ABSTRACT

In this work, we focus on verifiable random functions (VRF) that may resist quantum threats. VRFs have a wide range of applications and play a key role in Proof-of-Stake blockchains, such as Algorand. Our main proposal is a VRF construction, X-VRF, based on the XMSS signature scheme. In addition to being the first quantum-safe VRF proposal based on symmetric primitives, X-VRF is the first many-time quantum-safe VRF while existing quantum-safe constructions only support very few evaluations. Being based on symmetric-key primitives that have been studied extensively within the security community, X-VRF provides strong confidence that it can withstand quantum attacks in the long term.

Despite its stateful nature, we empower XMSS with the blockchain so that users do not need to maintain individual states. While increasing the usability of XMSS, our technique also enforces honest behaviour when creating an X-VRF output so as to satisfy the fundamental uniqueness property of VRFs.

We show how X-VRF can be used in the Algorand setting to extend it to a quantum-safe blockchain, and provide various instances of X-VRF, as each may suit a different setting. Our X-VRF instances are the most efficient quantum-safe many-time VRF proposals in the literature. Our extensive performance evaluation, analysis, and implementation indicates the effectiveness of our proposed constructions in practice. In particular, we show that X-VRF can maintain a very competitive throughput close to the existing Algorand protocol and can produce substantially more transactions per second than Bitcoin.

1 INTRODUCTION

There is an increasing concern that the security of some classical cryptosystems will be compromised due to advances in quantum computing technologies, especially in recent years where this capability is becoming more mainstream and available to the masses, e.g. quantum computing as a service [13]. It is well known that quantum computers are capable of efficiently solving the mathematical problems underlying the currently most popular cryptosystems, i.e., the integer factorization and discrete logarithm problems. A growing body of literature recognises the importance of post-quantum (a.k.a.

quantum-safe) cryptography, i.e., cryptographic constructions that remain secure even in the face of large quantum computers.

Making blockchains post-quantum have received considerable attention due to the severe security impact in case the underlying hardness assumptions are broken. Post-quantum cryptographic primitives relevant for blockchain are mainly designed using lattice-based cryptography [29], multivariate cryptography [11], hash-based cryptography [4] and code-based cryptography [27]. However, most of the developed primitives based on mathematical assumptions offer either signatures or public keys that are orders of magnitude larger than the currently used ones [28]. In contrast, solutions based on symmetric key primitives (e.g. hash-based cryptography) meet three important goals of post-quantum cryptography: efficiency, confidence, and usability [4]. Quantum-safe symmetric cryptography is not significantly different from the current symmetric cryptography (only the key size needs to be doubled). Most of the fundamental symmetric primitives have been defined and standardized for decades hence boosting confidence in using them. The other aforementioned post-quantum candidates are relatively new and perhaps may be broken when more cryptanalytic efforts to attack them are undertaken [4]. Furthermore, symmetric primitives have been deployed widely and are ready for integration into various applications.

Early blockchain systems (e.g. Bitcoin) are based on Proof-of-Work (PoW), which is a consensus mechanism that enables a “lottery” among the miners where the winner gets the reward and decides how to extend the blockchain (i.e., adds the next block). The first node who solves a difficult computational puzzle is the winner. Due to the costly nature of PoW, an alternative consensus mechanism based on Proof-of-Stake (PoS) has gained popularity [2]. The assumption behind PoS is that the majority of the wealth in the system is controlled by the honest participants (whereas in PoW, it is considered that the majority of the computing power belongs to the honest participants). An important cryptographic primitive that many PoS solutions rely on to provide the required security is Verifiable Random Functions (VRF). VRFs can also be used in different blockchain applications as we describe in later sections.

1.1 Verifiable Random Function (VRF)

Micali et al. [26] introduced the concept of VRF, a variant of Pseudo-random Functions (PRFs) satisfying a *verifiability* property. That is, the knowledge of a secret key enables one to evaluate the pseudo-random function and to prove the correctness of such evaluations without revealing the secret key or compromising the *pseudorandomness* of the function. In more detail, a VRF is associated with a secret key sk_{VRF} and the corresponding public key pk_{VRF} which can be used to verify the VRF output. Using this secret key sk_{VRF} , a user can compute the function $(y_{VRF}, \pi_{VRF}) \leftarrow \text{VRF Eval}(sk_{VRF}, x)$ at some input x and generate a corresponding proof π_{VRF} of the correct computation of y_{VRF} . The proof π_{VRF} can be verified using pk_{VRF} (and public parameters). Additionally to the pseudorandomness and verifiability properties, a secure VRF should also satisfy the notion of *uniqueness*, meaning that under a fixed public key and for one specific VRF input x , there cannot exist valid proofs $\widetilde{\pi_{VRF}}$ of correct computation corresponding to two *distinct* VRF output values $y_{VRF} \neq \widetilde{y_{VRF}}$.

1.2 VRFs in the Blockchain

VRFs are widely used in PoS blockchains to conduct secret cryptographic sortition such as to elect block proposers and voting committee members [8, 9, 14, 17, 18, 25] as well as various applications in smart contracts such as online lottery. In this paper we focus on the cryptographic sortition of VRFs in the blockchain.

Cryptographic sortition is an innovation of Algorand which enables a set of users to select themselves to participate in Algorand’s consensus protocol in a private manner. That is, they are not identified to anyone else; including potential adversaries [1]. The committee-based consensus protocol proposed by Gilad et al. [14] for Algorand leverages a VRF to implement cryptographic sortition. Moreover, the VRF arrangement in Algorand enables fair private non-interactive random selection of committee members, weighted by their account balances.¹ This random selection of committee members in Algorand also prevents attackers from targeting a specific committee member. Additionally, the use of a VRF in Algorand’s consensus protocol provides scalability and performance required to support millions of users. The core of Algorand’s blockchain is a Byzantine Agreement protocol that is executed among a small randomly chosen committee of users for each round [14]. More precisely, this protocol makes use of a VRF in the following way. Each user holds a secret/public key pair (sk_{VRF}, pk_{VRF}) . Let B be a block to be added. Each user should take the following steps to determine whether s/he is part of the committee [16]:

- (1) Compute $(y_{VRF}, \pi_{VRF}) \leftarrow \text{VRF Eval}(sk_{VRF}, Q)$ for the user secret key sk_{VRF} and a publicly known random seed Q and output a pseudorandom value y_{VRF} and a proof of correct computation π_{VRF} .
- (2) Check if y_{VRF} is in the target range $[0, P]$, where P is a parameter that depends on the current stake of the user. If this condition holds, the user will be a committee member for B .

The committee membership can be verified by all users in Algorand’s network by executing the verification algorithm of the VRF

with pk_{VRF} , Q , y_{VRF} and π_{VRF} as input, and additionally checking if $y_{VRF} \in [0, P]$. Algorand instantiates their protocol with a long-term (practically unlimited) stateless VRF based on elliptic curves (ECVRF).

Similarly, Ouroboros Praos [8] conducts a private test that is executed locally using a VRF to determine whether a participant belongs to the slot leader set for any slots within a specific time period.

The uniqueness, pseudorandomness and provability properties of the VRF play crucial roles in preventing brute-force attacks that try various output values y_{VRF} in order to find one that falls within the desired range. Moreover, the committee membership procedure as well as its verification are computationally inexpensive, making the consensus protocol highly scalable.

1.3 Our Contribution

In this work, we introduce the most efficient many-time post-quantum VRF construction, called X-VRF. It is built only from symmetric primitives, contrary to existing VRFs which require asymmetric cryptographic primitives. X-VRF is based on the stateful XMSS signature. Inheriting from the statefulness of XMSS, X-VRF is a stateful VRF (essentially a counter-VRF where the signer/verifier needs to store a single counter). In contrast to the classical applications of VRF which may require a stateless construction, for most of the blockchain settings it is often sufficient to employ a stateful primitive. In fact, the blockchain’s block number, which is already maintained by and available to all users, is the only state information required for our application of X-VRF. Therefore X-VRF in the blockchain environment is actually *stateless* from the point of view of a blockchain user (as the user does *not* need to store an individual state information). X-VRF can then be naturally deployed over Algorand, and utilize Algorand’s blockchain as the state counter. We believe this ‘blockchain-empowered’ XMSS/X-VRF construction can prove useful in other applications as well. We provide a technical overview of our approach in the next section.

We implement our construction under different settings and provide a thorough evaluation analysis that shows its efficiency and practicality. All of our settings provide a very efficient performance: the computation time for both the evaluation and verify functions is less than 1 ms. A user public key and a secret key are just 64 bytes and 132 bytes, respectively, while the proof size is only around 3 KB for all settings. The main difference between X-VRF instances is the trade-off between (one-time) key generation runtime, memory requirement and the lifetime of a key pair.

We further discuss the integration of our VRF into the Algorand blockchain. To support 100 nodes in the blockchain system, our VRF can achieve almost 1000 transactions per second (TPS). If we increase the number of nodes to 1000, our VRF can still achieve around 500 TPS. More importantly, all of our different settings provide a practically long to ultra long key lifetime, ranging from 45 hours to 20 years. When the key lifetime passes, the user just needs to generate a new key pair and broadcast this on the blockchain. The two existing practical post-quantum VRFs in the literature, LB-VRF [12] and ISO-VRF [24], only support a few VRF outputs to be generated by a key pair (i.e., they are not long-term VRFs). In the Algorand setting, the key lifetime of LB-VRF and ISO-VRF is just

¹A user would not benefit from having/creating multiple accounts.

in the order of seconds, meaning that committee members need to update their keys (almost) every round, which is quite costly.

For a good viewpoint of comparison, we also introduce a naive post-quantum VRF proposal that combines a symmetric-key PRF with a non-interactive zero-knowledge proof (NIZK) of correct evaluation. We pick the NIZK based on the proof system in [23] which also uses symmetric primitives and thus is fair to our comparison. As expected, this proposal yields a stateless VRF construction which we call SL-VRF. It is significantly more costly in terms of computation and communication in comparison to X-VRF while being long-term and stateless. Our experiment shows that SL-VRF is 500 to 5000 times slower than our X-VRF in evaluation and verification, while the proof size is also 13 times larger than our X-VRF.

1.4 Our Approach

Deterministic XMSS [6] is a good candidate for the construction of a post-quantum VRF as it is the most efficient post-quantum signature scheme constructed from symmetric primitives in terms of signature size. XMSS employs a hash tree, where each leaf uses a one-time signature scheme called WOTS⁺ [20]. WOTS⁺ is by construction unique (i.e., for any fixed message and public key, one can only create a single valid signature). However, by itself, deterministic XMSS does not satisfy the fundamental uniqueness property of a VRF since a user can use different tree leaves (that is, different WOTS⁺ keys) to construct a new (and of course different) XMSS signature even for the same message. Thus it is obvious that a user can generate two different valid XMSS signatures for a single message.

To satisfy the uniqueness of XMSS, we need to force the user to use a pre-determined WOTS⁺ key pair in signing. For this, we make use of the blockchain state, i.e., empower XMSS with blockchain. In particular, the block number of a particular round in the blockchain consensus can serve as a global counter, which we can use to force users to use a specific WOTS⁺ key pair at each round. More precisely, at block number K , when verifying the XMSS-based VRF output, the verifier also checks that the leaf index indicated by the authentication path is consistent with K (See Figure 2). As a result, this ensures that the user cannot choose between different WOTS⁺ keys and also allows users to avoid maintaining a local state. We formally prove that our X-VRF constructed from this approach satisfies all security requirements of a VRF.

On the other hand, due to the computational/storage cost of creating and storing a big hash tree, X-VRF cannot be used to create, say, 2^{64} outputs as each output consumes one leaf. We investigate various X-VRF instances with tradeoffs between computation, storage and lifetime of an X-VRF key pair. For example, X-VRF-27 (with 2^{27} leaves) construction offers a key lifetime of more than 20 years in the Algorand setting and hence can be seen as long-term VRF, though it requires a relatively long (around 2 days on a single core) one-time key generation process. Of course, this process can be optimized using standard techniques such as parallel processing or delegating computation.

1.5 Roadmap

The rest of the paper is organized as follows. In Section 2, we recall the important signatures and other cryptographic primitives that

are useful for our main constructions. In Section 3, we present the “natural” VRF construction, denoted as SL-VRF, a stateless long-term verifiable random function from a pseudorandom function and a NIZK protocol. Section 4 introduces our main construction, X-VRF, wherein we prove its security requirements. In Section 5, we discuss the implementation results and the evaluation of the two VRF constructions, and compare their performances. In Section 6, we describe the integration of our VRFs into the Algorand blockchain.

2 PRELIMINARIES

In this section we recall the cryptographic primitives WOTS⁺ (one-time signature), XMSS (stateful signature), and fundamental definitions used in this paper. For more details on the aforementioned signature schemes we refer to [6, 20]. For a hash function H (defined in Definition 1), let $H^w(m)$ denote the result of iteratively applying w times the function H with m as the input for the first iteration. $x \stackrel{\$}{\leftarrow} \mathcal{X}$ denotes sampling x uniformly from the domain \mathcal{X} from a random seed or at random.

2.1 Cryptographic Primitives

DEFINITION 1 (HASH-FUNCTION). A hash function is an efficient function defined by:

$$H : \{0, 1\}^* \rightarrow \{0, 1\}^n, D \leftarrow H(m) \quad (1)$$

that maps an arbitrary-length message m to an n -bit hash value denoted as the digest D . A hash function is expected to satisfy the following security properties:

Preimage Resistance: For any hash digest D , it is computationally infeasible to find a message m s.t. $H(m) = D$.

Collision Resistance: For any two messages $m_1 \neq m_2$, then $H(m_1) = H(m_2)$ with negligible probability.

Second Preimage Resistance: Given m , it is computationally infeasible to find $m' \neq m$ s.t. $H(m') = H(m)$.

DEFINITION 2 (PSEUDORANDOM FUNCTION (PRF)). A function PRF defined with a key space $\mathcal{K} \in \{0, 1\}^n$:

$$\text{PRF} : \mathcal{K} \times \{0, 1\}^n \rightarrow \{0, 1\}^n, y \leftarrow \text{PRF}(k, x) \quad (2)$$

is a pseudorandom function if the advantage of a polynomial-time adversary \mathcal{A} is $\text{Adv}_{\mathcal{A}}^{\text{PRF}} = |\Pr[\mathcal{A}^{\text{PRF}(k, \cdot)}(1^\lambda) = 1] - \Pr[\mathcal{A}^{f(\cdot)}(1^\lambda) = 1]| < \text{negl}(\lambda)$ where $k \leftarrow \mathcal{K}$ and f is a random function such that $f : \{0, 1\}^n \leftarrow \{0, 1\}^n$

DEFINITION 3 (WOTS⁺ [20]). WOTS⁺ is a Winternitz type one-time signature scheme where a public key is used to sign exactly one message m . WOTS⁺ is parametrized by the Winternitz parameter $w \in \{4, 16, 256\}$ (which determines the time-memory trade-off), the message length $|m|$, $\text{len}_1 = \left\lceil \frac{|m|}{\log(w)} \right\rceil$, $\text{len}_2 = \left\lceil \frac{\log(\text{len}_1(w-1))}{\log(w)} \right\rceil + 1$ and $\text{len} = \text{len}_1 + \text{len}_2$, where len is the number of n -bit string elements in WOTS⁺ keys and signatures. It is defined by the following three algorithms:

WOTS⁺.KeyGen(1^λ): The key generation algorithm on input the security parameter λ , outputs a pair of secret and public keys:

- (1) For $n = 2\lambda$, sample $k_1, \dots, k_{\text{len}} \stackrel{\$}{\leftarrow} \{0, 1\}^n$ and $\mathbf{r} = (r_0, \dots, r_{w-1})$ with $r_i \in \{0, 1\}^n$.

- (2) For $i = 1, \dots, \text{len}$ and a hash function H compute $y_i = c^w(k_i, \mathbf{r})$, where $c^j(x, \mathbf{r}) = H(c^{j-1}(x, \mathbf{r}) \oplus \mathbf{r}_j)$ for $j > 0$.
- (3) Output $\text{WOTS}^+.\text{sk} = (k_1, \dots, k_{\text{len}})$ and $\text{WOTS}^+.\text{pk} = (y_1, \dots, y_{\text{len}}, \mathbf{r})$.

$\text{WOTS}^+.\text{Sign}(\text{WOTS}^+.\text{sk}, \text{WOTS}^+.\text{pk}, m)$: The signing algorithm on input a message m , a secret key $\text{WOTS}^+.\text{sk} = (k_1, \dots, k_{\text{len}})$ and a public key $\text{WOTS}^+.\text{pk} = (y_1, \dots, y_{\text{len}}, \mathbf{r})$ outputs a signature $\text{WOTS}^+.\sigma$:

- (1) Parse m as $(m_1, \dots, m_{\text{len}_1})$ with $m_i \in [0, w - 1]$ and compute the checksum $C = \sum_{i=1}^{\text{len}_1} (w - 1 - m_i)$. Concatenate the message and the checksum to get $(b_1, \dots, b_{\text{len}})$ with $b_i \in [0, w - 1]$.
- (2) For $i = 1, \dots, \text{len}$, compute $\text{WOTS}^+.\sigma_i = c^{b_i}(k_i, \mathbf{r})$. Output the signature $\text{WOTS}^+.\sigma = (\text{WOTS}^+.\sigma_1, \dots, \text{WOTS}^+.\sigma_{\text{len}})$.

$\text{WOTS}^+.\text{Verify}(m, \text{WOTS}^+.\sigma, \text{WOTS}^+.\text{pk})$: The verification algorithm takes as input the message m the signature $\text{WOTS}^+.\sigma = (\text{WOTS}^+.\sigma_1, \dots, \text{WOTS}^+.\sigma_{\text{len}})$ and the public key $\text{WOTS}^+.\text{pk} = (y_1, \dots, y_{\text{len}}, \mathbf{r})$, and proceeds as follows:

- (1) Re-compute the checksum C from the message m to obtain $(b_1, \dots, b_{\text{len}})$.
- (2) Compute (and output) $\text{WOTS}^+.\text{pk}' \leftarrow (c^{w-1-b_1}(\text{WOTS}^+.\sigma_1, \mathbf{r}_{b_1+1, w-1}), \dots, c^{w-1-b_{\text{len}}}(\text{WOTS}^+.\sigma_{\text{len}}, \mathbf{r}_{b_{\text{len}}+1, w-1}), \mathbf{r})$
- (3) Accept if $\text{WOTS}^+.\text{pk} = \text{WOTS}^+.\text{pk}'$, reject otherwise

REMARK 1. The complete public key $\text{WOTS}^+.\text{pk}$ is necessary for $\text{WOTS}^+.\text{Verify}$ only if WOTS^+ is used as an independent signature scheme. In its integration to XMSS (see below) $\text{WOTS}^+.\text{Verify}$ does not output a Boolean value but directly outputs the re-computed $\text{WOTS}^+.\text{pk}'$ (in Step 2) from the signature $\text{WOTS}^+.\sigma$. Therefore, only the element \mathbf{r} of $\text{WOTS}^+.\text{pk}$ is needed in the input of $\text{WOTS}^+.\text{Verify}$ in XMSS.

REMARK 2. It is easy to see that no PPT adversary can create two distinct WOTS^+ signatures on the same message m and under the same public key $\text{WOTS}^+.\text{pk}$ assuming the hash function $H(\cdot)$ is collision-resistant. This uniqueness property is important for our VRF constructions.

DEFINITION 4 (XMSS [6]). XMSS is a stateful signature scheme constructed on the idea of a Merkle tree (see Figure 1). It is parameterized by the height h of the tree, the length n (in bits) of a message m and the Winternitz parameter w used in the underlying WOTS^+ one-time signature scheme. We only consider the deterministic XMSS construction, which consists of three algorithms:

$\text{XMSS}.\text{KeyGen}(1^\lambda)$: The key generation algorithm on input the security parameter λ outputs a pair consisting of secret and public keys:

- (1) Initialize $\text{PRF}.\text{sk} \xleftarrow{\$} \{0, 1\}^n$, $\text{XMSS}.\text{seed} \xleftarrow{\$} \{0, 1\}^n$ and $\text{XMSS}.\text{idx} = 0$;
- (2) For $i = 1, \dots, 2^h$ compute $\text{WOTS}^+.\text{seed}_i \leftarrow \text{PRF}(\text{PRF}.\text{sk}, i)$ and use $\text{WOTS}^+.\text{seed}_i$ as the random seed to generate $\text{WOTS}^+.\text{sk}_i$ and $\text{WOTS}^+.\text{pk}_i$ as in $\text{WOTS}^+.\text{KeyGen}$, where PRF is a pseudorandom function (see Definition 2 for a formal definition of a PRF).
- (3) Set $\text{XMSS}.\text{root}$ to be the root of the tree generated based on the 2^h WOTS^+ public keys and $\text{XMSS}.\text{seed}$ to generate the public bitmask b , which is used as a mask of the children of nodes

(an example is illustrated see Figure 1). The tree is not directly constructed using the WOTS^+ public keys as leaves but using their compression into a single n -bits value. The compression is the root of tree constructed with len elements of $\text{WOTS}^+.\text{sk}$ as leaves.

- (4) Output $\text{XMSS}.\text{idx}$, $\text{XMSS}.\text{sk} = (\text{PRF}.\text{sk}, \text{XMSS}.\text{root}, \text{XMSS}.\text{seed})$, $\text{XMSS}.\text{pk} = (\text{XMSS}.\text{root}, \text{XMSS}.\text{seed})$.

$\text{XMSS}.\text{Sign}(\text{XMSS}.\text{sk}, m, \text{XMSS}.\text{idx})$: The signing algorithm takes as input the secret key $\text{XMSS}.\text{sk} = (\text{PRF}.\text{sk}, \text{XMSS}.\text{root}, \text{XMSS}.\text{seed})$, $\text{XMSS}.\text{idx}$ and a message m , and outputs a signature $\text{XMSS}.\sigma$:

- (1) Compute $\text{WOTS}^+.\text{seed}_i \leftarrow \text{PRF}(\text{PRF}.\text{sk}, i)$ with $i = \text{XMSS}.\text{idx}$ and use $\text{WOTS}^+.\text{seed}_i$ to generate $\text{WOTS}^+.\text{sk}_i$ and $\text{WOTS}^+.\text{pk}_i$ (including \mathbf{r}) as in $\text{WOTS}^+.\text{KeyGen}$.
- (2) Generate the WOTS^+ signature $\text{WOTS}^+.\sigma \leftarrow \text{WOTS}^+.\text{Sign}(\text{WOTS}^+.\text{sk}_i, \text{WOTS}^+.\text{pk}_i, m)$
- (3) Add the authentication path $\text{XMSS}.\text{Auth}$ which is the path from the $\text{WOTS}^+.\text{pk}_i$, where $i = \text{XMSS}.\text{idx}$, to the root $\text{XMSS}.\text{root}$. (In the example in Figure 1 $\text{XMSS}.\text{idx} = (011)_2 = 3_{10}$ and the authentication path consists of the grey nodes)
- (4) Set $\text{XMSS}.\sigma = (\text{WOTS}^+.\sigma, i, \text{XMSS}.\text{Auth})$ for $i = \text{XMSS}.\text{idx}$ and increment $\text{XMSS}.\text{idx}$.
- (5) Output $\text{XMSS}.\sigma$.

$\text{XMSS}.\text{Verify}(\text{XMSS}.\text{pk}, m, \text{XMSS}.\sigma)$: The verification algorithm takes as input the public key $\text{XMSS}.\text{pk} = (\text{XMSS}.\text{root}, \text{XMSS}.\text{seed})$, the message m and the signature $\text{XMSS}.\sigma = (\text{WOTS}^+.\sigma, i, \text{XMSS}.\text{Auth})$, and computes:

- (1) Generate \mathbf{r} from $\text{WOTS}^+.\text{seed}_i \leftarrow \text{PRF}(\text{PRF}.\text{sk}, i)$
- (2) Compute $\text{WOTS}^+.\text{pk}' \leftarrow \text{WOTS}^+.\text{Verify}(m, \text{WOTS}^+.\sigma, \mathbf{r})$ (see Remark 1).
- (3) Compute a root r' starting from $\text{WOTS}^+.\text{pk}'$ and following the authentication path $\text{XMSS}.\text{Auth}$ and the direction indicated by i .
- (4) Accept if $\text{XMSS}.\text{root} = r'$, reject otherwise.

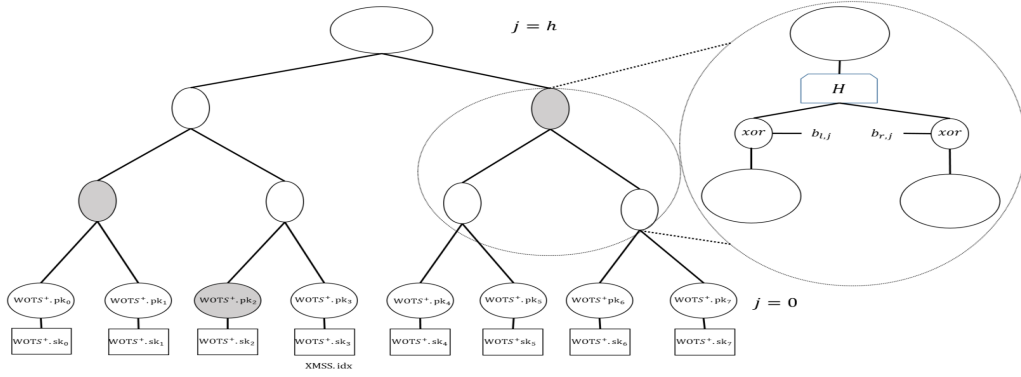

Note that each user keeps an $\text{XMSS}.\text{idx}$ value as some state information and increments it every time a signature is generated. However, there is no mechanism to enforce that the signer really consumes the leaves in this fashion. The verification still succeeds if a user decides to create the signature using some random leaf.

While WOTS^+ keys can only be used to sign once, XMSS keys can be used to sign 2^h times. For WOTS^+ , $|\text{WOTS}^+.\text{pk}| = |\text{WOTS}^+.\sigma| = \text{len} \cdot n$ bits. The public key in XMSS consists of only $2n$ bits, but the signatures are bigger than in WOTS^+ . We provide a summary of the parameters in Table 1.

REMARK 3. Observe that XMSS as defined above does not satisfy uniqueness as a signer can choose different tree leaves (i.e., different WOTS^+ keys) to sign the same message, leading to different signatures on the same message. We overcome this problem when we design our XMSS-based VRF construction.

2.2 Non-interactive Zero-Knowledge Proofs (NIZK)

Let $\mathcal{R} \subseteq \{0, 1\}^* \times \{0, 1\}^*$ be a binary relation and x, w denote the statement and the witness of this relation, respectively. Let Λ be the corresponding language defined as $\Lambda = \{x \mid \exists w \text{ s.t. } (x, w) \in \mathcal{R}\}$.

Figure 1: The XMSS tree construction.
Table 1: Summary of parameters

Parameter	Description
λ	level of post-quantum security
n	size of the hash function output and equal to $2 \cdot \lambda$
w	Winternitz parameter
len	number of n -bit values in WOTS+ keys and signatures. $\text{len} = \text{len}_1 + \text{len}_2$, with $\text{len}_1 = \left\lceil \frac{ m }{\log(w)} \right\rceil$ and $\text{len}_2 = \left\lfloor \frac{\log(\text{len}_1(w-1))}{\log(w)} \right\rfloor + 1$.
h	height of the hash tree (i.e., there are 2^h leaves)

DEFINITION 5 (NIZK). A non-interactive zero-knowledge proof Π_{NIZK} for the relation \mathcal{R} consists of the following probabilistic polynomial time algorithms:

Setup(1^λ): This algorithm takes as input the security parameter 1^λ and outputs a verification key vk .

Prove(x, w): On input a statement x and a witness w , this algorithm outputs a proof π .

Verify(x, vk, π): On input a verification key vk , a statement x and a proof π , output either 1 (if the proof is accepted) or 0.

A NIZK proof must satisfy the following security requirements:

Completeness: For all $(x, w) \in \mathcal{R}$ if we run $(\text{vk}) \leftarrow \text{Setup}(1^\lambda)$ then we have

$$\Pr[\pi \leftarrow \text{Prove}(x, w) : \text{Verify}(x, \text{vk}, \pi) = 1] = 1$$

Soundness: For all (possibly inefficient) adversaries \mathcal{A} , if we run $(\text{vk}) \leftarrow \text{Setup}(1^\lambda)$, then we have

$$\Pr[(x, \pi) \leftarrow \mathcal{A}^{\text{Verify}(\cdot, \text{vk}, \cdot)}(1^\lambda) : x \notin \mathcal{L} \wedge \text{Verify}(x, \text{vk}, \pi) = 1] = \text{negl}(\lambda)$$

Zero-Knowledge: For all PPT adversaries \mathcal{A} there exists a simulator $\mathcal{S} = (\mathcal{S}_1, \mathcal{S}_2)$, s.t. if we run $(\text{vk}) \leftarrow \text{Setup}(1^\lambda)$ and $(\bar{\text{vk}}, \bar{\tau}) \leftarrow \mathcal{S}_1(1^\lambda)$

then we have

$$\begin{aligned} & \Pr[\mathcal{A}^{\text{Prove}(\cdot, \cdot)}(1^\lambda, \text{vk}) = 1] \\ & - \Pr[\mathcal{A}^{\mathcal{S}_2(\bar{\text{vk}}, \bar{\tau})}(1^\lambda, \bar{\text{vk}}) = 1] = \text{negl}(\lambda) \end{aligned}$$

2.3 Verifiable Random Function (VRF)

DEFINITION 6 (VERIFIABLE RANDOM FUNCTION (VRF) [26]). A VRF with input length $\ell(\lambda)$ and output length $m(\lambda)$ consists of the following polynomial-time algorithms:

ParamGen(1^λ): On input the security parameter 1^λ , this probabilistic algorithm outputs some global, public parameter pp_{VRF} .

KeyGen(pp_{VRF}): On input public parameter pp_{VRF} this probabilistic algorithm outputs two binary strings, a secret key sk_{VRF} and a public key pk_{VRF} .

VRF Eval($\text{sk}_{\text{VRF}}, x$): On input a secret key sk_{VRF} and an input x this algorithm outputs the VRF value VRF and the corresponding proof π_{VRF} proving that VRF was correctly computed.

Verify($\text{pk}_{\text{VRF}}, \text{VRF}, x, \pi_{\text{VRF}}$): On input $(\text{pk}_{\text{VRF}}, \text{VRF}, x, \pi_{\text{VRF}})$ this probabilistic algorithm outputs either YES or NO.

A secure VRF satisfies the following properties:

Provability: If $(\text{VRF}, \pi_{\text{VRF}})$ is the output of $\text{VRF Eval}(\text{sk}_{\text{VRF}}, x)$, where the public and the secret key are honestly generated, then $\text{Verify}(\text{pk}_{\text{VRF}}, \text{VRF}, x, \pi_{\text{VRF}})$ outputs YES.

Pseudorandomness: Let $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$ be a polynomial-time adversary playing the following experiment $\text{Exp}_{\mathcal{A}}^{\text{PT}}$:

- (1) $\text{pp}_{\text{VRF}} \leftarrow \text{ParamGen}(1^\lambda)$
- (2) $(\text{pk}_{\text{VRF}}, \text{sk}_{\text{VRF}}) \leftarrow \text{KeyGen}(\text{pp}_{\text{VRF}})$
- (3) $(x, st) \leftarrow \mathcal{A}_1^{\text{OVRF Eval}(\text{sk}_{\text{VRF}}, \cdot)}(\text{pk}_{\text{VRF}})$
- (4) $(\text{VRF}, \pi_{\text{VRF}}) \leftarrow \text{VRF Eval}(\text{sk}_{\text{VRF}}, x)$
- (5) $\text{VRF}, \pi_{\text{VRF}} \xleftarrow{\$} \{0, 1\}^{m(\lambda)}$
- (6) $b \xleftarrow{\$} \{0, 1\}$
- (7) $b' \leftarrow \mathcal{A}_2^{\text{OVRF Eval}(\text{sk}_{\text{VRF}}, \cdot)}(\text{VRF}, b, st)$

where $\text{OVRF Eval}(\text{sk}_{\text{VRF}}, \cdot)$ is an oracle that on input a value x outputs VRF and π_{VRF} .

Any polynomial-time adversary \mathcal{A} that does not issue any queries to OVRF Eval on the value x , wins the above game with probability at most $1/2 + \text{negl}(\lambda)$.

Uniqueness: No values $(pk_{\text{VRF}}, y_{\text{VRF},1}, y_{\text{VRF},2}, x, \pi_{\text{VRF},1}, \pi_{\text{VRF},2})$ can satisfy $\text{Verify}(pk_{\text{VRF}}, y_{\text{VRF},1}, x, \pi_{\text{VRF},1}) = \text{Verify}(pk_{\text{VRF}}, y_{\text{VRF},2}, x, \pi_{\text{VRF},2}) = 1$, when $y_{\text{VRF},1} \neq y_{\text{VRF},2}$

Note: In contrast to the *unconditional* uniqueness property defined in [26] our VRF constructions satisfy *computational* uniqueness, where the running time of the adversary attacking the uniqueness property is polynomially bounded. This stems from the fact that we rely on the collision-resistance of a hash function.

3 SL-VRF: STATELESS VERIFIABLE RANDOM FUNCTION FROM PRF AND NIZK

We apply the idea of instantiating a VRF from a PRF+NIZK construction which has been introduced in [15]. Recent works like [7, 23] allows one to prove knowledge of a secret key k that generate $y \leftarrow \text{PRF}(k, x)$ where x, y are public information while preserving the secrecy of k , using symmetric primitives only. This means that PRF is an arithmetic circuit like a block cipher or a hash function. The current state of the art is the NIZK introduced by Katz et al. (KKW) [23] which is at the heart of post-quantum security of the digital signature Picnic [7] submitted at the NIST standardization process.

The KKW NIZK protocol introduced in [23] proves the knowledge of a secret key without revealing any information about it with the help of the input and outputs of a binary circuit like a PRF or a block cipher. KKW is instantiated using the concept of MPC-in-the-head introduced in [21]. MPC-in-the-head simulates a multi-party computation of the circuit between P parties. Then to prove the knowledge of the secret key the protocol reveals the views of all parties except one. The proof is verified by recomputing the output based on the view of $P - 1$ parties.

The size of the proof depends directly on the number of parties P of the MPC protocol. In the circuit, there are four different operations: Addition with a public constant, addition of values computed by all parties ("OR" gates), multiplication with a constant and multiplication of values computed by all parties ("AND" gates). Only the last one requires communication between the parties to be performed. This means that the proof contains the views of $P - 1$ parties for each "AND" gate of the circuit, and therefore its number needs to be optimized. For this reason, KKW works with the block cipher LowMC [3] which is a cryptographic primitive with low multiplicative complexity, i.e. low number of multiplications in a circuit ("AND" gates).

Ensuring Uniqueness: The idea behind our stateless VRF construction is to use the block cipher LowMC as a PRF to generate the random outputs and then prove with KKW the knowledge of the secret key sk_{VRF} . In other words, taking a message x as an input, a user generates the corresponding pseudo-random outputs $y \leftarrow \text{PRF}(sk_{\text{VRF}}, x)$ and then use the KKW protocol as the VRF proof. KKW protocol is made non-interactive using the Fiat-Shamir transform. However, KKW allows to prove the knowledge of the secret key that generates y from the public x without requiring the use of the public key linked to the secret key sk_{VRF} . This causes a problem for the uniqueness of the VRF. Indeed, a user could generate a different value y' for the same input x using another secret key sk_{VRF}' . Therefore, we modify the public key as follows: pk_{VRF} is now composed of two elements $pk_{\text{VRF},1}$ and $pk_{\text{VRF},2}$ such

that $pk_{\text{VRF},2} \leftarrow \text{PRF}(sk_{\text{VRF}}, pk_{\text{VRF},1})$. The evaluation procedure will prove that the secret key which generated y from x is the same as that generated $pk_{\text{VRF},2}$ from $pk_{\text{VRF},1}$ and so it is infeasible for a malicious user to change its secret key in order to generate another output of the VRF.

3.1 SL-VRF from PRF+NIZK Construction

ParamGen(1^λ): Pick a collision-resistant hash $H : \{0, 1\}^* \rightarrow \{0, 1\}^n$ (for the Fiat-Shamir transform) and a Pseudo-random function $\text{PRF} : \{0, 1\}^* \times \{0, 1\}^n \rightarrow \{0, 1\}^n$. Output public parameters $pp_{\text{VRF}} = (H, \text{PRF})$.

KeyGen(pp_{VRF}): On input public parameters computes $sk_{\text{VRF}} \xleftarrow{\$} \{0, 1\}^n$ and $pk_{\text{VRF},1} \xleftarrow{\$} \{0, 1\}^n$. Then it computes $pk_{\text{VRF},2} \leftarrow \text{PRF}(sk_{\text{VRF}}, pk_{\text{VRF},1})$ and sets $pk_{\text{VRF}} = (pk_{\text{VRF},1}, pk_{\text{VRF},2})$

VRF Eval(sk_{VRF}, x): Given sk_{VRF} and a message x , the algorithm follows this procedures:

- (1) $y \leftarrow \text{PRF}(sk_{\text{VRF}}, x)$
- (2) $pk.\text{check} \leftarrow (x, y, pk_{\text{VRF}})$
- (3) $\pi_{\text{NIZK}} \leftarrow \text{Prove}(pk.\text{check}, sk_{\text{VRF}})$. For a relation \mathcal{R} the NIZK proof π_{NIZK} holds iff:
 - (a) $y \leftarrow \text{PRF}(sk_{\text{VRF}}, x)$ and
 - (b) $pk_{\text{VRF},2} \leftarrow \text{PRF}(sk_{\text{VRF}}, pk_{\text{VRF},1})$.

This can be done due to the KKW [22, 23] procedure on a binary circuit composed of two PRFs (LowMC block cipher as explained before) linked with an additional "AND" gate, assuring that both statements are fulfilled.

VRF Verify(y, x, π_{NIZK}): On input $(\pi_{\text{NIZK}}, x, y)$ it runs NIZK verification algorithm $\text{Verify}(x, y, \pi_{\text{NIZK}})$ of the underlying KKW NIZK proof and outputs 0/1.

The security depends on the properties of the underlying PRF for a given key sk_{VRF} (collision resistance and one-wayness) and the security of KKW NIZK see [23])

SL-VRF Security Discussion. The provability of SL-VRF follows via direct investigation. As long as the underlying KKW NIZK proof is correct, SL-VRF is provable. The security, i.e. uniqueness and pseudorandomness of our SL-VRF depends on the properties of the underlying PRF. The uniqueness follows from two facts; first the PRF output is a deterministic function of the secret key sk_{VRF} and the input x , meaning that evaluating the PRF twice on the same value yields the same output. Secondly, the validity proof of the statement (3)(b) in the VRF evaluation procedure (VRF Eval) presented in Section 3.1 forces each user to use her fixed secret key for each evaluation and so ensures uniqueness due to the deterministic property of the PRF as explained before. The pseudorandomness of the VRF output is inherited from the corresponding pseudorandomness property of the underlying PRF.

In order to evaluate the efficiency of our SL-VRF, we need to analyse the underlying NIZK proof construction. A detailed evaluation is provided in Section 5.

4 X-VRF: VERIFIABLE RANDOM FUNCTION FROM XMSS

In this section we introduce a construction of a secure VRF from XMSS. As discussed in the introduction, naively extending XMSS to a VRF does not result in a secure construction as the uniqueness

property can easily be violated. In particular, when a user constructs a hash tree in XMSS, she is able to use any of the leaves (i.e., WOTS⁺ keys) to create the XMSS signature. As a result, XMSS by itself does not satisfy uniqueness.

This is indeed very problematic in a blockchain application that, for example, uses the VRF output to perform leader election (as in Algorand). More specifically, the user can simply create a huge hash tree, say, with N leaves for XMSS, and then she will be able to amplify his success probability of being elected by a factor of N as she can try to create the XMSS-based VRF output from each leaf and can output the one that is successful.

To circumvent this problem, we index every VRF evaluation and modify the uniqueness requirement to the case where for a fixed message and public key the VRF evaluations with the same index always lead to the same value. Then, in the later sections, we enforce all users to use a pre-determined index ctr when creating an XMSS-based VRF output. This way, the users does not have the ability to choose between multiple leaves and can only produce a single signature output on a message.

4.1 X-VRF from XMSS Construction

$\text{ParamGen}(1^\lambda)$: On input security parameter λ , output public parameters $\text{pp}_{\text{VRF}} = H$, for $H : \{0, 1\}^* \rightarrow \{0, 1\}^n$.

$\text{KeyGen}(\text{pp}_{\text{VRF}})$: On input public parameters pp_{VRF} ,

- (1) Run $(\text{XMSS.idx}, \text{XMSS.sk}, \text{XMSS.pk}) \leftarrow \text{XMSS.KeyGen}(1^\lambda)$,
- (2) Output $(\text{id}_{\text{XVRF}}, \text{pk}_{\text{VRF}}, \text{sk}_{\text{VRF}}) = (\text{XMSS.idx}, \text{XMSS.pk}, \text{XMSS.sk})$.

$\text{VRF Eval}(\text{sk}_{\text{VRF}}, x, \text{id}_{\text{XVRF}})$: On input $\text{sk}_{\text{VRF}} = \text{XMSS.sk}$, a message x and an index $\text{ctr} = \text{id}_{\text{XVRF}}$,

- (1) Run $\text{XMSS.}\sigma = (\text{WOTS}^+.\sigma, i, \text{XMSS.Auth}) \leftarrow \text{XMSS.Sign}(\text{XMSS.sk}, x, \text{ctr})$,
- (2) Set $\pi_{\text{VRF}} = \text{XMSS.}\sigma$,
- (3) Compute $y_{\text{VRF}} \leftarrow H(\text{XMSS.}\sigma, x)$,
- (4) Output $(\pi_{\text{VRF}}, y_{\text{VRF}})$.

$\text{VRF Verify}(\text{pk}_{\text{VRF}}, x, y_{\text{VRF}}, \pi_{\text{VRF}})$: On input $(\pi_{\text{VRF}}, y_{\text{VRF}})$, the public key pk_{VRF} and a VRF input x ,

- (1) Parse $\pi_{\text{VRF}} = \text{XMSS.}\sigma = (\text{WOTS}^+.\sigma, i, \text{XMSS.Auth})$,
- (2) If i and XMSS.Auth are inconsistent (i.e., if the leaf index indicated by XMSS.Auth is not equal to i), output NO.
- (3) Otherwise, if the verification of $\text{XMSS.}\sigma$ succeeds and $y_{\text{VRF}} = H(\text{XMSS.}\sigma, x)$, output YES.
- (4) Otherwise output NO.

In VRF Eval , the counter decides which leaf of XMSS tree is used and this is checked in VRF Verify . In our blockchain application, we enforce users to use a specific publicly known counter value so that the user cannot choose multiple leaves to create a VRF output at a particular point. This is crucial to guarantee uniqueness. It is indeed easy to establish a global counter value in the blockchain environment since it can simply be set to the block number $K \bmod N$, where N is a fixed public integer denoting the maximum number of rounds a key pair can be used. In particular, we set $N = 2^h$ for an XMSS tree of height h (See Figure 2 for an example with $N = 4$).

We also remark that with access to such a global counter, the users no longer need to store individual state information. That is, the VRF itself in a way becomes stateless as the users can simply

retrieve the block number from the blockchain and do not need to worry about maintaining a state themselves.

4.2 X-VRF Security Analysis

The most critical property we need to analyze is the uniqueness. Therefore, before proving the security of X-VRF construction, we first focus on the uniqueness of XMSS under the constraint that the index used to create the signature is the same.

LEMMA 1 (XMSS UNIQUENESS). *Let $\text{XMSS.}\sigma_1 = (\text{WOTS}^+.\sigma_1, i, \text{XMSS.Auth}^1)$ and $\text{XMSS.}\sigma_2 = (\text{WOTS}^+.\sigma_2, i, \text{XMSS.Auth}^2)$ be two valid XMSS signatures created by a PPT adversary on the same message m and under the same public key XMSS.pk and the same index i (i.e., $\text{XMSS.Verify}(\text{XMSS.pk}, m, \text{XMSS.}\sigma_1) = \text{XMSS.Verify}(\text{XMSS.pk}, m, \text{XMSS.}\sigma_2) = 1$). If the hash function used in the XMSS definition is collision-resistant, then $\text{XMSS.}\sigma_1 = \text{XMSS.}\sigma_2$ (i.e., XMSS is unique provided that the indices in the two signatures are the same).*

PROOF. Let XMSS.pk be a public key and m be a message. Fix an index $i \in [0, 2^h - 1]$. Also, let $\text{XMSS.}\sigma_1 = (\text{WOTS}^+.\sigma_1, i, \text{XMSS.Auth}^1)$ and $\text{XMSS.}\sigma_2 = (\text{WOTS}^+.\sigma_2, i, \text{XMSS.Auth}^2)$ be two valid signatures created by a PPT adversary on m using XMSS.pk and i . It is clear that $\text{XMSS.Auth}^1 = \text{XMSS.Auth}^2$ as the leaf index and the tree root is the same if the hash function is collision-resistant. We now just need to show that $\text{WOTS}^+.\sigma_1 = \text{WOTS}^+.\sigma_2$. This follows immediately from Remark 2. \square

THEOREM 1 (X-VRF SECURITY). *X-VRF is correct and satisfies the properties of computational uniqueness and pseudorandomness in the random oracle model. In particular, the uniqueness holds in the sense that the same ctr (or leaf index) must be used in VRF Eval as in Lemma 1.*

PROOF. We prove the three properties of Definition 6.

Correctness. The correctness of X-VRF follows via direct investigation. As long as the underlying XMSS scheme is correct, X-VRF is correct.

Uniqueness. To prove uniqueness of our X-VRF scheme by a reduction to the uniqueness property of the underlying XMSS scheme, we assume \mathcal{A}_{unq} being an adversary against uniqueness property of our X-VRF scheme. We can construct an adversary \mathcal{B}_{unq} against the uniqueness property of the underlying XMSS. Let $y_{\text{VRF}1}, y_{\text{VRF}2}$ be two different outputs and $\pi_{\text{VRF}1}, \pi_{\text{VRF}2}$ the two respective proofs generated by \mathcal{A}_{unq} on the same input x . We know that $y_{\text{VRF}i} = H(\text{XMSS.}\sigma_i, x)$ and $\pi_i = \text{XMSS.}\sigma_i$ for $i \in \{1, 2\}$. If $y_{\text{VRF}1} \neq y_{\text{VRF}2}$, then we must have $\text{XMSS.}\sigma_1 \neq \text{XMSS.}\sigma_2$. Set $m = x$ being the input message of the XMSS.Sign algorithm. Since x is the same in both signatures $\text{XMSS.}\sigma_1$ and $\text{XMSS.}\sigma_2$, it follows that the XMSS signature scheme is not unique, which contradicts the uniqueness property stated in Lemma 1.

Pseudorandomness. Let \mathcal{A}_{pr} be a PPT adversary against the pseudorandomness of our X-VRF scheme. Recall that $y_{\text{VRF}} = H(\text{XMSS.}\sigma, x)$ where H is modelled as a random oracle and $\text{XMSS.}\sigma$ is a signature on x . Also recall that $\text{XMSS.}\sigma$ contains $\text{WOTS}^+.\sigma$

which is the (iterated) hash of some completely random and independent n -bit strings unknown to \mathcal{A}_{pr} . So, any $\text{WOTS}^+.\sigma$ results in just some random bit string that is contained in $\text{XMSS}.\sigma$. Hence, the only way \mathcal{A}_{pr} can distinguish γ_{VRF} from a uniformly random value happens if \mathcal{A}_{pr} has queried H on the input $(\text{XMSS}.\sigma, x)$, which happens with negligible probability since \mathcal{A}_{pr} cannot query the signing oracle on x . From here, the pseudorandomness property follows. \square

5 IMPLEMENTATION AND EVALUATION

This section presents the implementation results of our X-VRF construction as well as the naive SL-VRF which is used as a baseline for comparison. Traditionally, VRF constructions from unique signatures require the signature to be stateless. However, we argue that in most of the blockchain applications a stateful VRF is sufficient as the blockchain can easily maintain the state.

5.1 Implementation Setup

Both SL-VRF and X-VRF have been implemented in C for a level of post-quantum security of $\lambda = 128$. We choose to work with SHA-256 as the hash function. The implementation of SL-VRF is based from [30]. It couples KKW [23] with the Fiat-Shamir transform to get a NIZK. The implementation of X-VRF is derived from the XMSS implementation provided in [19]. Both implementations were deployed on a machine with an Intel(R) Core i7-86500 CPU @ 1.90GHz 12GB of RAM.

5.2 VRF Proof Sizes.

Table 2 summarizes the proof size of each instance. As expected, the X-VRF constructions clearly outperform SL-VRF with proof sizes at least 13.3 times smaller. The VRF proof size in a X-VRF instance denoted by $|\text{X-VRF}.\pi_{\text{VRF}}|$ is computed by the following formula $|\text{X-VRF}.\pi_{\text{VRF}}| = h \cdot n + n \cdot \text{len}$. The VRF proof of our SL-VRF construction depends only of the size of the NIZK proof [22]. The size that we presented in Figure 2 differs from the one provided by Katz et al. [23], and the reason behind this is that we used the parameter of the NIST submission presented in [22] which has been optimized to give a compromise between algorithm efficiency and proof size. The size of the VRF proof for SL-VRF construction is denoted by $|\text{SL-VRF}.\pi_{\text{VRF}}|$, and we refer the reader to [22, 23] for further details.

5.3 Memory Requirements

In Table 2, we propose applicable memory requirements for our four instances of X-VRF. It is important to know that the memory capacity impact principally the X-VRF evaluation procedure. The X-VRF key generation procedure does not require expensive memory as the full XMSS tree does not need to be fully stored.

A capacious memory can reduce the offline computations for the XMSS evaluation procedure that are the authentication path selection (the grey nodes in Figure 1). Devices with high memory capacity will be able to store the whole XMSS tree and therefore avoid any offline computation. However, the required memory to store the full tree (together with the WOTS^+ keys) would be impractical particularly for the X-VRF-23 and X-VRF-27 instances which

would require respectively 35 GB and 350 GB to store the complete binary tree. Therefore, we propose to store the $h - 1$ levels of the XMSS tree (i.e., the whole tree except the bottom leaves and WOTS^+ keys). This means that offline computations are necessary every two evaluations and requires the computation of the two WOTS^+ key pairs based on a secret seed and a PRF. For example in Figure 1, if $\text{XMSS.index} = 0$, the offline phase computes both first WOTS^+ key pairs. Then, if $\text{XMSS.index} = 1$ there is no offline computation required as both first WOTS^+ key pairs have been generated. Then, when $\text{XMSS.index} = 2$ the offline computation will generate WOTS^+ key pairs number 2 and 3. The memory required with this technique for all instances is highlighted in Table 2. This advantage to have cheap offline computations ($\ll 1$ ms) needs to be done for only half of the X-VRF evaluations and most importantly it requires a maximum of 4GB of memory, which can be considered to be acceptable and be applicable to lightweight devices.

5.4 VRF Computation Efficiency

We further present four instances of X-VRF with different heights of the XMSS tree. We evaluated VRF with heights 15 (denoted as X-VRF-15), 19 (denoted as X-VRF-19), 23 (denoted as X-VRF-23) and 27 (denoted as X-VRF-27). This means each of these instances can generate, respectively, at most 2^{15} , 2^{19} , 2^{23} and 2^{27} VRF evaluations. Table 2 summarizes the performance of each instance. When it comes to the key generation procedure SL-VRF as expected outperforms all X-VRF instances, as it only requires the selection of a random element of n bits while all four instances of X-VRF need to generate XMSS tree with a greater height which leads to more computation.

Although the KeyGen of SL-VRF is much faster than that of X-VRF, the running time of the evaluation algorithm Eval of SL-VRF cannot compete with the stateful construction X-VRF. Eval of SL-VRF requires the simulation of MPC computation, which is quite costly.

Regarding the performance of the evaluation algorithm of X-VRF instances the performance of X-VRF is really competitive. The reason behind is that only the WOTS^+ signature needs to be computed at the spot, as the authentication path could be pre-computed. For X-VRF, the evaluation cost is at most $(w - 1) \cdot \text{len}$ calls of the cryptographic hash function. Our results demonstrates that X-VRF is at least 956 times faster than SL-VRF for the VRF evaluation.

The VRF verification of X-VRF also outperforms SL-VRF by at least 474 ms. The total cost verification for SL-VRF is the verification of a number of execution of the MPC-in-the-head with $P - 1$ parties (details presented in [22]), while X-VRF needs only a maximum of $h + w \cdot \text{len} + \log \text{len}$ calls to the hash function H . Note that verification runtime in the blockchain application is an important metric as this needs to be repeated by all (honest) committee members.

6 INTEGRATION TO ALGORAND

In this section, we discuss the details of our X-VRF integration into the Algorand consensus protocol. As discussed earlier, the uniqueness of X-VRF (and the underlying XMSS signature) crucially relies on enforcing the use of a *single* pre-determined counter ctr in $\text{VRF}(\text{E}, \text{or index } \text{XMSS.idx in } \text{XMSS.Sign})$. We can achieve this easily in the blockchain setting. In particular, there is already

Table 2: Performance evaluation of X-VRF, SL-VRF, ECVRF and LB-VRF. For LB-VRF, we report the results provided in [12]. For ISO-VRF, we report the results provided in [24]. For the memory requirement of X-VRF, an evaluator stores 2^h 256-bit values for $h \in \{15, 19, 23, 27\}$.

Instances	ECVRF	X-VRF-15	X-VRF-19	X-VRF-23	X-VRF-27	SL-VRF	LB-VRF	ISO-VRF

the block number that serves as a globally agreed, inalterable and publicly accessible counter. Let $N = 2^h$ be the number of leaves in XMSS and K be the block number. Then, we let the verifiers check that the ctr (or XMSS.idx) used at block number K is equal to $K \bmod N$. Therefore, every user is forced to use the leaves in a certain order and we can achieve uniqueness.

6.1 Performance Estimation

To illustrate our benchmark results better, it is important to understand the bottleneck of the current Algorand protocol. As of September 2020, Algorand’s mainnet employs over 1000 nodes, and

allows for roughly 5.4 MB of data propagated per block, as a result of their efficient consensus protocol. It consists of 5000 signed transactions, at 1064 bytes each, and 80 KB for VRF data. To break up the VRF part, 1000 nodes implies 1000 ECVRF proofs, which is around 80 KB of data. It is straightforward to see that the majority of the data is reserved for transactions. Under the assumption that a transaction is 1KB on average, and the signature is Ed25519, Algorand allows for 5K transactions per block, or, roughly 1K transaction per second (TPS) as Algorand generates a block in about 5 seconds.

Note that, in Algorand, although the final blocks only log transactions (while VRF payload are not included in the final blocks by design - the committee members only attest that they have seen

enough votes, without putting those information to the block for performance reasons), the actual data propagated through the network during each block is indeed the combination of VRF payload and the transaction payload. Therefore it makes sense to use this total payload size as the networks throughput limitation, rather than the actual blocksize. To summarize, we follow [12] and estimate the Algorand TPS throughput as follows:

$$\text{TPS} = \frac{\text{payload size} - \text{total VRF cost} \times \#\text{nodes}}{(\text{transaction size} + \text{signature size}) \times \text{blocktime}}$$

Note that as ‘refreshing’ a key pair happens much less frequently for X-VRF (in comparison to LB-VRF), the per-round cost of a key refreshment is negligible in our setting. Using the above formula, we estimate the TPS throughput of Algorand using our VRF in combination with different signature schemes that are used to authenticate transactions. In this computation, we make the following assumptions as in [12] for a fair comparison. We assume a payload size of 5.4 MB. We follow Algorand and assume 1 KB data for transaction size. As Algorand generates a block in about 5 seconds, we take blocktime as 5 seconds. The last moving part in the equation is the signature size. For this component, we consider the original Ed25519 signature used by Algorand, whose signature size is 64 bytes. In addition, we also consider two extreme cases in the post-quantum setting: (i) Rainbow² [10] -the shortest signature finalist candidate in NIST’s Post-Quantum Cryptography standardization process- whose signature size is as small as 66 bytes³, and (ii) SPHINCS⁺ [5], whose signature is 30696 bytes, which relies on symmetric primitives only. For X-VRF, we further set the tree heights as 15, 19, 23, 27. This means a user can use the same key in X-VRF for roughly 45 hours, 30.3 days, 1.33 years and more than 20 years, respectively. For SL-VRF, the nodes would not ever need to re-generate keys in practice. We will talk about X-VRF key schedules in the next section.

Turning to the performance comparison, as one shall see in Table 3, our X-VRF can be integrated into Algorand for all four settings. For the real world scenario (1000 nodes), with X-VRF we see a roughly 55% reduction in TPS for both Ed25519 and Rainbow. Note that it is a common understanding that post-quantum cryptography performs much worse, compared to classical ones. Hence, we believe that even a 55% reduction should be considered as a great achievement of our solution, rather than a drawback. The throughput for SPHINCS⁺ is much worse, recording 16 TPS on average. We note that even this case is still faster than Bitcoin (at 5 TPS). On the other hand, the stateless VRF SL-VRF does not perform well for large networks. Our simulation shows that the consensus is only possible for a network of at most around 100 nodes. When the number of nodes is higher, the blockchain capacity is not sufficient to transmit the SL-VRF payload, thus, making the protocol unusable.

6.2 Dual Key Scheduling

Now that we know our X-VRF provides a much more practical solution than SL-VRF, it is imperative to argue the usability of our stateful X-VRF. In our vision, a protocol should deploy both X-VRF and SL-VRF. X-VRF provides great performance, and should

²<https://www.pqcrainbow.org/>

³We note that the signature length of 48 bytes of an earlier Rainbow version is used in [12].

always be used when they are available. However, as per setup, an X-VRF key needs to be refreshed once in a while, requiring the user to be online at a certain time. This update requires an additional 64 bytes for VRF public keys, and a signature on the public key for authenticity, per cycle. We consider this cost to be negligible, compared to the rest of the cost as for X-VRF-23, for example, a cycle happens only every 1.33 years. In practice though, we cannot rule out the cases where users may lose their keys. For conservative purpose, nonetheless, it is desirable to have a backup plan: the user falls back to SL-VRF if he has consumed all X-VRF keys and has not uploaded a new X-VRF key (See Figure 2).

There are nonetheless two additional subtleties here. First, if every user needs to update their keys periodically, the network may be flooded by X-VRF keys that are never used. Our solution is as follows. For relay nodes who may be very frequently selected as committee members, we suggest that they use X-VRF. They are actually a very small portion of the user base, and account for the majority of VRF payloads. For casual users who perhaps will vote rarely in their lifetime, it is sufficient for them to use SL-VRF, which minimizes the number of key updates.

The other issue is with the VRF randomness. At a given round when the user does not have an X-VRF key, the user may actually choose to either upload a new X-VRF key, or use his default SL-VRF key. This breaks the uniqueness of the VRF. Our solution is to enforce the user to announce its new X-VRF key a few (say, k) rounds prior to it being active, where k is a system parameter, and is currently set to 10 by Algorand blockchain. This approach is indeed already adopted by Algorand with its ECVRF, to limit attackers with a large share of tokens from speculating the block randomness (derived from ECVRF) in the future. It is straightforward to see that, with this restriction, for any given round, if the user has announced an X-VRF key 10 blocks earlier, then it must use that key; otherwise it must use its SL-VRF key. Thus, uniqueness remains intact.

Eventually, we achieve a post-quantum blockchain that supports both X-VRF and SL-VRF. Under the assumption that most of the users will be online regularly, we further assert that the final TPS will be (very) close to the data for X-VRF in Table 3. Since this dual VRF is an orthogonal direction from this paper, we leave the rigorous analysis to future work.

6.3 X-VRF Instances

As explained previously, we propose four different instances of X-VRF and there are the only applicable constructions to Algorand’s 1000-node setting as the results in Table 3 demonstrate. Because of the stateful nature of the XMSS signature, there is a maximum number of possible VRF evaluations per key pair. Our goal in the choice of XMSS tree heights is to have VRF instances that can be used for at least one day in Algorand (X-VRF-15) without updating the keys, another for at least one month (X-VRF-19), third one for at least one year (X-VRF-23) and the last one (X-VRF-27) which could be used for more than 20 years. Each of these VRF instances has different advantages which can be summarized as follows. When using the X-VRF-15, the keys need to be updated every 45 hours. If we assume that each node stores the full XMSS tree it will require 1 MB of storage which is 256 times less than the memory required to store a XMSS tree when using the X-VRF-23 and even 4096 times

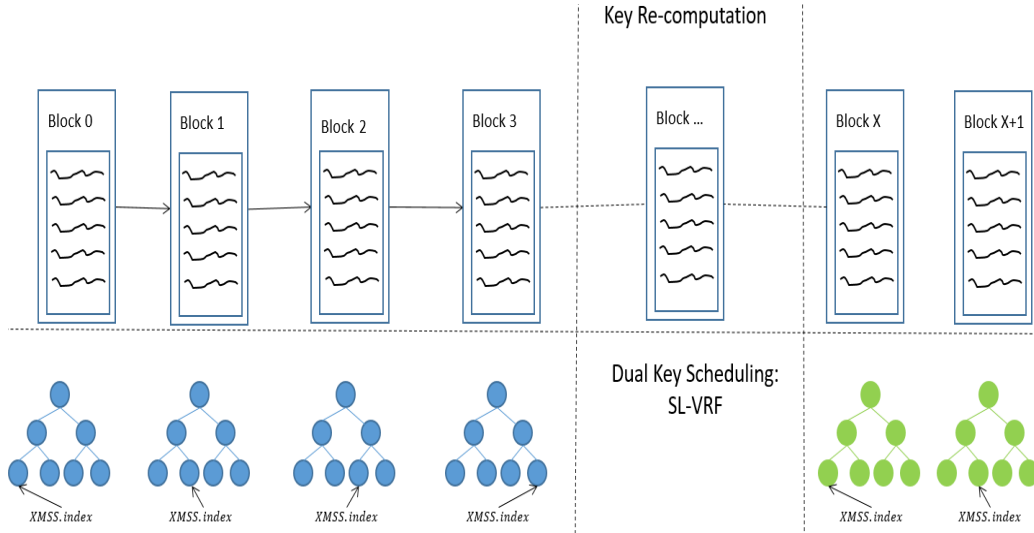

Figure 2: XMSS/X-VRF state and Blockchain

less than in the case of X-VRF-27. The main disadvantage of using X-VRF-15 is the regular key update that needs to be performed every 45 hours yielding several regular updates during the year. X-VRF-19 allows the network to update the keys only once per month but the computational cost of these monthly updates is 32 times higher than the cost needed when X-VRF-15 is used. X-VRF-23 offers the possibility to make this update only every 1.33 years but the cost of this update for each node takes 3.73 hours on our machine and is 256 times greater than the cost required in X-VRF-15. Finally our last instance, X-VRF-27 avoids the need of a key update for more than 20 years, the key generation would be only necessary when new nodes join the network or when a node has lost its key. The main advantage of this instance is that the network does not need to go through a regular key update similar to the SL-VRF instances. The disadvantage is the cost to join the network or the cost of losing the key which takes around two days on our machine and is 4096 times greater than the cost of an update in X-VRF-15.

Table 3 illustrates the expected TPS for each of X-VRF instances, and as explained previously the best performance is achieved with Rainbow signature scheme. For this part, we assume that nodes will not lose their key. For a network composed of 10 nodes, all X-VRF instances achieve the same expected TPS which means that in a network of 10 to 50 nodes instances with fewer key updates could be privileged. For a network of 100 nodes, X-VRF-15 achieves the best TPS, however its TPS difference with X-VRF-27 consists of only 8 transaction per second. When there are 1000 nodes the difference of TPS is logically larger, X-VRF-15 could process 72 transactions per second more than X-VRF-27 when using Ed25519 or Rainbow signature scheme. However, the synchronization of a generalized key update for a larger network could be more challenging and could slow down the process.

Memory Optimization. We presented in Section 5.3 the ideal memory requirement to achieve a balance between offline computations and memory consumption (See Table 2). However, it is important to know that these memory requirements are flexible and

can be adapted to user specified preconditions. As previously explained, the fast way to evaluate the VRF is to pre-store the path in the tree then compute the WOTS+ signature for the current round. However, the current node does not necessarily need to store $h - 1$ levels of the *full* tree. Indeed, the node can pre-compute and store only certain paths that are needed for the rounds in the near future. As the rounds progress, the paths that are no longer needed can be discarded and new paths can be pre-computed and stored. This way, we can keep the memory requirements at even lower levels. Overall, there are straightforward trade-offs to be considered depending on the user’s system specifications.

Choice of Instance. We showed that all four X-VRF constructions are promising post-quantum VRFs applicable in an existing network like Algorand. Each of them have different advantages going from memory consumption to key update times. To avoid the challenges of synchronizing key updates throughout the network, X-VRF-27 appears to be the best. If the focus is on achieving the best TPS and reducing the impact of key loss, then X-VRF-15 would be the best. X-VRF-23 provides a tradeoff between TPS and recurrence of key updates. Moreover, our proposition of dual key system by coupling X-VRF with SL-VRF combines the best of two worlds.

6.4 Comparison with current state of the art

To the best of our knowledge, there exist only two other *practical* post-quantum VRFs, the first one is provided in [12] using lattice-based techniques and we refer to it as LB-VRF. The second is introduced in [24] and referred to as ISO-VRF in this work. ISO-VRF is currently the only Isogeny-based post-quantum VRF. Table 3 presents the expected TPS in Algorand, as given in [12], for LB-VRF and for ISO-VRF, we computed the expected TPS in Algorand according to the parameters presented in [24].

X-VRF vs LB-VRF [12]. Our results show that all four X-VRF instances outperform LB-VRF when it comes to TPS for all node sizes due to its shortest proof size of X-VRF instances compared

to LB-VRF (see Table 2). As the number of nodes increases, the advantage of our constructions increases. Another disadvantage of LB-VRF is that the users need to update their keys at *every* round (block generation), hence every 5 seconds in the case of Algorand. Our X-VRF construction, on the other hand, can support the use of the same key pair for at least 45 hours; e.g. X-VRF-15, which has the shortest key life time. X-VRF-27 offers the possibility to work with the same key for more than 20 years. Even if it is difficult to compare the algorithms' performances because they were not executed on the same machine as LB-VRF numbers were taken from the original paper [12], X-VRF seems to be more efficient when it comes to VRF Evaluation performances as LB-VRF takes 3.1ms while the slowest X-VRF takes only 0.8 ms. The difference between both verification procedures is too small to draw any conclusion.

X-VRF vs ISO-VRF [24]. The comparison between our construction and ISO-VRF in Table 3 shows that ISO-VRF outperforms X-VRF when it comes to the expected TPS in Algorand. This difference of performance ensues directly from the shorter proof size of ISO-VRF compared to all four instances of X-VRF as illustrated in Table 2. However, more crucially is that the proof size of ISO-VRF presented in Table 2 has been directly taken from [24] which only offers post-quantum NIST-1 level of security, while X-VRF achieves at least level 2 of NIST post-quantum security. Secondly, the main advantage of X-VRF over ISO-VRF is that a key pair can be used for at least 45 hours while ISO-VRF, similarly to LB-VRF, needs to update their key after *every* round/block, so every 5 seconds. Another important advantage of X-VRF compared to ISO-VRF is the performance of the algorithms particularly of VRF Eval. It is important to note that ISO-VRF has not been implemented but its authors [24] estimated the time per evaluation to 12 seconds (see Table 2) without any parallelization. This makes ISO-VRF impractical compared to our construction which performs VRF Eval for a maximum of 0.8 ms. The X-VRF verification procedure also seems to outperform that of ISO-VRF's. The final advantage is the level of comprehension of X-VRF's security compared to ISO-VRF. Indeed, X-VRF is based on XMSS which is a mature primitive and has a security well understood by the research community. In contrast, ISO-VRF is a new approach and its security has not been studied.

7 CONCLUSION

In this paper, we introduced the first post-quantum verifiable random functions based on symmetric primitives. Our XMSS-based X-VRF proposals support a competitive number of transactions per second in a post-quantum PoS-based consensus protocol. It clearly outperforms the one-time lattice-based VRF when it comes to proof size and matches the one-time isogeny-based VRF while ensuring a higher security level. X-VRF is the first, and currently only, post-quantum VRF allowing to evaluate multiple inputs with the same key pair. Being based on long-studied symmetric primitives, all X-VRF instance provide strong security assurances while also being highly efficient and strongly outperforming current state of the art performances.
