18) and (21) imply that, given L_j , Chall and \bar{z}_j , there is a one-to-one correspondence between \bar{A}_j and $(\bar{z}_{d,j}, \bar{z}_{u,j})$, and \bar{B}_j and $(\bar{z}_{e,j}, \bar{z}_{v,j})$. This is because (\bar{d}_j, \bar{e}_j) in the real distribution and $(\bar{z}_{d,j}, \bar{z}_{e,j})$ in the simulated distribution are uniformly random pairs in $\mathbb{Z}_{\bar{N}} \times \mathbb{Z}_{\bar{N}}$. Then, as long as all the \bar{z}_j 's of both distributions are statistically indistinguishable, so are the transcripts parts related to \bar{N} . We will analyze the distribution of \bar{z}_j at the end of the proof.

Second, assuming that N divides the order of h modulo N^2 , $C_{d_1}, \dots, C_{d_{r-1}}$ are uniformly random elements in $\mathbb{Z}_{N^2}^*$ in both transcripts. Indeed, in the real distribution, $\mu_1, \dots, \mu_{r-1} \sim U(\mathbb{Z}_N)$ thus fully randomize the \mathbb{Z}_N -components while $\rho_1, \dots, \rho_{r-1} \sim U(\mathbb{Z}_N^*)$ fully randomize the \mathbb{Z}_N^* -component over the group $\mathbb{Z}_{N^2}^* \simeq \mathbb{Z}_N \times \mathbb{Z}_N^*$. Moreover, in the simulated distribution, those elements are directly drawn from $U(\mathbb{Z}_{N^2}^*)$. As for the triple (z_y, z_w, C_{d_0}) , for a fixed choice of $\{C_{d_k}\}_{k=1}^{r-1}$, $\{\bar{z}_j\}_{j=1}^r$ and Chall , equations (22) and (19) give a one-to-one relation between $(z_y, z_w) \in \mathbb{Z}_N \times \mathbb{Z}_N^*$ and C_{d_0} in both transcripts whose distributions are the same since μ_0 of the real distribution and z_y of the simulated distribution are uniformly random element over \mathbb{Z}_N .

Finally, we show that the statistical distance between the distributions of \bar{z}_j in the real case and the simulated case is negligible for all $j \in [r]$. For $j \in [r]$, the statistical distance is 0 if $\ell_j = 0$. If $\ell_j = 1$, we have to bound the statistical distance between $U([\text{Chall} + 2^\lambda, \text{Chall} + B_\lambda])$ and $U([2^\lambda, B_\lambda])$, where $B_\lambda = 2^{2\lambda} - 1$. We compute

$$\begin{aligned} & \sum_{i=0}^{\infty} \left| \Pr[z_j \leftarrow U([2^\lambda, B_\lambda] + \text{Chall}) : z_j = i] - \Pr[z_j \leftarrow U([2^\lambda, B_\lambda]) : z_j = i] \right| \\ & \leq \sum_{i=2^\lambda}^{2^\lambda + \text{Chall} - 1} 2^{1-2\lambda} + \sum_{i=B_\lambda+1}^{\text{Chall} + B_\lambda} 2^{1-2\lambda} \leq 2 \cdot \text{Chall} \cdot 2^{1-2\lambda} \leq 2^{2-\lambda}. \end{aligned}$$

When the order of h is a multiple of N and the order of \bar{h} is a multiple of \bar{N} , this shows that both distributions are within distance $r \cdot 2^{2-\lambda}$, with $r = \mathcal{O}(\log \lambda)$. \square

5 Logarithmic-Size Ring Signatures in the Standard Model from DCR and LWE

In Supplementary Material D, we give a simplified version of the scheme where the signer erases its random coins after each signature generation. The main difference between the two constructions is the commitment scheme that allows committing to the signer’s position in the ring.

The proof of unforgeability departs from [42] in that we cannot replay the adversary with a different random oracle. Instead, we use Paillier as a dual-mode commitment, which is made extractable at some step to enable the extraction of bits $\ell_1^* \dots \ell_r^* \in \{0, 1\}^r$ from the commitments $\{L_j^*\}_{j=1}^r$ contained in the forgery $\Sigma^* = ((L_1^*, \dots, L_r^*), \pi^*)$. The next step is to have the reduction guess which honestly generated public key $vk^{(i^*)}$ will belong to the signer identified by decoding the forgery. Then, $vk^{(i^*)}$ is replaced by a random element of $\mathbb{Z}_{N^2}^*$ in order to force the adversary to break the simulation-soundness of Π^{uss} by arguing that $vk^{(i^*)}$ is a commitment to 0, which it is not. The use of two distinct moduli allows us to decode $\ell_1^*, \dots, \ell_r^* \in \{0, 1\}^r$ from $\{L_j^*\}_{j=1}^r$ (which is necessary to check that $\ell^* = \ell_1^* \dots \ell_r^*$ still identifies the expected verification key $vk^{(i^*)}$) even when we rely on the DCR assumption to modify the distribution of $vk^{(i^*)}$.

The security proof relies on erasures because the NIZK simulator is used in all signing queries. Hence, if the adversary makes a corruption query $\text{Corrupt}(i)$ after a signing query involving $sk^{(i)}$, the challenger’s loophole is to claim that it erased the signer’s randomness in signing queries of the form (i, \cdot, \cdot) .

To avoid erasures, we adapt the security proof in such a way that the NIZK simulator only simulates signatures on behalf of the expected target user i^* . All other users’ signatures are faithfully generated, thus allowing the challenger to reveal consistent randomness explaining their generation. Since user i^* is not corrupted with noticeable probability, the challenger never has to explain the generation of a simulated signature. This strategy raises a major difficulty since decoding $\ell_1^* \dots \ell_r^*$ from $\{L_j^*\}_{j=1}^r$ is only possible when these are extractable commitments. Unfortunately, the NIZK simulator cannot answer signing queries (i^*, \cdot, \cdot) by computing $\{L_j^*\}_{j=1}^r$ as perfectly binding commitments as this would not preserve the statistical ZK property of the Σ -protocol of Section 4.3. Moreover, relying on computational ZK does not work because we need the guessed index i^* to be statistically independent of the adversary’s view until the forgery stage. If we were to simulate signatures using computational NIZK proofs, they would information-theoretically leak the index i^* of the only user for which the NIZK simulator is used in signing queries (i^*, \cdot, \cdot) . To resolve this problem, we use a tag-based commitment scheme which is perfectly hiding in all signing queries and extractable in the forgery (with noticeable probability).

We thus commit to the string $\ell \in \{0, 1\}^r$ using the dense \mathcal{R}_{BM} -lossy PKE scheme of Section 3.2. We use the property that, depending on which tag is used to generate a commitment, it either behaves as perfectly hiding or extractable commitment. In the perfectly hiding mode, we also exploit its density property to ensure the statistical ZK property.

The construction uses the trapdoor Σ -protocol of Section 4.3 to prove membership of the parametrized language

$$\begin{aligned} \mathcal{L}_V^{1-R}(h, \bar{h}_{\text{VK}}) := \{ & ((C_0, \dots, C_{R-1}), (L_1, \dots, L_r)) \in (\mathbb{Z}_{N^2}^*)^R \times (\mathbb{Z}_{\bar{N}^2}^*)^r \mid \quad (23) \\ & \exists y \in \mathbb{Z}_N, w \in \mathbb{Z}_N^*, s_1, \dots, s_r \in \mathbb{Z}_{\bar{N}}, t_1, \dots, t_r \in \mathbb{Z}_{\bar{N}}^*, \\ & (\ell_1, \dots, \ell_r) \in \{0, 1\}^r : C_\ell = h^y \cdot w^N \bmod N^2 \\ & \wedge L_j = (1 + \bar{N})^{\ell_j} \cdot \bar{h}_{\text{VK}}^{s_j} \cdot t_j^{\bar{N}} \bmod \bar{N}^2 \quad \forall j \in [r] \}, \end{aligned}$$

with $R = 2^r$ and $\ell = \sum_{j=1}^r \ell_j \cdot 2^{j-1}$, where \bar{h}_{VK} changes in each signature.

The construction relies on the following ingredients:

- A trapdoor Σ -protocol $\Pi' = (\text{Gen}'_{\text{par}}, \text{Gen}'_{\mathcal{L}}, P', V')$ for the parametrized language \mathcal{L}_V^{1-R} defined in (23).
- A strongly unforgeable one-time signature scheme $\text{OTS} = (\mathcal{G}, \mathcal{S}, \mathcal{V})$ with verification keys of length $\ell_v \in \text{poly}(\lambda)$.
- An admissible hash function $\text{AHF} : \{0, 1\}^{\ell_v} \rightarrow \{0, 1\}^L$, for some $L \in \text{poly}(\lambda)$.
- A dense \mathcal{R} -lossy PKE scheme $\mathcal{R}\text{-LPKE} = (\text{Par-Gen}, \text{Keygen}, \text{LKeygen}, \text{Encrypt}, \text{Decrypt})$ for $\mathcal{R}_{\text{BM}} : \mathcal{K} \times \mathcal{T} \rightarrow \{0, 1\}$, where $\mathcal{K} = \{0, 1, \perp\}^L$ and $\mathcal{T} = \{0, 1\}^L$.

Our erasure-free ring signature goes as follows.

CRSGen(1^λ): Given a security parameter λ , conduct the following steps.

1. Generate $\text{par} \leftarrow \text{Gen}_{\text{par}}(1^\lambda)$ for the trapdoor Σ -protocol of Section 4.3.
2. Generate an RSA modulus $N = pq$ and choose an element $h \leftarrow U(\mathbb{Z}_{N^2}^*)$, which has order divisible by N w.h.p.
3. Choose an admissible hash function $\text{AHF} : \{0, 1\}^{\ell_v} \rightarrow \{0, 1\}^L$. Generate public parameters $\Gamma \leftarrow \text{Par-Gen}(1^\lambda, 1^L, 1^{|N|})$ for the dense \mathcal{R}_{BM} -lossy PKE scheme of Section 3.2 with $\zeta = 1$, which is associated with the bit-matching relation $\mathcal{R}_{\text{BM}} : \mathcal{K} \times \mathcal{T} \rightarrow \{0, 1\}$. Choose a random initialization value $K \leftarrow U(\mathcal{K})$ and generate lossy keys $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K)$. Parse pk as $\text{pk} := (\bar{N}, \{\bar{v}_{i,b}\}_{i \in [L], b \in \{0,1\}})$, for an RSA modulus $\bar{N} = \bar{p}\bar{q}$, where $\bar{v}_{i,b} \sim U(\mathbb{Z}_{\bar{N}^2}^*)$ for each $i \in [L]$, $b \in \{0, 1\}$.
4. Generate a pair $(\text{crs}, \tau_{\text{zk}}) \leftarrow \text{Gen}_{\mathcal{L}}(\text{par}, \mathcal{L}_V^{1-R})$ comprised of the CRS crs of an USS argument Π^{uss} (recalled in Supplementary Material B) for the language \mathcal{L}_V^{1-R} defined in (23) with a simulation trapdoor τ_{zk} . The common reference string crs contains $\text{crs}'_{\mathcal{L}} = \{N, \bar{N}\}$, which is part of a CRS $\text{crs}' = (\{\lambda\}, \text{crs}'_{\mathcal{L}})$ for the Σ -protocol of Section 4.3.

Output the common reference string $\rho = (\text{crs}, h, \text{AHF}, \text{pk}, \Gamma, \text{OTS})$, where OTS is the specification of a one-time signature scheme.

Keygen(ρ): Pick $w \leftarrow U(\mathbb{Z}_N^*)$, $y \leftarrow U(\mathbb{Z}_N)$ and compute $C = h^y \cdot w^N \bmod N^2$. Output (sk, vk) , where $sk = (w, y)$ and $vk = C$.

Sign(ρ, sk, M, R): Given a ring $R = \{vk_0, \dots, vk_{R-1}\}$ (we assume that $R = 2^r$ for some $r \in \mathbb{N}$), a message M and a secret key $sk = (w, y) \in \mathbb{Z}_N^* \times \mathbb{Z}_N$, let $\ell \in \{0, \dots, R-1\}$ the index such that $vk_\ell = h^y \cdot w^N \bmod N^2$.

1. Generate a one-time signature key pair $(\text{VK}, \text{SK}) \leftarrow \text{OTS}.\mathcal{G}(1^\lambda)$ and let $\text{VK}' = \text{AHF}(\text{VK}) \in \{0, 1\}^L$. Compute $\bar{h}_{\text{VK}} = \prod_{j=1}^L \bar{v}_{j, \text{VK}'[j]} \bmod \bar{N}^2$.
2. For each $j \in [r]$, choose $s_j \leftarrow U(\mathbb{Z}_{\bar{N}})$, $t_j \leftarrow U(\mathbb{Z}_{\bar{N}}^*)$ and compute a commitment $L_j = (1 + \bar{N})^{\ell_j} \cdot \bar{h}_{\text{VK}}^{s_j} \cdot t_j^{\bar{N}} \bmod \bar{N}^2$.
3. Define $\text{lbl} = \text{VK}$ and compute a NIZK argument $\pi \leftarrow \text{P}(\text{crs}, \mathbf{x}, \mathbf{w}, \text{lbl})$ that $\mathbf{x} \triangleq ((vk_0, \dots, vk_{R-1}), (L_1, \dots, L_r)) \in \mathcal{L}_V^{1-R}(h, \bar{h}_{\text{VK}})$ by running the prover P of Supplementary Material B with the Σ -protocol of Section 4.3 using the witness $\mathbf{w} = ((\ell_1, \dots, \ell_r), w, (s_1, \dots, s_r), (t_1, \dots, t_r))$.
4. Generate a one-time signature $\text{sig} \leftarrow \text{OTS}.\mathcal{S}(\text{SK}, (\mathbf{x}, M, R, \pi))$.

Output the signature $\Sigma = (\text{VK}, (L_1, \dots, L_r), \pi, \text{sig})$.

Verify (ρ, M, Σ, R) : Given a signature $\Sigma = (\text{VK}, (L_1, \dots, L_r), \pi, \text{sig})$, a message M and a ring $R = \{vk_0, \dots, vk_{R-1}\}$, return 0 if these do not parse properly. Otherwise, let $\text{lbl} = \text{VK}$ and return 0 if $\text{OTS}.\mathcal{V}(\text{VK}, (\mathbf{x}, M, R, \pi), \text{sig}) = 0$. Otherwise, run $\text{V}(\text{crs}, \mathbf{x}, \pi, \text{lbl})$ which outputs 1 iff π is a valid argument that $((vk_0, \dots, vk_{R-1}), (L_1, \dots, L_r)) \in \mathcal{L}_V^{1-R}(h, \bar{h}_{\text{VK}})$.

In Supplementary Material E, we provide concrete efficiency estimations showing that, in terms of signature length, the above realization competes with its random-oracle-model counterpart. We now state our main security results.

Theorem 5.1. *The scheme provides unforgeability if: (i) OTS is a strongly unforgeable one-time signature; (ii) The scheme of Section 3.2 is a secure dense \mathcal{R}_{BM} -lossy PKE scheme; (iii) The DCR assumption holds; (iv) Π^{uss} is an unbounded simulation-sound NIZK argument for the parametrized language \mathcal{L}_V^{1-R} .*

Proof. To prove the result, we consider a sequence of games starting with the real unforgeability experiment and ending with a game where we give a direct reduction from the simulation-soundness of Π^{uss} . In each game, we call W_i the event that the challenger outputs 1.

Game₀: This is the real unforgeability experiment. The adversary \mathcal{A} receives a CRS ρ and is granted access to a key generation oracle **Keygen**, a signing oracle **Sign** and a corruption oracle **Corrupt**. At the i -th query to **Keygen**, the challenger returns a verification key of the form $vk^{(i)} = h^{y_i} \cdot w_i^{\bar{N}} \bmod N^2$ for some $w_i \leftarrow U(\mathbb{Z}_{\bar{N}}^*)$, $y_i \leftarrow U(\mathbb{Z}_{\bar{N}})$ and keeps $sk^{(i)} = (w_i, y_i)$ for later use. If \mathcal{A} makes a corruption query **Corrupt** (i) , the challenger reveals $sk^{(i)}$. At each signing query (i, M, R) , the challenger returns \perp if R contains a key $vk \notin \mathbb{Z}_{\bar{N}^2}^*$. Otherwise, it runs $\Sigma \leftarrow \text{Sign}(\rho, sk, M, R)$ and returns Σ to \mathcal{A} . When \mathcal{A} halts, it outputs a triple (M^*, R^*, Σ^*) , where $R^* = \{vk_0^*, \dots, vk_{R-1}^*\}$ and $\Sigma^* = (\text{VK}^*, (L_1^*, \dots, L_r^*), \pi^*, \text{sig}^*)$, and the challenger outputs 1 if: (i) $\text{Verify}(\rho, M^*, \Sigma^*, R^*) = 1$; (ii) R^* only consists of uncorrupted keys produced by the **Keygen** oracle; (iii) No signing query (\cdot, M^*, R^*) was made. By definition, we have $\Pr[W_0] = \text{Adv}_{\mathcal{A}}^{\text{unforge}}(\lambda)$.

Game₁: This is like **Game₀** except that we introduce a failure event. The challenger initially chooses a random index $i^* \leftarrow U([Q_V])$, where Q_V is the number of **Keygen**-queries. The challenger \mathcal{B} outputs 0 if \mathcal{A} outputs a forgery

$\Sigma^* = (\text{VK}^*, (L_1^*, \dots, L_r^*), \pi^*, \text{sig}^*)$ containing a VK^* that coincides with a verification key contained in the output of a signing query of the form (i^*, \cdot, \cdot) . If the failure event does not occur, the challenger outputs the same result as in Game_0 . The strong unforgeability of OTS implies that $\Pr[W_1]$ cannot noticeably differ from $\Pr[W_0]$. We can easily turn \mathcal{B} into a one-time-signature forger such that $|\Pr[W_1] - \Pr[W_0]| \leq Q_V \cdot Q_S \cdot \text{Adv}_{\mathcal{B}}^{\text{ots}}(\lambda)$.

Game₂: This is like Game_1 with one change at step 3 of CRSGen . Instead of sampling $K \leftarrow U(\mathcal{K})$ uniformly, the challenger runs $K \leftarrow \text{AdmSmp}(1^\lambda, Q_S, \delta)$ to generate a key $K \in \{0, 1, \perp\}^L$ for an admissible hash function $\text{AHF} : \{0, 1\}^{\ell_v} \rightarrow \{0, 1\}^L$, where Q_S is an upper bound on the number of signing queries. Then, the sampled key K is used as an initialization value to generate $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K)$. By the second indistinguishability property of the dense \mathcal{R}_{BM} -lossy PKE scheme (which holds in the statistical sense), changing the initialization value does not impact \mathcal{A} 's view. In particular, the scheme of Section 3.2 has the property that the distribution of lossy public keys is perfectly independent of K . It follows that $\Pr[W_2] = \Pr[W_1]$.

Game₃: This game is like Game_2 with one change. When \mathcal{A} halts and outputs $\Sigma^* = (\text{VK}^*, (L_1^*, \dots, L_r^*), \pi^*, \text{sig}^*)$, the challenger checks if the conditions

$$F_{\text{ADH}}(K, \text{VK}^{(1)}) = \dots = F_{\text{ADH}}(K, \text{VK}^{(Q_S)}) = 1 \wedge F_{\text{ADH}}(K, \text{VK}^*) = 0 \quad (24)$$

are satisfied, where VK^* is the one-time verification key in the forgery and $\text{VK}^{(1)}, \dots, \text{VK}^{(Q_S)}$ are those involved in signing queries of the form (i^*, \cdot, \cdot) . If these conditions do not hold, the challenger aborts and returns 0. For simplicity, we assume that \mathcal{B} aborts at the beginning of the game if it detects that there exists $j \in [Q_S]$ such that $F_{\text{ADH}}(K, \text{VK}^{(j)}) = 0$ (recall that the verification keys $\{\text{VK}^{(j)}\}_{j=1}^{Q_S}$ used in signing queries (i^*, \cdot, \cdot) can be chosen at the outset of the game by \mathcal{B}). If conditions (24) are satisfied, the challenger returns 1 whenever the challenger of Game_2 does. Letting Fail denote the event that \mathcal{B} aborts because (24) does not hold, we have $W_3 = W_2 \wedge \neg \text{Fail}$. Since K is perfectly independent of the distribution of keys produced by LKeygen , we can apply Theorem 2.6 to argue that there is a noticeable function $\delta(\lambda)$ such that $\Pr[\neg \text{Fail}] \geq \delta(\lambda)$. This implies

$$\Pr[W_3] = \Pr[W_2 \wedge \neg \text{Fail}] \geq \delta(\lambda) \cdot \Pr[W_2] , \quad (25)$$

where the inequality stems from the fact that Fail is independent of W_1 since K is statistically independent of \mathcal{A} 's view.

We note that, if conditions (24) are satisfied in Game_3 , the sequence of one-time verification keys $(\text{VK}^{(1)}, \dots, \text{VK}^{(Q_S)}, \text{VK}^*)$ satisfies $\mathcal{R}_{\text{BM}}(K, \text{VK}^*) = 1$ and $\mathcal{R}_{\text{BM}}(K, \text{VK}^{(j)}) = 0$ for all $j \in [Q_S]$.

Game₄: We modify the distribution of crs. At step 3 of CRSGen , we generate the keys for \mathcal{R} -LPKE as injective keys $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{Keygen}(\Gamma, K)$ instead

of lossy keys $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K)$. The weak indistinguishability property (i) of \mathcal{R} -LPKE (see Definition 2.10) ensures that $\Pr[W_4]$ and $\Pr[W_3]$ are negligibly far apart. Indeed, we can immediately build a reduction \mathcal{B} from this property of \mathcal{R} -LPKE in order to transition from Game_3 to Game_4 . We thus have $|\Pr[W_4] - \Pr[W_3]| \leq \mathbf{Adv}_{\mathcal{B}}^{\text{indist-LPKE-1}}(\lambda) \leq \mathbf{Adv}^{\text{DCR}}(\lambda)$.

Game₅: In this game, the challenger uses the secret key $\text{sk} = (\bar{p}, \bar{q}, K)$ produced by $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{Keygen}(\Gamma, K)$ (which contains the factors of $\bar{N} = \bar{p}\bar{q}$) to extract the content of commitments $\{(L_j^*, \bar{A}_j^*)\}_{j=1}^r$ contained in \mathcal{A} 's forgery. Note that, if the conditions (24) introduced in Game_3 are satisfied, \mathcal{A} 's output $\Sigma^* = (\text{VK}^*, (L_1^*, \dots, L_r^*), \pi^*, \text{sig}^*)$ involves an injective tag VK^* , which allows extracting the content of all commitments generated for this tag. If the challenger does not fail, it thus obtains $\{(\ell_j^*, \bar{a}_j^*)\}_{j=1}^r$ and also outputs 0 if there exists $j \in [r]$ such that $\ell_j^* \notin \{0, 1\}$. Otherwise, it obtains a string $\ell_1^* \dots \ell_r^* \in \{0, 1\}^r$ and reconstructs the index $\ell^* = \sum_{k=1}^r \ell_k^* \cdot 2^{k-1} \in \mathbb{Z}_R$ of the verification key $vk_{\ell^*}^* = C_{\ell^*}^*$ in the ring $\mathbb{R}^* = \{vk_0^*, \dots, vk_{R-1}^*\}$. If $\ell_j^* \notin \{0, 1\}$ for some $j \in [r]$, the soundness of Π^{uss} (and thus its simulation-soundness) is broken and we have $|\Pr[W_5] - \Pr[W_4]| \leq 2^{-\Omega(\lambda)} + \mathbf{Adv}^{\text{uss}}(\lambda)$.

Game₆: This game is like Game_5 with the following change. Recall that, in Game_1 and subsequent games, the challenger initially chooses a random index $i^* \leftarrow U([Q_V])$. Now, we let the challenger abort and output 0 if the verification key $vk_{\ell^*}^*$ contained in \mathbb{R}^* does not coincide with the verification key $vk^{(i^*)}$ returned by the challenger at the i^* -th query to the Keygen oracle. In addition, the challenger aborts and outputs 0 if \mathcal{A} makes the corruption query $\text{Corrupt}(i^*)$. Otherwise (i.e., if $vk_{\ell^*}^* = vk^{(i^*)}$ and $sk^{(i^*)}$ is not corrupted), the challenger outputs the same bit as in Game_5 . Since i^* is chosen independently of \mathcal{A} 's view, it is correct with probability $1/Q_V$, where Q_V is the number of Keygen -queries. We thus have $\Pr[W_6] = \Pr[W_5]/Q_V$.

Game₇: This game is identical to Game_6 except that, in all signing queries (i, M, \mathbb{R}) , such that $i = i^*$,⁸ the challenger simulates the Sign oracle by running the NIZK simulator of Π^{uss} instead of using the real witness. Namely, the commitments $\{L_j\}_{j=1}^r$ of each signature $\Sigma = (\text{VK}, (L_1, \dots, L_r), \pi, \text{sig})$ still commit to the binary decomposition (ℓ_1, \dots, ℓ_r) of $vk^{(i^*)}$'s location in \mathbb{R} but π is simulated without using $sk^{(i^*)}$ nor $((\ell_1, \dots, \ell_r), t_1, \dots, t_r)$. Recall that, when $h \in \mathbb{Z}_{N^2}^*$ and $\bar{h} = \bar{h}_{\text{VK}} \in \mathbb{Z}_{\bar{N}^2}^*$ have order at least N and \bar{N} , respectively, the trapdoor Σ -protocol of Section 4.3 is statistically special zero-knowledge. Also, all commitments generated using \mathcal{R} -LPKE are perfectly hiding when \bar{h}_{VK} has order at least \bar{N} . Moreover, the latter condition is met when (24) holds since, in this case, the zero-knowledge simulator computes the commitments (L_1, \dots, L_r) and $\{(\bar{A}_j, \bar{B}_j)\}_{j=1}^r$ on lossy tags $\text{VK}^{(j)}$. The statistical ZK properties of Π^{uss} and the underlying trapdoor Σ -protocol then ensure that $|\Pr[W_7] - \Pr[W_6]| \leq Q_S \cdot 2^{-\Omega(\lambda)}$.

⁸ Signing queries (i, M, \mathbb{R}) with $i \neq i^*$ are still faithfully answered in such a way that we do not need to rely on erasures when users $i \neq i^*$ are corrupted after a signing query of the form (i, \dots) .

Game₈: This game is like **Game₇** except that we change the distribution of the CRS $\rho = (\text{crs}, h, \text{pk}, \Gamma, \text{OTS})$. Instead of sampling h uniformly in $\mathbb{Z}_{N^2}^*$, we now choose it as a random N -th residue. Namely, the challenger now sets $h = h_0^N \bmod N^2$, where $h_0 \leftarrow U(\mathbb{Z}_N^*)$. Under the DCR assumption in $\mathbb{Z}_{N^2}^*$, this change has no noticeable impact on \mathcal{A} 's forging probability and a straightforward reduction shows that $|\Pr[W_8] - \Pr[W_7]| \leq \mathbf{Adv}^{\text{DCR}}(\lambda)$.

We note that, due to the modification introduced in **Game₈**, all public keys produced by the **Keygen** oracle live in the subgroup of N -th residues in $\mathbb{Z}_{N^2}^*$.

Game₉: We change the distribution of $vk^{(i^*)} = C^{(i^*)}$ and sample $C^{(i^*)} \leftarrow U(\mathbb{Z}_{N^2}^*)$ uniformly instead of sampling it as an N -th residue in $\mathbb{Z}_{N^2}^*$. Since the secret key $sk^{(i^*)}$ is not used in **Game₈**, we can rely on the DCR assumption in $\mathbb{Z}_{N^2}^*$ and argue that $|\Pr[W_9] - \Pr[W_8]| \leq \mathbf{Adv}^{\text{DCR}}(\lambda)$.

In **Game₉**, we claim that $\Pr[W_9] \leq \mathbf{Adv}^{\text{uss}}(\lambda) + 2^{-\Omega(\lambda)}$ as, except with probability $1/N < 2^{-\Omega(\lambda)}$, the challenger can only output 1 if \mathcal{A} breaks the simulation-soundness of Π^{uss} . Indeed, W_9 only occurs if $vk_{\ell^*}^* = vk^{(i^*)}$ (which implies that no query **Corrupt**(i^*) was made); π^* is a valid argument for the statement $((vk_0^*, \dots, vk_{R-1}^*), (L_1^*, \dots, L_r^*)) \in \mathcal{L}_V^{1-R}(h, \bar{h}_{\text{VK}^*})$; and no signing query (i, M^*, R^*) has been made for any $vk^{(i)} \in \mathbf{R}^*$ (in particular for $i = i^*$). Since $vk_{\ell^*}^*$ was sampled uniformly in $\mathbb{Z}_{N^2}^*$, it is *not* an N -th residue except with probability $1/N$. This shows that, except with probability $2^{-\Omega(\lambda)}$, W_9 only occurs when π^* is an accepting argument for a false statement $\mathbf{x}^* \in \mathcal{L}_V^{1-R}(h, \bar{h}_{\text{VK}^*})$ on an unqueried label $\text{lbl}^* \triangleq \text{VK}^*$.

Putting the above altogether, we can bound the adversary's advantage as

$$\mathbf{Adv}_A^{\text{unforge}}(\lambda) \leq \frac{1}{\delta} \cdot (2Q_V + 1) \cdot \left(\mathbf{Adv}^{\text{uss}}(\lambda) + \mathbf{Adv}^{\text{DCR}}(\lambda) + Q_S \cdot 2^{-\Omega(\lambda)} \right) + Q_S \cdot Q_V \cdot \mathbf{Adv}^{\text{ots}}(\lambda)$$

where Q_V is the number of **Keygen**-queries and Q_S is the number of signing queries. \square

The proof of anonymity follows from the fact that all commitments are perfectly hiding when the CRS ρ is configured as in the real scheme. The proof of **Theorem 5.2** is identical to that of **Theorem D.2** in Supplementary Material **D**.

Theorem 5.2. *The above construction instantiated with the trapdoor Σ -protocol of Section 4.3 provides full anonymity under key exposure provided Π^{uss} is a statistical NIZK argument for the language $\mathcal{L}_V^{1-R}(h, \bar{h}_{\text{VK}})$ of (23) when the order of h is a multiple of N and the order of \bar{h}_{VK} is a multiple of \bar{N} .*

Supplementary Material

A Non-Interactive Zero-Knowledge and Simulation-Sound Arguments

We recall the definitions of NIZK proofs. Since it is sufficient for our applications, we allow the common reference string to be generated as a function of the language \mathcal{L} .

In addition, we consider NIZK argument systems where each argument comes with a label lbl taken as input by both the prover and the verifier.

Definition A.1. *A non-interactive zero-knowledge (NIZK) argument system Π for a language \mathcal{L} associated with an NP relations R consists of four PPT algorithms $(\text{Gen}_{\text{par}}, \text{Gen}_{\mathcal{L}}, \text{P}, \text{V})$ with the following syntax:*

- $\text{Gen}_{\text{par}}(1^\lambda)$ takes as input a security parameter λ and outputs public parameters par .
- $\text{Gen}_{\mathcal{L}}(1^\lambda, \mathcal{L}, \tau_{\mathcal{L}})$ takes as input a security parameter λ , the description of \mathcal{L} which specifies a statement length N , and a membership testing trapdoor $\tau_{\mathcal{L}}$ for \mathcal{L} . It outputs the language-dependent part $\text{crs}_{\mathcal{L}}$ of the common reference string $\text{crs} = (\text{par}, \text{crs}_{\mathcal{L}})$.
- $\text{P}(\text{crs}, x, w, \text{lbl})$ is a proving algorithm taking as input the common reference string crs , a statement $x \in \{0, 1\}^N$, a witness w such that $(x, w) \in R$ and a label lbl . It outputs a proof π .
- $\text{V}(\text{crs}, x, \pi, \text{lbl})$ is a verification algorithm taking as input a common reference string crs , a statement $x \in \{0, 1\}^N$, and a proof π . It outputs 1 or 0.

Moreover, Π should satisfy the following properties. For simplification we denote below by Setup an algorithm that runs successively Gen_{par} and $\text{Gen}_{\mathcal{L}}$ to generate a common reference string.

- **Completeness:** For any $(x, w) \in R$ and any $\text{lbl} \in \{0, 1\}^*$, we have

$$\Pr \left[\text{crs} \leftarrow \text{Setup}(1^\lambda, \mathcal{L}), \right. \\ \left. \pi \leftarrow \text{P}(\text{crs}, x, w, \text{lbl}) : \text{V}(\text{crs}, x, \pi, \text{lbl}) = 1 \right] \geq 1 - \text{negl}(\lambda).$$

- **Soundness:** For any $x \in \{0, 1\}^N \setminus \mathcal{L}$ and any PPT prover P^* , we have

$$\Pr \left[\text{crs} \leftarrow \text{Setup}(1^\lambda, \mathcal{L}), (\pi, \text{lbl}) \leftarrow P^*(\text{crs}, x) : \text{V}(\text{crs}, x, \pi, \text{lbl}) = 1 \right] \leq \text{negl}(\lambda).$$

- **Zero-Knowledge:** There is a PPT simulator $(\text{Sim}_0, \text{Sim}_1)$ such that, for any PPT adversary \mathcal{A} , we have

$$\left| \Pr[\text{crs} \leftarrow \text{Setup}(1^\lambda, \mathcal{L}) : 1 \leftarrow \mathcal{A}^{\text{P}(\text{crs}, \cdot, \cdot)}(\text{crs})] \right. \\ \left. - \Pr[(\text{crs}, \tau_{\text{zk}}) \leftarrow \text{Sim}_0(1^\lambda, \mathcal{L}) : 1 \leftarrow \mathcal{A}^{\text{O}(\text{crs}, \tau_{\text{zk}}, \cdot, \cdot)}(\text{crs})] \right| \leq \text{negl}(\lambda).$$

Here, $P(\text{crs}, \cdot, \cdot)$ is an oracle that outputs \perp on input of $(x, w, \text{lbl}) \notin R$ and outputs a valid proof $\pi \leftarrow P(\text{crs}, x, w, \text{lbl})$ otherwise; $\mathcal{O}(\text{crs}, \tau_{\text{zk}}, \cdot, \cdot)$ is an oracle that outputs \perp on input of (x, w, lbl) such that $(x, w) \notin R$ and outputs a simulated argument $\pi \leftarrow \text{Sim}_1(\text{crs}, \tau_{\text{zk}}, x, \text{lbl})$ on input of (x, w, lbl) such that $(x, w) \in R$. Note that this simulated proof π is generated independently of the witness w provided as input.⁹

The notion of soundness captured by Definition A.1 is *non-adaptive* in that the statement is given as input to the dishonest prover and chosen independently of the common reference string. The stronger notion of *adaptive soundness* allows the target statement to be chosen by the adversary after having received the common reference string. It is known (see, e.g., [58]) that perfect or statistical NIZK arguments cannot provide adaptive soundness under falsifiable assumptions. The reason lies in the impossibility of recognizing when the adversary wins and outputs a proof for a false statement. One way to bypass the impossibility results is to consider *trapdoor languages*, where a trapdoor can be used to recognize false statements. In our application to ring signatures, we will consider a notion of adaptive soundness for trapdoor languages.

Definition A.1 captures a notion of multi-theorem zero-knowledge, which allows the adversary to obtain proofs for multiple statements. Feige *et al.* [35] gave a generic transformation of a multi-theorem NIZK argument system from a single-theorem one (where the adversary can only invoke the oracle once).

SIMULATION-SOUNDNESS. We now recall the definition of simulation-soundness introduced in [62], which informally captures the adversary’s inability to create a new proof for a false statement x^* even after having seen simulated proofs for possibly false statements $\{x_i\}_i$ of its choice.

In the following, in order to allow a challenger to efficiently check the winning condition (ii) in the security experiment, we restrict ourselves to *trapdoor languages*, where a language-specific trapdoor $\tau_{\mathcal{L}}$ makes it possible to determine if a given statement $x^* \in \{0, 1\}^N$ belongs to the language \mathcal{L} with overwhelming probability. This restriction has no impact on our applications where we always have a membership testing trapdoor $\tau_{\mathcal{L}}$ at our disposal.

Definition A.2 ([62,31]). *Let a language \mathcal{L} . A NIZK argument system for \mathcal{L} provides **unbounded simulation soundness** if no PPT adversary has noticeable advantage in this game.*

1. *The challenger chooses a membership testing trapdoor $\tau_{\mathcal{L}}$ that allows recognizing elements of \mathcal{L} . Let $\text{Sim} = (\text{Sim}_0, \text{Sim}_1)$ be an efficient NIZK simulator for \mathcal{L} . The challenger runs $(\text{crs}, \tau_{\text{zk}}) \leftarrow \text{Sim}_0(1^\lambda, \mathcal{L})$ and gives $(\text{crs}, \tau_{\mathcal{L}})$ to the adversary \mathcal{A} .*
2. *The adversary \mathcal{A} is given oracle access to $\text{Sim}_1(\text{crs}, \tau_{\text{zk}}, \cdot, \cdot)$. At each query, \mathcal{A} chooses a statement $x \in \{0, 1\}^N$ and a label $\text{lbl} \in \{0, 1\}^*$. It obtains a simulated argument $\pi \leftarrow \text{Sim}_1(\text{crs}, \tau_{\text{zk}}, x, \text{lbl})$.*

⁹ In particular, Sim_1 can be run on any statement x , even $x \notin \mathcal{L}$.

3. \mathcal{A} outputs $(x^*, \text{lbl}^*, \pi^*)$.

Let \mathcal{Q} be the set of all simulation queries and responses $(x_i, \text{lbl}_i, \pi_i)$ made by \mathcal{A} to $\text{Sim}_1(\text{crs}, \tau_{\text{zk}}, \cdot, \cdot)$. The adversary \mathcal{A} wins if the following conditions are satisfied: (i) $(x^*, \text{lbl}^*, \pi^*) \notin \mathcal{Q}$; (ii) $x^* \notin \mathcal{L}$; and (iii) $V(\text{crs}, x^*, \pi^*, \text{lbl}^*) = 1$. The adversary's advantage $\text{Adv}_{\mathcal{A}}^{\text{USS}}(\lambda)$ is its probability of success taken over all coin tosses.

B Simulation-Sound NIZK Arguments from Trapdoor Σ -Protocols

In [50], the authors construct unbounded simulation-sound NIZK arguments by combining a trapdoor Σ -protocol and an \mathcal{R} -lossy public-key encryption scheme.

B.1 The Argument System

In order to apply the construction of [50] to trapdoor Σ -protocols with r bad challenges, we need a CI hash function for efficiently enumerable relations $R \subseteq \mathcal{X} \times \mathcal{Y}$ where, for each $x \in \mathcal{Y}$, the set $\mathcal{Y}_x = \{y \in \mathcal{Y} \mid (x, y) \in R\}$ has cardinality at most $|\mathcal{Y}_x| \leq r$ and is efficiently computable from x .

The hash function of Peikert and Shiehian [59] provides this property. They provide a correlation intractable hash function for efficiently searchable relations. The bootstrapping theorem of [59] actually implies the existence of such a hash family under the LWE assumption with polynomial approximation factors. In [15], it was further observed that any CI hash function for efficiently searchable relations is also correlation intractable for efficiently enumerable relations.

The construction hereunder thus adapts [50] using the following ingredients:

- A trapdoor Σ -protocol $\Pi' = (\text{Gen}'_{\text{par}}, \text{Gen}'_{\mathcal{L}}, \text{P}', \text{V}')$ for the same language \mathcal{L} with challenge space $\mathcal{C} = \{0, 1\}^\lambda$ and which satisfies the properties of Definition 2.8. This language is assumed to be a trapdoor language in that its description can be sampled with a trapdoor $\tau_{\mathcal{L}}$ allowing to test membership of \mathcal{L} . In addition, $\text{BadChallenge}(\tau_{\Sigma}, \text{crs}, x, \mathbf{a})$ should be computable within time $T \in \text{poly}(\lambda)$ for any input $(\tau_{\Sigma}, \text{crs}, x, \mathbf{a})$.
- A strongly unforgeable one-time signature scheme $\text{OTS} = (\mathcal{G}, \mathcal{S}, \mathcal{V})$ with verification keys of length $\ell_v \in \text{poly}(\lambda)$.
- An admissible hash function $\text{AHF} : \{0, 1\}^{\ell_v} \rightarrow \{0, 1\}^L$, for some $L \in \text{poly}(\lambda)$ with $L > \ell_v$, which induces the relation $\mathcal{R}_{\text{BM}} : \{0, 1, \perp\}^L \times \{0, 1\}^{\ell_v} \rightarrow \{0, 1\}$.
- An \mathcal{R} -lossy PKE scheme $\mathcal{R}\text{-LPKE} = (\text{Par-Gen}, \text{Keygen}, \text{LKeygen}, \text{Encrypt}, \text{Decrypt}, \text{Opener}, \text{LOpener})$ for the relation $\mathcal{R}_{\text{BM}} : \{0, 1, \perp\}^L \times \{0, 1\}^L \rightarrow \{0, 1\}$ with public (resp. secret) key space \mathcal{PK} (resp. \mathcal{SK}). We assume that Decrypt is computable within time T . We denote the message (resp. ciphertext) space by MsgSp (resp. CtSp) and the randomness space by R^{LPKE} . Let also D_R^{LPKE} denote the distribution from which the random coins of Encrypt are sampled.

- A correlation intractable hash family $\mathcal{H} = (\text{Gen}, \text{Hash})$ with output length λ for the class \mathcal{R}_{CI} of relations that are efficiently enumerable within time T .

It is required that P' outputs a first prover message \mathbf{a} which fits in the message space MsgSp of \mathcal{R} -LPKE.

The argument system $\Pi^{\text{uss}} = (\text{Gen}_{\text{par}}, \text{Gen}_{\mathcal{L}}, P, V)$ allows P and V to input a label lbl consisting of public data that can be bound to non-interactive arguments in a non-malleable way. The construction proceeds as follows.

Gen_{par}(1^λ): Run $\text{par} \leftarrow \text{Gen}'_{\text{par}}(1^\lambda)$ and output par .

Gen_L(par, \mathcal{L}): Given public parameters par and a language $\mathcal{L} \subset \{0, 1\}^N$, the CRS is generated as follows.

1. Generate a CRS $\text{crs}'_{\mathcal{L}} \leftarrow \text{Gen}'_{\mathcal{L}}(\text{par}, \mathcal{L})$ for the trapdoor Σ -protocol Π' .
2. Choose a random member $\text{AHF} : \{0, 1\}^{\ell_v} \rightarrow \{0, 1\}^L$ of an admissible hash function family.
3. Generate public parameters $\Gamma \leftarrow \text{Par-Gen}(1^\lambda, 1^L, 1^B)$ for the \mathcal{R}_{BM} -lossy PKE scheme where $\mathcal{R}_{\text{BM}} : \mathcal{K} \times \mathcal{T} \rightarrow \{0, 1\}$ is the bit-matching relation and $B \in \text{poly}(\lambda)$ is the length of the first prover messages. Given the spaces $\mathcal{K} = \{0, 1, \perp\}^L$ and $\mathcal{T} = \{0, 1\}^L$ specified by Γ , choose a random initialization value $K \leftarrow \mathcal{K}$ and generate lossy keys $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K)$.
4. Generate a key $k \leftarrow \text{Gen}(1^\lambda)$ for a correlation intractable hash function with output length λ .

Output the language-dependent $\text{crs}_{\mathcal{L}} := (\text{crs}'_{\mathcal{L}}, k)$ and the simulation trapdoor $\tau_{\text{zk}} := \text{sk}$, which is the lossy secret key of \mathcal{R} -LPKE. The global common reference string consists of $\text{crs} = (\text{par}, \text{crs}_{\mathcal{L}}, \text{pk}, \text{AHF}, \text{OTS})$.

P($\text{crs}, x, w, \text{lbl}$): To prove a statement x for a label $\text{lbl} \in \{0, 1\}^*$ using $w \in R(x)$, generate a one-time signature key pair $(\text{VK}, \text{SK}) \leftarrow \mathcal{G}(1^\lambda)$. Then,

1. Compute $(\mathbf{a}', st') \leftarrow P'(\text{crs}'_{\mathcal{L}}, x, w)$ using the prover of Π' . Then, compute $\mathbf{a} \leftarrow \text{Encrypt}(\text{pk}, \text{AHF}(\text{VK}), \mathbf{a}'; \mathbf{r})$ using random coins $\mathbf{r} \leftarrow D_R^{\text{LPKE}}$.
2. Compute $\text{Chall} = \text{Hash}(k, (x, \mathbf{a}, \text{VK})) \in \{0, 1\}^\lambda$.
3. Compute $\mathbf{z}' = P'(\text{crs}'_{\mathcal{L}}, x, w, \mathbf{a}', \text{Chall}, st')$. Define $\mathbf{z} = (\mathbf{z}', \mathbf{a}', \mathbf{r})$.
4. Generate $\text{sig} \leftarrow \mathcal{S}(\text{SK}, (x, \mathbf{z}, \text{lbl}))$ and output $\boldsymbol{\pi} = (\text{VK}, \mathbf{z}, \text{sig})$.

V($\text{crs}, x, \boldsymbol{\pi}, \text{lbl}$): Given a statement x , a label lbl as well as a purported proof $\boldsymbol{\pi} = (\text{VK}, (\mathbf{a}, \mathbf{z}), \text{sig})$, return 0 if $\mathcal{V}(\text{VK}, (x, \mathbf{z}, \text{lbl}), \text{sig}) = 0$. Otherwise,

1. Write \mathbf{z} as $\mathbf{z} = (\mathbf{z}', \mathbf{a}', \mathbf{r})$ and return 0 if they do not parse properly (in particular, if $\mathbf{r} \notin R^{\text{LPKE}}$). Otherwise, set $\mathbf{a} = \text{Encrypt}(\text{pk}, \text{AHF}(\text{VK}), \mathbf{a}'; \mathbf{r})$.
2. Let $\text{Chall} = \text{Hash}(k, (x, \mathbf{a}, \text{VK}))$. If $V'(\text{crs}'_{\mathcal{L}}, x, (\mathbf{a}', \text{Chall}, \mathbf{z}')) = 1$, return 1. Otherwise, return 0.

The NIZK simulator uses a technique due to Damgård [29], which uses a trapdoor commitment scheme to achieve a straight-line simulation of 3-move zero-knowledge proofs in the common reference string model.

Theorem B.1 ([50]). *The above argument is multi-theorem zero-knowledge if the trapdoor Σ -protocol Π' is special zero-knowledge.*

Proof. The proof was given in [50, Theorem 3.3]. For completeness, we recall the simulator $(\text{Sim}_0, \text{Sim}_1)$ which uses the lossy secret key $\tau_{\text{zk}} = \text{sk}$ of \mathcal{R} -LPKE to simulate transcripts $(\mathbf{a}, \text{Chall}, \mathbf{z})$ without using the witnesses. Namely, on input of $\text{par} \leftarrow \text{Gen}_{\text{par}}(1^\lambda)$, Sim_0 generates $\text{crs}_{\mathcal{L}}$ by proceeding identically to $\text{Gen}_{\mathcal{L}}$ while Sim_1 is described hereunder.

Sim₁($\text{crs}, \tau_{\text{zk}}, x, \text{lbl}$): On input a statement $x \in \{0, 1\}^N$, a label lbl and the simulation trapdoor $\tau_{\text{zk}} = \text{sk}$, algorithm Sim_1 proceeds as follows.

1. Generate a one-time signature key pair $(\text{VK}, \text{SK}) \leftarrow \mathcal{G}(1^\lambda)$. Let $\mathbf{0}^{|\mathbf{a}'|}$ the all-zeroes string of the same length as the first prover message of Π' . Compute $\mathbf{a} \leftarrow \text{Encrypt}(\text{pk}, \text{AHF}(\text{VK}), \mathbf{0}^{|\mathbf{a}'|}; \mathbf{r}_0)$ using random coins $\mathbf{r}_0 \leftarrow D_R^{\text{LPKE}}$ independently sampled from the distribution D_R^{LPKE} .
2. Compute $\text{Chall} = \text{Hash}(k, (x, \mathbf{a}, \text{VK})) \in \{0, 1\}^\lambda$.
3. Run the ZK simulator $(\mathbf{a}', \mathbf{z}') \leftarrow \text{ZKSim}(\text{crs}_{\mathcal{L}}, x, \text{Chall})$ of Π' to obtain a simulated transcript $(\mathbf{a}', \text{Chall}, \mathbf{z}')$ of Π' for the challenge $\text{Chall} \in \{0, 1\}^\lambda$.
4. Using the lossy secret key sk of \mathcal{R} -LPKE, compute random coins $\mathbf{r} \leftarrow \text{LOpener}(\text{pk}, \text{sk}, \text{AHF}(\text{VK}), \mathbf{a}, \mathbf{0}^{|\mathbf{a}'|}, \mathbf{a}', \mathbf{r}_0)$ which explain \mathbf{a} as an encryption of \mathbf{a}' under the tag $\text{AHF}(\text{VK})$. Then, define $\mathbf{z} = (\mathbf{z}', \mathbf{a}', \mathbf{r})$.
5. Generate a one-time signature $\text{sig} \leftarrow \mathcal{S}(\text{SK}, (x, \mathbf{z}, \text{lbl}))$ and output the proof $\boldsymbol{\pi} = (\text{VK}, \mathbf{z}, \text{sig})$.

We refer to [50, Theorem 3.3] for a proof that the simulation is indistinguishable from a real argument. In particular, the proof shows that zero-knowledge holds in the statistical sense if Π' is statistically special ZK. \square

Theorem B.2 states the unbounded simulation-soundness property. The proof is identical to that of [50, Theorem 3.4] with a slight modification since we consider efficiently enumerable relations (and not only unique-output efficiently searchable relations). The difference with the proof of [50] is just syntactical since we need a BadChallenge function that outputs an enumerable set instead of a single element of the challenge space.

As in [50], the proof uses the \mathcal{R} -lossy PKE scheme as a trapdoor commitment to equivocate lossy encryptions of the first prover message in Π' while forcing the adversary's fake proof to take place on an extractable commitment.

Theorem B.2. *The above non-interactive argument system provides unbounded simulation-soundness if: (i) OTS is a strongly unforgeable one-time signature; (ii) \mathcal{R} -LPKE is an \mathcal{R}_{BM} -lossy PKE scheme; (iii) \mathcal{H} is correlation-intractable for all relations that are enumerable within time T , where T denotes the maximal running time of algorithms $\text{BadChallenge}(\cdot, \cdot, \cdot, \cdot)$ and $\text{Decrypt}(\cdot, \cdot, \cdot)$.*

Proof. We consider a sequence of games where, for each i , we define a variable $W_i \in \{\text{true}, \text{false}\}$ where $W_i = \text{true}$ if and only if the adversary wins in Game_i .

Game₀: This is the real game of Definition A.2. Namely, the challenger runs $(\text{crs}, \tau_{\text{zk}}) \leftarrow \text{Sim}_0(\text{par}, 1^N)$ and gives $\text{crs} = (\text{par}, \text{crs}_{\mathcal{L}}, \Gamma, \text{pk}, \text{AHF}, \Pi^{\text{ots}})$ to the adversary \mathcal{A} . At the same time, the challenger generates a trapdoor $\tau_{\mathcal{L}}$ for the language \mathcal{L} in such a way that it can efficiently test if \mathcal{A} 's output satisfies the winning condition (ii). The adversary is granted oracle access to $\text{Sim}_1(\text{crs}, \tau_{\text{zk}}, \cdot, \cdot)$. At each query, \mathcal{A} chooses a statement $x \in \{0, 1\}^N$ with a label lbl and the challenger replies by returning a simulated argument $\pi \leftarrow \text{Sim}_1(\text{crs}, \tau_{\text{zk}}, x, \text{lbl})$. When \mathcal{A} halts, it outputs a triple $(x^*, \pi^*, \text{lbl}^*)$, where $\pi^* = (\text{VK}^*, \mathbf{z}^*, \text{sig}^*)$. The Boolean variable W_0 is thus set to $W_0 = \text{true}$ under the following three conditions: (i) $(x^*, \text{lbl}^*, \pi^*) \notin \mathcal{Q}$, where $\mathcal{Q} = \{(x_i, \text{lbl}_i, \pi_i)\}_{i=1}^Q$ denotes the set of queries to $\text{Sim}_1(\text{crs}, \tau_{\text{zk}}, \cdot, \cdot)$ and the corresponding responses $\pi_i = (\text{VK}^{(i)}, \mathbf{z}_i = (\mathbf{z}'_i, \mathbf{a}'_i, \mathbf{r}_i), \text{sig}_i)$; (ii) $x^* \notin \mathcal{L}$; and (iii) $V(\text{crs}, x^*, \pi^*, \text{lbl}^*) = 1$. We may assume w.l.o.g. that the one-time verification keys $\{\text{VK}^{(i)}\}_{i=1}^Q$ are chosen ahead of time at the beginning of the game. By definition we have $\text{Adv}_{\mathcal{A}}^{\text{uss}}(\lambda) = \Pr[W_0]$.

Game₁: This is like Game₀ except that the challenger \mathcal{B} sets $W_1 = \text{false}$ if \mathcal{A} outputs a fake proof $(x^*, \pi^*, \text{lbl}^*)$, where $\pi^* = (\text{VK}^*, \mathbf{z}^*, \text{sig}^*)$ contains a VK^* that coincides with the verification key $\text{VK}^{(i)}$ contained in an output $\pi_i = (\text{VK}^{(i)}, \mathbf{z}_i, \text{sig}_i)$ of $\text{Sim}_1(\text{crs}, \tau_{\text{zk}}, \cdot, \cdot)$. The strong unforgeability of OTS implies that $\Pr[W_1]$ cannot noticeably differ from $\Pr[W_0]$. We can easily turn \mathcal{B} into a forger such that $|\Pr[W_1] - \Pr[W_0]| \leq \text{Adv}_{\mathcal{B}}^{\text{ots}}(\lambda)$.

Game₂: This game is like Game₁ with the following changes. At step 2 of $\text{Gen}_{\mathcal{L}}$, the challenger runs $K \leftarrow \text{AdmSmp}(1^\lambda, Q, \delta)$ to generate a key $K \in \{0, 1, \perp\}^L$ for an admissible hash function $\text{AHF} : \{0, 1\}^{\ell_v} \rightarrow \{0, 1\}^L$, where Q is an upper bound on the number of adversarial queries. By the second indistinguishability property of the \mathcal{R}_{EM} -lossy PKE scheme (which holds in the statistical sense), we know that changing the initialization value does not significantly affect \mathcal{A} 's view. It follows that $|\Pr[W_2] - \Pr[W_1]| \leq 2^{-\Omega(\lambda)}$.

Game₃: This game is identical to Game₂ with one modification. When the adversary halts and outputs x^* , the challenger checks if the conditions

$$F_{\text{ADH}}(K, \text{VK}^{(1)}) = \dots = F_{\text{ADH}}(K, \text{VK}^{(Q)}) = 1 \wedge F_{\text{ADH}}(K, \text{VK}^*) = 0 \quad (26)$$

are satisfied, where VK^* is the one-time verification key in the adversary's output and $\text{VK}^{(1)}, \dots, \text{VK}^{(Q)}$ are those in adversarial queries. If these conditions do not hold, the challenger aborts and sets $W_3 = \text{false}$. For simplicity, we assume that \mathcal{B} aborts at the very beginning of the game if it detects that there exists $i \in [Q]$ such that $F_{\text{ADH}}(K, \text{VK}^{(i)}) = 0$ (recall that $\{\text{VK}^{(i)}\}_{i=1}^Q$ are chosen at the outset of the game by \mathcal{B}). If conditions (26) are satisfied, the challenger sets $W_3 = \text{true}$ whenever $W_1 = \text{true}$. Letting Fail denote the event that \mathcal{B} aborts because (26) does not hold, we have $W_3 = W_2 \wedge \neg \text{Fail}$. Since the key K of the admissible hash function is statistically independent of the adversary's view, we can apply Theorem 2.6 to argue that there is a noticeable function $\delta(\lambda)$ such that $\Pr[\neg \text{Fail}] \geq \delta(\lambda)$. This implies

$$\Pr[W_3] = \Pr[W_2 \wedge \neg \text{Fail}] \geq \delta(\lambda) \cdot \Pr[W_2] , \quad (27)$$

where the inequality stems from the fact that **Fail** is independent of W_1 since K is statistically independent of \mathcal{A} 's view.

We note that, if conditions (26) are satisfied in **Game**₃, the sequence of one-time verification keys $(\mathbf{VK}^{(1)}, \dots, \mathbf{VK}^{(Q)}, \mathbf{VK}^*)$ satisfies $\mathcal{R}_{\text{BM}}(K, \mathbf{VK}^*) = 1$ and $\mathcal{R}_{\text{BM}}(K, \mathbf{VK}^{(i)}) = 0$ for all $i \in [Q]$.

Game₄: We modify the oracle $\text{Sim}_1(\text{crs}, \tau_{\text{zk}}, \cdot, \cdot)$ and by exploiting the equivocation property of \mathcal{R} -LPKE for lossy tags (instead of lossy keys). At the i -th query (x_i, lbl_i) to $\text{Sim}_1(\text{crs}, \tau_{\text{zk}}, \cdot, \cdot)$, we must have $F_{\text{ADH}}(K, \mathbf{VK}^{(i)}) = 1$ (meaning that $\mathbf{VK}^{(i)}$ is a lossy tag as $\mathcal{R}_{\text{BM}}(K, \mathbf{VK}^{(i)}) = 0$) if \mathcal{B} did not abort. This allows \mathcal{B} to equivocate \mathbf{a} using the trapdoor key tk instead of the lossy secret key sk of \mathcal{R} -LPKE. Namely, at step 4 of Sim_1 , the modified $\text{Sim}_1(\text{crs}, \tau_{\text{zk}}, \cdot, \cdot)$ oracle computes random coins

$$\mathbf{r}_i \leftarrow \text{Opener}(\text{pk}, \text{tk}, \text{AHF}(\mathbf{VK}^{(i)}), \mathbf{a}_i, \mathbf{0}^{|\mathbf{a}'_i|}, \mathbf{a}'_i, \mathbf{r}_{i,0})$$

instead of running LOpener using sk . We define the variable W_4 exactly as W_3 . Since Opener and LOpener output samples from statistically close distributions on all lossy tags $\mathbf{VK}^{(i)}$, this implies $|\Pr[W_4] - \Pr[W_3]| \leq 2^{-\Omega(\lambda)}$.

Game₅: We now modify the distribution of crs . At step 2 of Gen , we generate the keys for \mathcal{R} -LPKE as injective keys $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{Keygen}(\Gamma, K)$ instead of lossy keys $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{LKeygen}(\Gamma, K)$. The indistinguishability property (i) of \mathcal{R} -LPKE ensures that $\Pr[W_5]$ and $\Pr[W_4]$ are negligibly far apart. Recall that this indistinguishability property ensures that the distributions of pairs (pk, tk) produced by Keygen and LKeygen are computationally indistinguishable. We can thus easily build a distinguisher \mathcal{B} against \mathcal{R} -LPKE that bridges between **Game**₄ and **Game**₅ (by using tk to simulate $\text{Sim}_1(\text{crs}, \tau_{\text{zk}}, \cdot, \cdot)$ as in **Game**₄). It comes that $|\Pr[W_5] - \Pr[W_4]| \leq \text{Adv}_{\mathcal{B}}^{\text{indist-LPKE}}(\lambda)$.

Due to the modification introduced in **Game**₅, if the conditions (26) are satisfied, we have $\mathcal{R}_{\text{BM}}(K, \text{AHF}(\mathbf{VK}^*)) = 1$, meaning that the adversary's fake proof $\boldsymbol{\pi}^* = (\mathbf{VK}^*, \mathbf{z}^* = (\mathbf{z}'^*, \mathbf{a}'^*, \mathbf{r}^*), \text{sig}^*)$ involves an injective tag \mathbf{VK}^* . Since pk is now an injective key, this implies that $\mathbf{a}^* = \text{Encrypt}(\text{pk}, \text{AHF}(\mathbf{VK}^*), \mathbf{a}'^*; \mathbf{r}^*)$ is an injective encryption of \mathbf{a}'^* under the tag \mathbf{VK}^* using the randomness \mathbf{r}^* .

Game₆: We change the distribution of $\text{crs} = (\text{par}, (\text{crs}'_{\mathcal{L}}, k), \text{pk}, \text{AHF}, \text{OTS})$ by relying on the CRS indistinguishability property of the trapdoor Σ -protocol Π' . Namely, we use the $\text{TrapGen}'$ algorithm of Definition 2.8 to generate $\text{crs}'_{\mathcal{L}}$ as $(\text{crs}'_{\mathcal{L}}, \tau_{\Sigma}) \leftarrow \text{TrapGen}'(\text{par}, \mathcal{L}, \tau_{\mathcal{L}})$ instead of $\text{crs}'_{\mathcal{L}} \leftarrow \text{Gen}'_{\mathcal{L}}(\text{par}, \mathcal{L})$. We immediately have $|\Pr[W_6] - \Pr[W_5]| \leq \text{Adv}_{\mathcal{A}}^{\text{indist-}\Sigma}(\lambda)$.

We note that the trapdoor τ_{Σ} produced by $\text{TrapGen}'$ in **Game**₆ can be used in later games to compute the BadChallenge function of the trapdoor Σ -protocol Π' . To evaluate BadChallenge , we also use the secret key sk produced by $(\text{pk}, \text{sk}, \text{tk}) \leftarrow \text{Keygen}(\Gamma, K)$ which allows decrypting \mathbf{a}^* when $\mathcal{R}_{\text{BM}}(K, \text{AHF}(\mathbf{VK}^*)) = 1$.

Game₇: In this game, we use the decryption algorithm of \mathcal{R} -LPKE. If \mathcal{B} did not fail, we know that \mathcal{A} 's output $\pi^* = (\text{VK}^*, \mathbf{z}^* = (\mathbf{z}'^*, \mathbf{a}'^*, \mathbf{r}^*), \text{sig}^*)$ involves an injective tag VK^* , so that $\mathbf{a}^* = \text{Encrypt}(\text{pk}, \text{AHF}(\text{VK}^*), \mathbf{a}'^*; \mathbf{r}^*)$ is a statistically binding commitment to \mathbf{a}'^* . With probability $2^{-\Omega(\lambda)}$, there thus exists only one message \mathbf{a}'^* such that $\mathbf{a}^* = \text{Encrypt}(\text{pk}, \text{AHF}(\text{VK}^*), \mathbf{a}'^*; \mathbf{r}^*)$ for some $\mathbf{r}^* \in R^{\text{LPKE}}$. We thus consider the relation R_{bad} defined by

$$\begin{aligned} ((x, \mathbf{a}, \text{VK}), \text{Chall}) \in R_{\text{bad}} &\Leftrightarrow x \notin \mathcal{L} \quad \wedge \\ &\text{Chall} \in \text{BadChallenge}(\tau_\Sigma, \text{crs}'_{\mathcal{L}}, x, \text{Decrypt}(\text{sk}, \text{AHF}(\text{VK}), \mathbf{a})). \end{aligned} \quad (28)$$

We now set $W_7 = \text{false}$ if

$$\begin{aligned} &\text{Hash}(k, (x^*, \mathbf{a}^*, \text{VK}^*)) \\ &\notin \text{BadChallenge}(\tau_\Sigma, \text{crs}'_{\mathcal{L}}, x^*, \text{Decrypt}(\text{sk}, \text{AHF}(\text{VK}^*), \mathbf{a}^*)), \end{aligned} \quad (29)$$

where $\mathbf{a}^* = \text{Encrypt}(\text{pk}, \text{AHF}(\text{VK}^*), \mathbf{a}'^*; \mathbf{r}^*)$, and $W_7 = W_6$ otherwise. The decryption property under injective tags implies $|\Pr[W_7] - \Pr[W_6]| \leq 2^{-\Omega(\lambda)}$ since, unless \mathbf{a}^* does not decrypt to \mathbf{a}'^* , π^* cannot correctly verify if (29) holds.

In **Game₇**, we claim that $\Pr[W_7] \leq \text{Adv}_{\mathcal{A}}^{\text{CI}}(\lambda)$ since, if we had

$$\text{Hash}(k, (x^*, \mathbf{a}^*, \text{VK}^*)) \in \text{BadChallenge}(\tau_\Sigma, \text{crs}'_{\mathcal{L}}, x^*, \text{Decrypt}(\text{sk}, \text{AHF}(\text{VK}^*), \mathbf{a}^*)),$$

it would break the correlation-intractability of \mathcal{H} for the relation R_{bad} .

Putting the above altogether, we obtain

$$\begin{aligned} \text{Adv}_{\mathcal{A}}^{\text{uss}}(\lambda) &\leq 2^{-\Omega(\lambda)} + \text{Adv}_{\mathcal{B}}^{\text{ots}}(\lambda) + \frac{1}{\delta(\lambda)} \cdot \left(\text{Adv}_{\mathcal{B}}^{\text{indist-LPKE}}(\lambda) \right. \\ &\quad \left. + \text{Adv}_{\mathcal{B}}^{\text{indist-}\Sigma}(\lambda) + \text{Adv}_{\mathcal{B}}^{\text{CI}}(\lambda) + 2^{-\Omega(\lambda)} \right), \end{aligned}$$

which completes the proof. \square

C Deferred Material for the Trapdoor Σ -Protocols of Section 4

C.1 Trapdoor Σ -Protocols With Small Challenge Space for Linearly Homomorphic Encryptions of 0

We consider additively homomorphic encryption schemes $(\mathcal{K}, \mathcal{E}, \mathcal{D})$ where the message space \mathcal{M} , the randomness space \mathcal{R} and the ciphertext space \mathcal{C} form groups $(\mathcal{M}, +)$, $(\mathcal{R}, +)$ and (\mathcal{C}, \cdot) for operations $+$ and \cdot , respectively. For any public key pk produced as $(pk, sk) \leftarrow \mathcal{K}(1^\lambda)$, any messages $m_1, m_2 \in \mathcal{M}$ and randomness $r_1, r_2 \in \mathcal{R}$, we require that

$$\mathcal{E}_{pk}(m_1; r_1) \cdot \mathcal{E}_{pk}(m_2; r_2) = \mathcal{E}_{pk}(m_1 + m_2; r_1 + r_2).$$

In addition, we assume that the order $|\mathcal{R}|$ of the group $(\mathcal{R}, +)$ is public and that this group is efficiently samplable. We describe a trapdoor Σ -protocol for the language $\mathcal{L} := \{c \in \mathcal{C} \mid \exists r \in \mathcal{R} : c = \mathcal{E}_{pk}(0; r)\}$.

Gen_{par}(1^λ) : Define public parameters $\mathbf{par} = \{\lambda, t\}$ consisting of a security parameter $\lambda \in \mathbb{N}$ and an integer $t = \mathcal{O}(\log \lambda)$ that defines a challenge space $\{0, 1\}^t$ such that all prime divisors of $|\mathcal{M}|$ are strictly larger than 2^t .

Gen_L($\mathbf{par}, \mathcal{L}$) : Given public parameters \mathbf{par} as well as a description of a language \mathcal{L} which specifies a public key pk produced by \mathcal{K} , define the language-dependent $\mathbf{crs}_{\mathcal{L}} = \{pk\}$. The global common reference string is

$$\mathbf{crs} = (pk, \mathbf{crs}_{\mathcal{L}}).$$

TrapGen($\mathbf{par}, \mathcal{L}, \tau_{\mathcal{L}}$) : Given \mathbf{par} , the description of a language \mathcal{L} that specifies a public key produced by $(pk, sk) \leftarrow \mathcal{K}(1^\lambda)$, and a membership-testing trapdoor $\tau_{\mathcal{L}} = sk$ consisting of a secret key underlying pk , output $\mathbf{crs} = (pk, \mathbf{crs}_{\mathcal{L}})$, which defines $\mathbf{crs} = (pk, \mathbf{crs}_{\mathcal{L}})$, and the trapdoor $\tau_{\Sigma} = sk$.

P(\mathbf{crs}, x, w) \leftrightarrow **V**(\mathbf{crs}, x) : Given \mathbf{crs} , a statement $x = \mathcal{E}_{pk}(0; w)$ for some $w \in \mathcal{R}$, the prover P and the verifier V interact in the following way.

1. P chooses $r \leftarrow \mathcal{R}$ and sends $a = \mathcal{E}_{pk}(0; r)$ to V .
2. V sends a random challenge $\mathbf{Chall} \in \{0, 1\}^t$, which is interpreted as an integer in $\{0, 1, \dots, 2^t - 1\}$.
3. P computes the response $z = r + \mathbf{Chall} \cdot w \in \mathcal{R}$ and sends it to V .
4. V checks if $z \in \mathcal{R}$ and $a \cdot x^{\mathbf{Chall}} = \mathcal{E}_{pk}(0; z)$. If these conditions do not both hold, V halts and returns \perp .

BadChallenge($\mathbf{par}, \tau_{\Sigma}, \mathbf{crs}, x, a$) : Given $\tau_{\Sigma} = sk$, parse the first prover message as $a \in \mathcal{C}$ and return \perp if it does not parse properly. Otherwise, if there exists $j \in \{0, 1, \dots, 2^t - 1\}$ such that $\mathcal{D}_{sk}(a \cdot x^j) = 0$, return $\mathbf{Chall} = j$. If no such j exists, return $\mathbf{Chall} = \perp$.

When the above construction is instantiated using the Elgamal encryption scheme, we obtain a variant of the Chaum-Pedersen protocol [21] that allows proving the equality of discrete logarithms. The latter protocol was previously shown [24] to be a trapdoor Σ -protocol with binary challenges. Here, we observe that the challenge space can actually be of size $\mathcal{O}(\log \lambda)$ while keeping **BadChallenge** efficient.

Lemma C.1. *The above construction is a trapdoor Σ -protocol for \mathcal{L} .*

Proof. The CRS indistinguishability follows immediately from the fact that both the real CRS produced by **Gen_L** and the one generated by **TrapGen** have exactly the same distribution.

We next prove the special ZK property by providing a transcript simulator. Given as inputs \mathbf{crs} , a statement $x \in \mathcal{C}$ and a challenge $\mathbf{Chall} \in \{0, 1\}$, the simulator first samples $z \leftarrow U(\mathcal{R})$ uniformly, computes $a = \mathcal{E}(0; z) \cdot x^{-\mathbf{Chall}}$ and outputs (a, z) . Since we assumed that $(\mathcal{R}, +)$ is efficiently samplable and has

public order, z is distributed as in the real protocol: in both the real protocol and the simulation, a is uniquely determined by the challenge Chall , the statement x and the response z . Hence, if $x \in \mathcal{L}$, the simulated transcript (a, Chall, z) is statistically close to a real transcript with challenge Chall .

Soundness follows from the homomorphism. The verification equations of two valid transcripts $(a, \text{Chall}_0, z_0), (a, \text{Chall}_1, z_1)$ imply $x^{\text{Chall}_1 - \text{Chall}_0} = \mathcal{E}(0; z_1 - z_0)$, where we assume w.l.o.g. that $\text{Chall}_1 > \text{Chall}_0$. Since $\text{Chall}_1 - \text{Chall}_0$ is co-prime with the group order $|\mathcal{M}|$, this implies that $x \in \mathcal{L}$.

We finally show that BadChallenge provides the correct result. Let $x \notin \mathcal{L}$ be a false statement. Note that we cannot simultaneously have $\mathcal{D}_{\text{sk}}(a \cdot x^i) = 0$ and $\mathcal{D}_{\text{sk}}(a \cdot x^j) = 0$ for distinct $i, j \in \{0, 1, \dots, 2^t - 1\}$ as the additively homomorphic property would imply $\mathcal{D}_{\text{sk}}(x^{j-i}) = 0$, which would contradict the hypothesis that $x \notin \mathcal{L}$ since $\gcd(j - i, |\mathcal{M}|) = 1$.

Therefore, BadChallenge can always compute the only $\text{Chall} \in \{0, 1, \dots, 2^t - 1\}$ for which a valid response exists after $2^t = \text{poly}(\lambda)$ executions of $\mathcal{D}_{\text{sk}}(\cdot)$. \square

C.2 Compact Extractable Instance-Dependent Trapdoor Commitments

In this section, we show that our trapdoor Σ -protocol of Section 4.1 improves the expansion rate of extractable instance-dependent trapdoor commitments [24]. While the construction of [24, Section 5.2.2] commits to λ -bit messages using $O(\lambda)$ group elements, we just need one Paillier ciphertext.

By adapting a construction from [24, Section 5.2.3], these improved EIDTC schemes make it possible to construct more efficient delayed-input trapdoor Σ -protocols where the SHVZK holds for adaptively chosen inputs. By applying the Fiat-Shamir heuristic, this in turn provides more efficient NIZK arguments with adaptive ZK and non-adaptive soundness.¹⁰ While this property is already achieved by our USS argument of Section B (for this purpose, it can actually be simplified by replacing the \mathcal{R} -lossy PKE scheme with a standard equivocal lossy PKE¹¹ scheme, as suggested in [50]), it is plausible that EIDTC will find other applications in the future.

We first recall the definition of extractable instance-dependent trapdoor commitment from [24].

Definition C.2. *An extractable instance-dependent trapdoor commitment (EIDTC) with message space \mathcal{M} for a polynomial-time relation R (associated with a language \mathcal{L} in $\text{NP} \cap \text{co-NP}$) is a tuple of PPT algorithms $(\text{Gen}, \text{Com}, \text{Dec}, \text{Fake}_1, \text{Fake}_2, \text{Ext})$ with the following specification.*

¹⁰ Brakerski *et al.* [8] achieve both properties at the same time using *instance-universal* trapdoor Σ -protocols, where the BadChallenge function is computable without knowing the instance x .

¹¹ We can also achieve adaptive soundness if the public key of the equivocal lossy PKE scheme is configured in its injective mode. In this case, the proof of soundness does not modify the distribution of the CRS and we can prove adaptive soundness as in [24, Theorem 4].

- Gen**(1^λ): is a randomized algorithm that inputs a security parameter $\lambda \in \mathbb{N}$ and outputs a CRS ρ together with a trapdoor τ .
- Com**(ρ, Msg): is a randomized algorithm that inputs the CRS ρ and a message $\text{Msg} \in \mathcal{M}$. It outputs a tuple $(\text{com}, T, \alpha, \text{dec})$ comprised of an instance $T \in \tilde{\mathcal{L}}$, a witness α such that $(T, \alpha) \in R_{\tilde{\mathcal{L}}}$, a commitment com , and the corresponding decommitment dec .
- Dec**($\rho, (\text{com}, T, \text{dec}), \text{Msg}$): is a deterministic verification algorithm that takes as input the CRS ρ , a message Msg , and a triple $(\text{com}, T, \text{dec})$ in the output space of **Com**. It outputs 0 or 1.
- Fake**₁(ρ): is a randomized algorithm that takes as input the CRS. It outputs a fake commitment com together with an instance $T \in \mathcal{L}$ (instead of $T \in \tilde{\mathcal{L}}$) and some equivocation information rand .
- Fake**₂($\rho, (\text{com}, T, \text{rand}), \text{Msg}$): is a (possibly randomized) algorithm that inputs the CRS ρ , a message Msg , and a triple $(\text{com}, T, \text{rand})$ produced by **Fake**₁. It outputs a decommitment dec .
- Ext**($\rho, (\text{com}, T), \tau$): is a deterministic algorithm that takes as input the CRS ρ , a commitment-instance pair (com, T) , and a trapdoor τ . It outputs a message $\text{Msg} \in \mathcal{M}$ or an error symbol \perp .

Ciampi *et al.* [24, Section 5.2.1] gave a DDH-based construction of EIDTC trapdoor commitment, which is derived from a trapdoor Σ -protocol for the language of Diffie-Hellman tuples. The construction can be generically written by adapting a well-known construction (see, e.g., [23, Section 2.4]) of instance-dependent trapdoor commitments from Σ -protocols.

EIDTC FROM TRAPDOOR Σ -PROTOCOLS. The description below assumes a trapdoor Σ -protocol allows for languages \mathcal{L} that can be chosen with a trapdoor (e.g., the factorization of N in the DCR case) allowing to recognize elements of \mathcal{L} . The message space \mathcal{M} of the commitment scheme is the challenge space \mathcal{C} of the underlying trapdoor Σ -protocol.

- Gen**(1^λ): Choose a language description \mathcal{L} possibly with a membership-testing trapdoor $\tau_{\mathcal{L}}$. Generate a common reference string $\text{crs} = (\text{par}, \text{crs}_{\mathcal{L}})$ for the trapdoor Σ -protocol $\Pi = (\text{Gen}_{\text{par}}, \text{Gen}, \text{TrapGen}, \text{P}, \text{V}, \text{BadChallenge}, \text{ZKSim})$ associated with \mathcal{L} by generating the language-dependent component $\text{crs}_{\mathcal{L}}$ as $(\text{crs}_{\mathcal{L}}, \tau_{\Sigma}) \leftarrow \text{TrapGen}(\text{par}, \mathcal{L}, \tau_{\mathcal{L}})$. Output $\rho = \text{crs}$ and $\tau = \tau_{\Sigma}$.
- Com**(ρ, Msg): Given $\rho = \text{crs}$ and $\text{Msg} \in \mathcal{M}$, choose $(T, \alpha) \in R_{\tilde{\mathcal{L}}}$. Then, compute $(\text{com}, \text{dec}) := (\mathbf{a}, \mathbf{z}) \leftarrow \text{ZKSim}(\text{crs}, T, \text{Msg})$ and output $(\text{com}, T, \alpha, \text{dec})$.
- Dec**($\rho, (\text{com}, T, \text{dec}), \text{Msg}$): Given $\rho = \text{crs}$, $T, \text{Msg} \in \mathcal{M}$ and $(\text{com}, \text{dec}) = (\mathbf{a}, \mathbf{z})$, return 1 if $\text{V}(\text{crs}, T, (\mathbf{a}, \text{Msg}, \mathbf{z})) = 1$ and 0 otherwise.
- Fake**₁(ρ): Given $\rho = \text{crs}$, choose $(T, \alpha) \in R_{\mathcal{L}}$. Compute $(\mathbf{a}, st) \leftarrow \text{P}(\text{crs}, T, \alpha)$ using the real prover of Π . Output $\text{com} := \mathbf{a}$ and $\text{rand} = (st, \alpha)$.
- Fake**₂($\rho, (\text{com}, T, \text{rand}), \text{Msg}$): Given $\rho = \text{crs}$, a message $\text{Msg} \in \mathcal{M}$, a fake commitment $\text{com} = \mathbf{a}$ and its equivocation information $\text{rand} = (st, \alpha)$, compute $\mathbf{z} = \text{P}(\text{crs}, T, \alpha, \mathbf{a}, \text{Msg}, st)$ and output $\text{dec} = \mathbf{z}$.
- Ext**($\rho, (\text{com}, T), \tau$): Given $\rho = \text{crs}$, and instance T , the trapdoor $\tau = \tau_{\Sigma}$ and a commitment $\text{com} = \mathbf{a}$, return the output of $\text{BadChallenge}(\tau_{\Sigma}, \text{crs}, T, \mathbf{a})$.

Since the message space of the EIDTC coincides with the challenge space of Π , our DCR-based trapdoor Σ -protocol of Section 4.1 immediately provides a space-efficient EIDTC scheme that allows committing to exponentially many bits using one Paillier ciphertext.

Theorem C.3 (Adapted from [24, Theorem 7]). *The above construction is an EIDTC if the underlying Σ -protocol is a trapdoor Σ -protocol.*

Proof. The proof is a direct adaptation of [23, Theorem 5] and [24, Theorem 7]. Here, the extractability property follows from the fact that, for any $T \notin \mathcal{L}$, any possible first message sent by the prover leaves room for only one bad challenge, which is computable by the `BadChallenge` function using the trapdoor τ_Σ . \square

C.3 Trapdoor Σ -Protocol for Multiplicative Relations Between Paillier/Damgård-Jurik Ciphertexts

We show that our NIZK argument on composite residuosity can be adapted to prove multiplicative relations between Paillier or Damgård-Jurik ciphertexts. To this end, we show that a Σ -protocol described by Cramer, Damgård and Nielsen [27] can be turned into a trapdoor Σ -protocol ensuring soundness without parallel repetitions. For example, it can be used as a building block for a standard-model instantiation of the Damgård-Jurik voting protocol [30].

Let $N = pq$ denote an RSA modulus. We give a trapdoor Σ -protocol for the language

$$\begin{aligned} \mathcal{L}^{\text{mult}} := \{ & (C_\alpha, C_\beta, C_\gamma) \in (\mathbb{Z}_{N^{\zeta+1}}^*)^3 \mid \exists (\alpha, \beta) \in \mathbb{Z}_N^\zeta, (s_\alpha, s_\beta, s_\gamma) \in (\mathbb{Z}_N^*)^3 : \\ & C_\alpha = (1 + N)^\alpha \cdot s_\alpha^{N^\zeta} \pmod{N^{\zeta+1}}, \\ & C_\beta = (1 + N)^\beta \cdot s_\beta^{N^\zeta} \pmod{N^{\zeta+1}}, \quad C_\gamma = C_\beta^\alpha \cdot s_\gamma^{N^\zeta} \pmod{N^{\zeta+1}} \}. \end{aligned}$$

The trapdoor Σ -protocol is identical to the one of [27, Section 8] but we show that it has an efficient `BadChallenge` function.

Gen_{par}(1^λ): Given the security parameter λ , define $\text{par} = \{\lambda\}$.

Gen_L($\text{par}, \mathcal{L}^{\text{mult}}$): Given public parameters par as well as a description of a language $\mathcal{L}^{\text{mult}}$, consisting of an RSA modulus $N = pq$ with p and q prime satisfying $p, q > 2^{l(\lambda)}$, for some polynomial $l : \mathbb{N} \rightarrow \mathbb{N}$ such that $l(\lambda) > \lambda$, define the language-dependent $\text{crs}_L = \{N\}$. The global CRS is

$$\text{crs} = (\{\lambda\}, \text{crs}_L).$$

TrapGen($\text{par}, \mathcal{L}^{\text{mult}}, \tau_L$): Given par , the description of a language $\mathcal{L}^{\text{mult}}$ that specifies an RSA modulus N , and a membership-testing trapdoor $\tau_L = (p, q)$ consisting of the factorization of $N = pq$, output the language-dependent $\text{crs}_L = \{N\}$ which defines $\text{crs} = (\{\lambda\}, \text{crs}_L)$ and the trapdoor $\tau_\Sigma = (p, q)$.

P(crs, x, w) \leftrightarrow **V**(crs, x): Given a crs , a statement $x = (C_\alpha, C_\beta, C_\gamma) \in (\mathbb{Z}_{N^2}^*)^3$, the prover P (who has $w = (\alpha, \beta, s_\alpha, s_\beta, s_\gamma)$) and the verifier V interact in the following way:

1. P chooses $r \leftarrow U(\mathbb{Z}_{N^\zeta})$, $u, v \leftarrow U(\mathbb{Z}_N^*)$ and sends V the following:

$$A_1 = C_\beta^r \cdot u^{N^\zeta} \bmod N^{\zeta+1}, \quad A_2 = (1 + N)^r \cdot v^{N^\zeta} \bmod N^{\zeta+1}.$$

2. V sends a random challenge $\text{Chall} \leftarrow U(\{0, \dots, 2^\lambda - 1\})$ to P .

3. P sends V the response $(z, z_1, z_2) \in \mathbb{Z}_{N^\zeta} \times \mathbb{Z}_N^* \times \mathbb{Z}_N^*$, where

$$\begin{aligned} z &= r + \text{Chall} \cdot \alpha \bmod N^\zeta, \\ z_1 &= v \cdot s_\alpha^{\text{Chall}} \bmod N, \\ z_2 &= u \cdot s_\gamma^{\text{Chall}} \cdot C_\beta^{\lfloor (r + \text{Chall} \cdot \alpha) / N^\zeta \rfloor} \bmod N. \end{aligned}$$

4. V checks if

$$\begin{aligned} A_1 \cdot C_\gamma^{\text{Chall}} &= C_\beta^z \cdot z_2^{N^\zeta} \bmod N^{\zeta+1}, \\ A_2 \cdot C_\alpha^{\text{Chall}} &= (1 + N)^z \cdot z_1^{N^\zeta} \bmod N^{\zeta+1}. \end{aligned}$$

and returns 0 if these conditions are not satisfied.

BadChallenge($\text{par}, \tau_\Sigma, \text{crs}, x, a$) : Given a trapdoor $\tau_\Sigma = (p, q)$, a statement $x = (C_\alpha, C_\beta, C_\gamma) \in (\mathbb{Z}_{N^{\zeta+1}}^*)^3$ and a first prover message $a = (A_1, A_2) \in (\mathbb{Z}_{N^{\zeta+1}}^*)^2$, decrypt x and a so as to obtain a triple $(\alpha, \beta, \gamma) = \mathcal{D}_{\tau_\Sigma}(x) \in (\mathbb{Z}_{N^\zeta})^3$ and a pair $(a_1, a_2) = \mathcal{D}_{\tau_\Sigma}(a) \in (\mathbb{Z}_{N^\zeta})^2$. Note that, if $x \notin \mathcal{L}^{\text{mult}}$, we have $\gamma \neq \alpha \cdot \beta \bmod N^\zeta$. Consider the following linear system with the unknowns $(\text{Chall}, z) \in \mathbb{Z}_{N^\zeta}^2$:

$$\begin{aligned} z - \text{Chall} \cdot \alpha &\equiv a_2 \pmod{N^\zeta} \\ \beta \cdot z - \text{Chall} \cdot \gamma &\equiv a_1 \pmod{N^\zeta}. \end{aligned} \tag{30}$$

Let $d_x = \gcd(\alpha\beta - \gamma, N^\zeta)$, so that $\gcd(\alpha\beta - \gamma, N^\zeta/d_x) = 1$. Any solution of (30) also satisfies the system

$$\begin{aligned} z - \text{Chall} \cdot \alpha &\equiv a_2 \pmod{N^\zeta/d_x} \\ \beta \cdot z - \text{Chall} \cdot \gamma &\equiv a_1 \pmod{N^\zeta/d_x}, \end{aligned}$$

which has a unique solution $(\text{Chall}', z') \in (\mathbb{Z}_{N^\zeta/d_x})^2$. If this solution is such that $\text{Chall}' \in \{0, \dots, 2^\lambda - 1\}$, return $\text{Chall} = \text{Chall}'$. Otherwise, return \perp .

D Simpler Ring Signatures in the Erasure Setting

In this section, we describe a simpler variant of our main scheme where the signer is required to erase its random coins after each signature generation. The main difference is the commitment scheme that allows computing $\{L_j\}_{j=1}^r$. Instead of computing each L_j using an \mathcal{R}_{BM} -lossy PKE scheme, the simplified construction uses the Paillier-based commitment of [17].

CRSGen(1^λ) : Given a security parameter λ , conduct the following steps.

1. Generate $\text{par} \leftarrow \text{Gen}_{\text{par}}(1^\lambda)$ for the trapdoor Σ -protocol of Section 4.3.
2. Generate RSA moduli $N = pq$ and $\bar{N} = \bar{p}\bar{q}$ such that $p, q, \bar{p}, \bar{q} > 2^{l(\lambda)}$, for some polynomial $l : \mathbb{N} \rightarrow \mathbb{N}$, and choose $h \leftarrow U(\mathbb{Z}_{N^2}^*)$, $\bar{h} \leftarrow U(\mathbb{Z}_{\bar{N}^2}^*)$.
3. Generate a pair $(\text{crs}, \tau_{\text{zk}}) \leftarrow \text{Gen}_{\mathcal{L}}(\text{par}, \mathcal{L}_{\sqrt{\cdot}}^{1-R})$ consisting of the common reference string $\text{crs} = (\text{par}, (\text{crs}'_{\mathcal{L}}, \text{pk}_{\text{LPKE}}, k, \text{AHF}, \text{OTS}))$ of a simulation-sound argument Π^{uss} for the language $\mathcal{L}_{\sqrt{\cdot}}^{1-R}(h, \bar{h})$ defined in (12) together with a simulation trapdoor $\tau_{\text{zk}} := \text{sk}_{\text{LPKE}}$. In crs , the language-dependent $\text{crs}'_{\mathcal{L}} = \{N, \bar{N}\}$ is part of a common reference string $\text{crs}' = (\{\lambda\}, \text{crs}'_{\mathcal{L}})$ for the Σ -protocol of Section 4.3.

Output the common reference string $\rho = \text{crs}$.

Keygen(ρ) : Pick $w \leftarrow U(\mathbb{Z}_N^*)$, $y \leftarrow U(\mathbb{Z}_N)$ and compute $C = h^y \cdot w^N \bmod N^2$. Output (sk, vk) , where $sk = (w, y)$ and $vk = C$.

Sign(ρ, sk, M, R) : Given a ring $R = \{vk_0, \dots, vk_{R-1}\}$ (we assume that $R = 2^r$ for some $r \in \mathbb{N}$), a message M and a secret key $sk = (w, y) \in \mathbb{Z}_N^* \times \mathbb{Z}_N$, let $\ell_1 \cdots \ell_r = \ell \in \{0, \dots, R-1\}$ be the index such that $vk_\ell = h^y \cdot w^N \bmod N^2$.

1. For each $j \in [r]$, choose $s_j \leftarrow U(\mathbb{Z}_{\bar{N}})$ and $t_j \leftarrow U(\mathbb{Z}_{\bar{N}}^*)$, and compute the commitment $L_j = (1 + \bar{N})^{\ell_j} \cdot \bar{h}^{s_j} \cdot t_j^{\bar{N}} \bmod \bar{N}^2$ to the bit ℓ_j .
2. Define the label $\text{lbl} = (M, R)$ and generate a NIZK argument $\pi \leftarrow \text{P}(\text{crs}, \mathbf{x}, \mathbf{w}, \text{lbl})$ that $\mathbf{x} \triangleq ((vk_0, \dots, vk_{R-1}), (L_1, \dots, L_r)) \in \mathcal{L}_{\sqrt{\cdot}}^{1-R}(h, \bar{h})$ by running the prover P of Supplementary Material B with the Σ -protocol of Section 4.3 using $\mathbf{w} = (y, w, \{(\ell_j, s_j, t_j)\}_{j=1}^r)$.

Output the signature $\Sigma = ((L_1, \dots, L_r), \pi)$ and erase all random coins.

Verify(ρ, M, Σ, R) : Given a signature $\Sigma = ((L_1, \dots, L_r), \pi)$, a message M and a ring $R = \{vk_0, \dots, vk_{R-1}\}$, return 0 if any of these does not parse properly. Otherwise, let $\text{lbl} = (M, R)$ and return $\text{V}(\text{crs}, \mathbf{x}, \pi, \text{lbl})$ which outputs 1 iff π is a valid argument that $((vk_0, \dots, vk_{R-1}), (L_1, \dots, L_r)) \in \mathcal{L}_{\sqrt{\cdot}}^{1-R}(h, \bar{h})$.

Theorem D.1. *The above ring signature instantiated using the trapdoor Σ -protocol of Section 4.3 provides unforgeability assuming reliable erasures and under the assumptions that: (i) The DCR assumption holds; (ii) Π^{uss} is an unbounded simulation-sound NIZK argument for the language $\mathcal{L}_{\sqrt{\cdot}}^{1-R}(h, \bar{h})$.*

Proof. We use a sequence of games starting with the real experiment and ending with a game where we give a direct reduction from the simulation-soundness of Π^{uss} . For each i , W_i is the event that the challenger outputs 1 in Game_i .

Game₀: This is the real experiment. The adversary \mathcal{A} receives a CRS ρ and has access to a key generation oracle **Keygen**, a signing oracle **Sign** and a corruption oracle **Corrupt**. At the i -th query to **Keygen**, the challenger returns a verification key $vk^{(i)} = h^{y_i} \cdot w_i^N \bmod N^2$ for some $w_i \leftarrow U(\mathbb{Z}_N^*)$, $y_i \leftarrow U(\mathbb{Z}_N)$ and keeps $sk^{(i)} = (w_i, y_i)$ for later use. If \mathcal{A} makes a corruption query **Corrupt**(i), the challenger reveals $sk^{(i)}$ to \mathcal{A} . At each signing query (i, M, R) , the challenger returns \perp if R contains a key $vk \notin \mathbb{Z}_{N^2}^*$. Otherwise, it runs

$\Sigma \leftarrow \text{Sign}(\rho, sk, M, R)$ and returns Σ to \mathcal{A} . When \mathcal{A} halts, it outputs a triple (M^*, R^*, Σ^*) , where $R^* = \{vk_0^*, \dots, vk_{R^*-1}^*\}$ and $\Sigma^* = ((L_1^*, \dots, L_r^*), \pi^*)$, and the challenger outputs 1 if: (i) $\text{Verify}(\rho, M^*, \Sigma^*, R^*) = 1$; (ii) R^* only contains uncorrupted keys produced by Keygen ; (iii) No signing query (\cdot, M^*, R^*) was made. By definition, we have $\Pr[W_0] = \text{Adv}_{\mathcal{A}}^{\text{unforge}}(\lambda)$.

Game₁: This game is like Game_0 except that, in all signing queries (i, M, R) , the challenger simulates the Sign oracle by running the NIZK simulator of Π^{uss} instead of using the real witness. Namely, the commitments $\{L_j\}_{j=1}^r$ of each signature $\Sigma = ((L_1, \dots, L_r), \pi)$ still commit to the bits (ℓ_1, \dots, ℓ_r) of $vk^{(i)}$'s location in R but π is simulated without using $sk^{(i)} = (w_i, y_i)$ nor $\{(\ell_j, s_j, t_j)\}_{j=1}^r$. Recall that the trapdoor Σ -protocol of Section 4.3 is statistically special ZK when $h \sim U(\mathbb{Z}_{N^2}^*)$ and $\bar{h} \sim U(\mathbb{Z}_{\bar{N}^2}^*)$. The statistical NIZK property of Π^{uss} , ensures that $|\Pr[W_1] - \Pr[W_0]| \leq Q_S \cdot 2^{-\Omega(\lambda)}$.

Game₂: This game is like Game_1 except that we change the distribution of crs in $\rho = \text{crs}$. For the parameters, we now sample $h_0 \leftarrow U(\mathbb{Z}_N^*)$ and $\bar{h}_0 \leftarrow U(\mathbb{Z}_{\bar{N}}^*)$ and compute $h = h_0^N \bmod N^2$ and $\bar{h} = \bar{h}_0^{\bar{N}} \bmod \bar{N}^2$ as uniformly random composite residues. Under the DCR assumption in $\mathbb{Z}_{N^2}^*$ and $\mathbb{Z}_{\bar{N}^2}^*$, these changes have no noticeable impact on \mathcal{A} 's forging probability and a straightforward reduction shows that $|\Pr[W_2] - \Pr[W_1]| \leq 2 \cdot \text{Adv}^{\text{DCR}}(\lambda)$.

Game₃: In this game, the challenger uses the factorization of $\bar{N} = \bar{p}\bar{q}$ to decrypt the Paillier ciphertexts $\{L_j^*\}_{j=1}^r$ contained in \mathcal{A} 's forgery. The challenger obtains $\{\ell_j^*\}_{j=1}^r$ and outputs 0 if there exists $j \in [r]$ such that $\ell_j^* \notin \{0, 1\}$. Otherwise, it obtains a string $\ell_1^* \dots \ell_r^* \in \{0, 1\}^r$ and reconstructs the index $\ell^* = \sum_{k=1}^r \ell_k^* \cdot 2^{k-1} \in \mathbb{Z}_R$ of the verification key $vk_{\ell^*}^* = C_{\ell^*}^*$ in the ring $R^* = \{vk_0^*, \dots, vk_{R^*-1}^*\}$. If $\ell_j^* \notin \{0, 1\}$ for some $j \in [r]$, the soundness of Π^{uss} is broken and we have $|\Pr[W_3] - \Pr[W_2]| \leq \text{Adv}^{\text{uss}}(\lambda)$.

Game₄: This game is like Game_3 with one change. At the outset of the game, the challenger draws $i^* \leftarrow U([Q_V])$ as a guess that $vk_{\ell^*}^*$ coincides with the verification key $vk^{(i^*)}$ returned by the challenger at the i^* -th query to the Keygen oracle. If the guess eventually turns out to be wrong or if \mathcal{A} makes the corruption query $\text{Corrupt}(i^*)$, the challenger aborts and outputs 0. Otherwise (i.e., if $vk_{\ell^*}^* = vk^{(i^*)}$), it outputs the same bit as in Game_3 . Since i^* is chosen independently of \mathcal{A} 's view, it is correct with probability $1/Q_V$, where Q_V is the number of Keygen -queries. We thus have $\Pr[W_4] = \Pr[W_3]/Q_V$.

Game₅: We change the distribution of $vk^{(i^*)} = C^{(i^*)}$ and sample $C^{(i^*)} \leftarrow U(\mathbb{Z}_{N^2}^*)$ uniformly instead of sampling it as an N -th residue in $\mathbb{Z}_{N^2}^*$. As a result, the signing oracle may now return simulated arguments for false statements. However, since the challenger uses neither the factorization of N nor the secret key $sk^{(i^*)}$ in Game_4 , we can rely on the DCR assumption in $\mathbb{Z}_{N^2}^*$ to argue that $|\Pr[W_5] - \Pr[W_4]| \leq \text{Adv}^{\text{DCR}}(\lambda)$.

In Game_5 , we claim that $\Pr[W_5] \leq \text{Adv}^{\text{uss}}(\lambda) + 2^{-\Omega(\lambda)}$ as, except with probability $1/N < 2^{-\Omega(\lambda)}$, the challenger only outputs 1 if \mathcal{A} manages to break the simulation-soundness of Π^{uss} . Indeed, W_5 only occurs if $vk_{\ell^*}^* = vk^{(i^*)}$ (which

implies that $sk^{(i^*)}$ was not corrupted); π^* is a valid argument for the statement $((vk_0^*, \dots, vk_{R-1}^*), (L_1^*, \dots, L_r^*)) \in \mathcal{L}_{\mathbb{V}}^{1-R}$; and no signing query (i, M^*, R^*) has been made for any $vk^{(i)} \in R^*$ (in particular for $i = i^*$). Since vk_{ℓ^*} was sampled uniformly in $\mathbb{Z}_{N^2}^*$, it is *not* an N -th residue except with probability $1/N$. If W_5 occurs, this necessarily implies that π^* is an accepting argument for a false statement $\mathbf{x}^* \in \mathcal{L}_{\mathbb{V}}^{1-R}$ on an unqueried label $\text{lbl}^* \triangleq (M^*, R^*)$.

Putting the above altogether, we can bound the adversary's advantage as

$$\mathbf{Adv}_{\mathcal{A}}^{\text{unforge}}(\lambda) \leq (2 + Q_V) \cdot (\mathbf{Adv}^{\text{uss}}(\lambda) + \mathbf{Adv}^{\text{DCR}}(\lambda)) + (Q_S + Q_V) \cdot 2^{-\Omega(\lambda)}$$

where Q_V and Q_S are the number of **Keygen**-queries and signing queries. \square

The proof of anonymity follows from the fact that the Paillier-based commitments are perfectly hiding when the parameters contained in ρ are configured in such a way that the order of h (*resp.* \bar{h}) in $\mathbb{Z}_{N^2}^*$ (*resp.* in $\mathbb{Z}_{\bar{N}^2}^*$) is at least N (*resp.* \bar{N}). Then, the statistical NIZK property of Π^{uss} ensures that the signatures produced by any two distinct signers have statistically indistinguishable distributions.

Theorem D.2. *The above scheme instantiated with the trapdoor Σ -protocol of Section 4.3 provides full anonymity under key exposure provided Π^{uss} is a statistical NIZK argument for the language $\mathcal{L}_{\mathbb{V}}^{1-R}(h, \bar{h})$.*

Proof. We consider a sequence of statistically indistinguishable games that ends with a game where the adversary has no advantage. In each game, we call W_i the event that the adversary outputs 1 in **Game** _{i} .

Game₀: This is the real anonymity game. Namely, the adversary is granted access to a **Keygen** oracle that returns a pair $(vk^{(i)}, sk^{(i)})$ at each query. In the challenge phase, the adversary \mathcal{A} chooses a message M^* together with a ring $R^* = \{vk_0^*, \dots, vk_{R^*-1}^*\}$ and two indices $i_0, i_1 \in \mathbb{Z}_R$ such that $vk_{i_0}^*$ and $vk_{i_1}^*$ were both produced by the **Keygen** oracle. The challenger then flips a fair coin $b \leftarrow U(\{0, 1\})$ and computes $\Sigma^* \leftarrow \text{Sign}(\rho, sk_{i_b}^*, M^*, R^*)$. At the end of the game, the adversary outputs a bit $b' \in \{0, 1\}$ and the challenger outputs 1 if and only if $b' = b$.

Game₁: In this game, the challenger generates $\Sigma^* = ((L_1^*, \dots, L_r^*), \pi^*)$ without using $sk_{i_b}^*$. Namely, (L_1^*, \dots, L_r^*) are still generated as Paillier commitments to the binary representation of i_b but π^* is obtained by running the NIZK simulator of Π^{uss} . The latter's statistical NIZK property guarantees that $|\Pr[W_1] - \Pr[W_0]| \leq 2^{-\Omega(\lambda)}$. More precisely, when all dual-mode commitments are computed in their perfectly hiding mode, the trapdoor Σ -protocol of Section 4.3 provides statistical special zero-knowledge. In this setting, Π^{uss} is statistically ZK.

In **Game**₁, we have $\Pr[W_1] = 1/2$ since (L_1^*, \dots, L_r^*) are perfectly hiding commitments and π^* is generated independently of $b \in \{0, 1\}$. \square

E Optimized Ring Signature Size

We evaluate the size of signatures $\Sigma = (\text{VK}, (L_1, \dots, L_r), \pi, \text{sig})$ in the erasure-free scheme of Section 5. If we use a DCR-based instantiation of the generic one-time signature suggested by Mohassel [54], we can re-use a Paillier modulus N_{ots} from the CRS of our ring signature to generate many one-time key pairs. In this case, VK has the size of 3 group elements modulo N_{ots} and the signature sig has the size of 2 group elements (as described at the end of this section). The size of (L_1, \dots, L_r) amounts to r elements modulo \bar{N}^2 . We now focus on the size of the NIZK argument $\pi \leftarrow \text{P}(\text{crs}, \mathbf{x}, \mathbf{w}, \text{lbl})$.

Recall that the instance $\mathbf{x} \triangleq ((vk_0, \dots, vk_{R-1}), (L_1, \dots, L_r))$ is in the language $\mathcal{L}_V^{1-R}(h, \bar{h}_{\text{VK}})$ given in equation (23). While verifying a signature requires \mathbf{x} and \bar{h}_{VK} , the ring $\mathbb{R} = (vk_0, \dots, vk_{R-1})$ is not part of the signature and \bar{h}_{VK} can be recomputed from VK and the CRS. Moreover, $\text{lbl} = \text{VK}$, so that we are left with evaluating the size of π . Now, we parse $\pi = (\text{VK}', \mathbf{z}, \text{sig}')$ as in Section B, where $(\text{VK}', \text{sig}')$ is another one-time key pair. It is actually easy to avoid the need for a second pair $(\text{VK}', \text{sig}')$ as the ring signature can actually recycle the one-time pair (VK, sig) from the simulation-sound argument π without affecting the security. We decided to use separate one-time pairs in the description for the sake of clarity and modularity.

In the optimized version, we are left with evaluating the size of the response $\mathbf{z} = (\mathbf{z}', \mathbf{a}', \mathbf{r})$, where $\mathbf{a}' = (\{(\bar{A}_j, \bar{B}_j)\}_{j=1}^r, \{C_{d_k}\}_{k=0}^{r-1})$ is the first message; $\mathbf{z}' = (z_y, z_w, \{(\bar{z}_j, \bar{z}_{d,j}, \bar{z}_{e,j}, \bar{z}_{u,j}, \bar{z}_{v,j})\}_{j=1}^r)$ the response of the 1-out-of- R trapdoor Σ -protocol of Section 4.3; and \mathbf{r} is the random coin used to encrypt \mathbf{a}' with the \mathcal{R} -lossy PKE scheme of Section 3.1. We can further optimize the signature by not including $\{(\bar{A}_j, \bar{B}_j)\}_{j=1}^r$ and C_{d_0} in π and replacing them by the challenge Chall in the argument system of Section B since they can be recomputed given \mathbf{z}' , Chall and $\{C_{d_k}\}_{k=1}^{r-1}$, as done in equations (21)-(22). The resulting ring signature is easily seen to be equivalent to its original version.

Eventually, we assume that all moduli have the same bitlength and that the modulus \tilde{N} of the \mathcal{R} -lossy PKE is the largest one. This allows encoding \mathbf{a}' as a single plaintext modulo \tilde{N}^{6r} in the \tilde{N}^2 -adic representation since we have $3r$ elements modulo a square modulus. Therefore, $\mathbf{r} = (\tilde{r}, \tilde{s}) \in \mathbb{Z}_{\tilde{N}}^* \times \mathbb{Z}_{\tilde{N}^{6r}}$ and we can estimate the global length as follows, where we count an element modulo the ζ -th power of a modulus N as ζ elements of \mathbb{Z}_N .

- One λ -bit string for Chall and 5 elements for (VK, sig) ;
- $2r$ elements modulo N : $r - 1$ for $\{C_{d_k}\}_{k=1}^{r-1}$ and 2 for (z_y, z_w) ;
- $6r$ elements modulo \tilde{N} : r for $\{L_j\}_{j=1}^r$ and $4r$ for $\{(\bar{z}_{d,j}, \bar{z}_{e,j}, \bar{z}_{u,j}, \bar{z}_{v,j})\}_{j=1}^r$;
- r strings of $2\lambda + 1$ bits each for $\{\bar{z}_j\}_{j=1}^r$;
- $6r + 1$ elements modulo \tilde{N} for the random coins \mathbf{r} of the \mathcal{R} -lossy PKE scheme.

This amounts to a total size bounded by the size of $15r + 7$ elements modulo \tilde{N} . Interestingly, the signature length is only roughly three times as large as in a ring signature obtained by applying the standard Fiat-Shamir heuristic under the DCR assumption in the random oracle model. In a ROM-based version

of our scheme, we can apply Fiat-Shamir to our Σ -protocol of Section 4.3 and simulation-soundness comes for free without using tag-based commitments or even one-time signatures. Even though we can apply exactly the same proof strategy as Groth and Kohlweiss [42] using more efficient DCR-based commitments of the form $L_j = g^{\ell_j} \cdot r^N \bmod N$, the signature size only drops to $5r + 1$ elements of \mathbb{Z}_N .

Short Keys. Each user's public key consists of a single element $vk = C$ over $\mathbb{Z}_{N^2}^*$ and the secret key is a pair $(w, y) \in \mathbb{Z}_N^* \times \mathbb{Z}_N$. In both cases, the size is equivalent to that of two elements of \mathbb{Z}_N .

A Concrete DCR-based One-Time Signature. For completeness, we describe a strongly unforgeable one-time signature scheme based on a chameleon hash function (or, equivalently, a trapdoor commitment) under the DCR assumption, which follows the blueprint of [54]. Using a DCR-based variant of Mohassel's generic construction allows recycling the modulus N across different one-time key generations. Since the chameleon hashing trapdoors are N -th roots, the factorization of N can remain unknown to signers. For this reason, we give a construction that does not rely on the factoring-based instantiation of [54] since we already have RSA moduli in the CRS and signers can re-use them. The construction hereunder can be proven strongly unforgeable under the RSA assumption with public exponent $e = N$, which is implied by the DCR assumption, as shown in [56].

CRSGen(1^λ): Given a security parameter λ , generate an RSA modulus $N = pq$ satisfying $p, q > 2^{l(\lambda)}$, where $l : \mathbb{N} \rightarrow \mathbb{N}$ is a polynomial, choose $H \leftarrow \mathcal{H}$ from a family \mathcal{H} of collision-resistant hash functions. Return $pp = (N, H)$.

Keygen(pp): Choose random $u, v, w \leftarrow U(\mathbb{Z}_N^*)$ and compute $g = u^N \bmod N$, $h = v^N \bmod N$ and $c = w^N \bmod N$ (which is seen as a commitment to 0 with commitment key g). Return $osk = (u, v, w)$ and $ovk = (g, h, c)$.

Sign(ovk, osk, m): Given a secret key $osk = (u, v, w)$, pick $s \leftarrow U(\mathbb{Z}_N^*)$ and compute $d = h^m \cdot s^N \bmod N$ and $e = H(g, h, d)$. Then, use w and u to equivocate c for the message e . Namely, compute $r = w \cdot u^{-e} \bmod N$ and output the signature $\sigma = (r, s)$.

Verify(ovk, m, σ): Given $\sigma = (r, s)$ and a verification key $ovk = (g, h, c)$, output 1 if $c = g^e \cdot r^N \bmod N$, where $d = h^m \cdot s^N \bmod N$ and $e = H(g, h, d)$, and 0 otherwise.

Since it is well-known that $c = g^e \cdot r^N \bmod N$ and $d = h^m \cdot s^N \bmod N$ are trapdoor commitments, the strong unforgeability directly follows from [54].
