## Abstract

We present staircase attack, the first attack on the incentive mechanism of the Proof-of-Stake (PoS) protocol used in the Ethereum 2.0 beacon chain. Our attack targets the penalty of the incentive mechanism that penalizes inactive participation. Our attack can make honest validators suffer from penalties, even if they strictly follow the specifications of the protocol. We show both theoretically and experimentally that if the adversary controls 29.6% stake in a moderate-size system, the attack can be launched continuously, so eventually *all* honest validators will lose their incentives. In contrast, the adversarial validators can still receive incentives, and the stake owned by the adversary can eventually exceed the 1/3 threshold (system assumption), posing a threat to the security properties of the system.

In practice, the attack feasibility is directly related to two parameters: the number of validators and the parameter MAX\_ATTESTATIONS, the maximum number of attestations (i.e., votes) that can be included in each block. We further modify our attack such that, with the current system setup (850,000 validators and MAX\_ATTESTATIONS = 128), our attack can be launched continuously with a probability of 80.25%. As a result, the incentives any honest validator receives are only 28.9% of its fair share.

## 1 Introduction

Ethereum [43], one of the most popular blockchain systems, upgraded to 2.0 in Sep 2022. The system now uses a Proof-of-Stake (PoS) protocol called Gasper as its core consensus scheme [11], a Byzantine fault-tolerant (BFT) protocol that tolerates Byzantine failures (i.e., arbitrary failures). Different from conventional BFT protocols [12, 14–16, 22, 23, 46, 47] that assume the adversary does not control over one-third of nodes (also called validators) or Nakamoto consensus (the consensus protocol of Bitcoin and Ethereum 1.0) that assumes

the adversary does not control over 50% computational power, PoS assumes that the adversary does not control more than one-third of the total stake, where stake, in general, refers to the account balance of the validators.

The PoS protocol of Ethereum assumes a partially synchronous network [17], where there exists an unknown upper bound for message processing and transmission. The protocol is a combination of Casper friendly finality gadget (FFG) [10] and a variant of the GHOST fork-choice rule [38] called Hybrid Latest Message Driven Greedy Heaviest-Observed Sub-Tree (HLMD GHOST). The protocol is epoch-based, and there are many slots in each epoch, divided by physical clocks. In each epoch, HLMD GHOST selects the *canonical chain* based on the received block proposals. Informally speaking, an honest block proposer will extend the canonical chain when creating a new block, and an honest validator only votes for blocks on the canonical chain (so the system is somewhat *live*). Additionally, Casper is a gadget that essentially counts the number of votes (also called attestations) so eventually some blocks are finalized and honest validators will finalize the same chain (so the system is *safe*).

Almost all PoS protocols [11, 21, 25] make an implicit assumption similar to conventional BFT: all honest validators are always online, and the system cannot support an unknown number of validators that may go to sleep [34]. This is in sharp contrast to the Nakamoto consensus. While some academic efforts have been made to study PoS in the sleepy model [4, 29], Ethereum utilizes the *incentive* mechanism to encourage validators to stay online. The incentive mechanism for attestations consists of *rewards* and *penalties*. In particular, validators whose attestations are finalized on-chain will receive rewards, and validators whose attestations are not finalized on-chain for a sufficiently long period of time will suffer from penalties<sup>①</sup>. The incentive mechanism has been very successful in practice. According to the report pro-

<sup>①</sup>Corresponding author

<sup>②</sup>Corresponding author

<sup>①</sup>Note that penalties are different from *slashing conditions* [10]. Slashing conditions aim to penalize malicious behaviors such as equivocation, e.g., a validator votes for blocks from two conflicting branches. In contrast, penalties discourage inactive participation where validators do not vote.

vided by *rated.network*, the participation rate of Ethereum has reached 99.6%<sup>①</sup>. Indeed, validators are incentivized to make the system both safe and live so they can continue gaining rewards from the blockchain.

**An attack on the attestation incentive mechanism.** We present for the first time an attack on the incentive mechanism of Ethereum PoS, and we call it *staircase attack*<sup>②</sup>. Our work focuses on the rewards and penalties for attestations only, so we use *attestation incentives* to denote the incentive mechanism we study in this paper. Our attack can be launched even if the network is synchronous, i.e., there exists a known upper bound for message transmission and processing. The goal of our attack is to force honest validators to be penalized, even if they strictly follow the specifications of the protocol. We begin with a warm-up attack where a single Byzantine validator, upon some *opportune epoch*, is able to make some honest validators suffer from penalties without any cost. We then extend the attack to a scenario where Byzantine validators controlling 29.6% of the total stake may collude. After an opportune epoch, the Byzantine validators can make half of the honest validators suffer from penalties in *every* epoch. As a result, eventually, *all* honest validators will lose their incentives. Meanwhile, none of the Byzantine validators suffer from any penalties at all. The consequence of our attack is thus the same as *discouragement attack* [9]: the fraction of the stake controlled by the adversary may continue to increase, posing safety threats. However, [9] only briefly mentions the concept and does not provide the attack strategies. Therefore, we consider our attack the first concrete instantiation of a discouragement attack.

Our attack utilizes a parameter used in both HLMD GHOST and Casper called the *last justified checkpoint LJ*. In Ethereum PoS, Casper updates the *LJ* parameter, and HLMD GHOST determines the canonical chain based on the *LJ* parameter. The design of Ethereum PoS identifies the *LJ* parameter as a *frozen* parameter that is not supposed to change within an epoch. However, as Byzantine validators may withhold their blocks (and attestations) and release them at any time, an honest validator might update *LJ* in the middle of an epoch. We show that by deliberately packing the attestations from *all* Byzantine validators into one block and withholding such a block, the honest validators always change their *LJ* in the middle of an epoch. As a result, the canonical chain (output by HLMD GHOST) may switch from an old branch to a new one. Thus, attestations from honest validators included in the old branch will be discarded and the corresponding honest validators will be penalized.

**Evaluation of the attack.** We implement our attack using an Ethereum implementation *Prysm* and conduct experiments using 1,000 validators. Our experimental results match our

theoretical analysis: if the adversary controls 29.6% validators, *all* honest validators lose their incentives. As the fraction of stake controlled by the adversary grows, honest validators may suffer from stake loss. For instance, if the adversary controls 33.3% stake, all honest validators are expected to suffer from a 20% stake loss compared to their fair share.

**Attack feasibility and insights.** Ethereum has over 850,000 validators as of Oct 2023. When demonstrating the feasibility of our attack in such a large-scale system, we find a somewhat surprising result. Specifically, the feasibility of our attack is related to two parameters: the number of validators and the number of attestations each block can carry, i.e., the `MAX_ATTESTATIONS` parameter. Based on the system setup of Ethereum, if we fix the `MAX_ATTESTATIONS` parameter, our attack can be launched for a system with fewer than 16,384 validators. Alternatively, for a system with 850,000 validators, the attack can be launched if the `MAX_ATTESTATIONS` parameter is increased from 128 to 2,048.

We further modify our attack to *accommodate* the system parameters of today’s Ethereum system. With the modification, our attack can be continued in each epoch with a probability of 80.25%, given that the adversary controls 33% of the total stake. As a result, the attestation incentives of an honest validator become only 28.9% of the fair share. As the largest mining pool today already controls 32.66% of the total stake<sup>③</sup>, our attack can cause discouragement to honest validators.

**Responsible disclosure.** For ethical reasons, we disclosed our findings to the Ethereum Foundation in April 2023, and the development team has taken measures since then to mitigate the attack. With the mitigation, the probability of continuing the attack in each epoch is significantly reduced. The modified version will become effective in the next update of the system. The communication and the mitigation can be found at <https://github.com/ethereum/consensus-specs/pull/3339#issuecomment-1637117341>.

Our attack and analysis show some interesting insights that may lead to future research directions. First, the incentive mechanism is usually considered an economic factor in a system and has never been considered in the design of Byzantine-fault tolerant consensus protocols [11]. However, the attacks on the incentive mechanism may make the PoS protocol violate its own assumption (i.e., the fraction of stake controlled by the adversary) and the security goals. Indeed, the stake of the adversary may exceed one-third of the total stake so eventually the safety and liveness of the system might be violated. Therefore, it is interesting to learn whether the security properties regarding the incentive mechanism can be considered in the design of the consensus protocols. Second, in PoS protocols like Gaspar used in Ethereum, the number

<sup>①</sup>Data source (accessed in Oct 2023): <https://www.rated.network/>

<sup>②</sup>We call it staircase attack because the branches the adversary constructs in the attack look like a staircase (see Figure. 8).

<sup>③</sup>Data source *rated.network* (accessed in Oct 2023) : <https://www.rated.network/>

of attestations that can be included in each block proposal is closely related to both the incentives of validators and the security goals of the system. Such a counter-intuitive finding shows that the value of the MAX\_ATTESTATIONS parameter (and its closely related parameters) is not an easy engineering decision and should be set up carefully.

**Our contributions.** Our paper makes the following contributions.

- We propose staircase attack on the incentive mechanism of Ethereum’s PoS protocol. We begin with an attack without considering the number of validators and the value of the MAX\_ATTESTATIONS parameter. We show that when the adversary controls at least 29.6% of the total stake, the attack can be launched continuously and eventually make *all* honest validators lose their incentives.
- We implement the attack using 1,000 validators. By conducting each experiment for one day (225 epochs), we show that an adversary controlling 29.6% stake makes *all* honest validators lose their incentives; if an adversary controls 33% stake, all honest validators are expected to suffer from a 20% of stake loss compared to their fair share.
- Our feasibility analysis shows that the number of validators and the MAX\_ATTESTATIONS parameter have a direct impact on whether the attack can be continuously launched. Based on today’s system setup of Ethereum, our attack can be launched under the following two conditions: the system has no more than 16,384 validators; the MAX\_ATTESTATIONS parameter is increased from 128 to 2,048. We further modify our attack such that with a probability of 80.25%, the attack can be continued in the next epoch and the expected attestation incentives of honest validators become only 28.9% of their fair share.

## 2 Related Work

**Identified attacks against Ethereum PoS only.** Many efforts have been made to analyze Ethereum PoS since Ethereum announced its plans to upgrade to 2.0, as summarized in Table 1.

*Balancing attack.* A balancing attack aims to split honest validators into two parts, forcing them to vote for two conflicting branches with the same weight. Consequently, both chains can not be finalized and the system suffers from liveness issues [29, 37]. Ethereum fixed the balancing attack [8] using a *proposal boosting* mechanism [36]. In short, proposal boosting is a "temporary" weight assigned to the block proposed and received in the current slot. As the two branches do not have the same weight, the situation created in the balancing attack will not last forever. Later, it was shown that the balancing attack can be revised to bypass the proposal boosting mechanism [30]. In all the balancing attacks we are aware of, the cost of the adversary is that at least one Byzantine validator will suffer from the slashing condition. According

to the specification of Ethereum, slashed validators will suffer from stake loss and eventually be removed from the system.

*Bouncing Attack.* In a bouncing attack, checkpoints from two branches are justified one after the other. As a result, the canonical chain jumps from one chain to another and neither branch can not be finalized, causing a liveness issue [28, 35]. Ethereum’s upgrade in March 2023 fixed all known bouncing attacks [20]. Our attacks are designed based on the latest specifications.

*Reorg Attack.* In reorg attacks [32, 37], the adversary reorganizes the chain to increase the fraction of the blocks from Byzantine validators on the canonical chain to gain more profit [24, 44, 49], decrease the *chain quality* [33] and lower the performance of the system. An interesting fact is that the reorg attacks in [32, 37] are fixed by proposal boosting mechanism [8]. It was later mentioned informally that the proposal boosting mechanism does not fully address the issue and a revised attack called *sandwich attack* is proposed [13].

In contrast, to the best of our knowledge, we present the first work that attacks the incentive mechanism by making honest validators suffer from penalties. Additionally, the adversary does not suffer from the slashing conditions.

**Identified attacks against PoS in general.** We summarize some identified attacks against PoS in general, some of which are applicable to Ethereum PoS as well.

*Nothing-at-stake attack.* A nothing-at-stake attack refers to the attack where an adversary is willing to contribute to multiple forks at no cost (as the validators in PoS do not have to compete to propose or vote) [7, 25, 26]. The goal of nothing-at-stake attacks is usually the liveness and the performance of the system. The *avalanche attack* is an example to PoS GHOST [30]. In the attack, it was shown that by deliberately working on multiple forks at the same time, the canonical chain consists of blocks only from the adversary, so the system is not live anymore. Note that Ethereum does not suffer from nothing-at-stake attack, as a validator that equivocates (e.g., it votes for two conflicting blocks) will be slashed.

*Long-range attack.* In a long-range attack, the adversary first acquires the secret keys of some validators after they withdraw their stake (and leave the system). The adversary then revises the blocks proposed previously and rewrites the history of the blockchain. Many protocols are designed to prevent the attack [2, 3, 25, 42, 45]. The Casper protocol [10] used in Ethereum is a solution to the long-range attack.

*Grinding attack.* Most PoS protocols use pseudorandom functions (e.g., verifiable random functions (VRF) [27]) to select block proposers. The way the randomness is generated usually depends on the blocks in the canonical chain [41]. In practice, the roles of the nodes might be learned in advance. Accordingly, a validator eligible to propose a block can manipulate the value of the randomness (and the validators eligible to propose subsequently) [1, 7]. The goal is to improve the adversary’s chances of being selected as a block proposer (to

gain extra profits or decrease the chain quality).

*Selfish mining.* Selfish mining is an attack first known in Proof-of-Work (PoW) [18]. In selfish mining, a mining pool (with a number of validators) may collude [48] and gain more revenue than the fair share. Selfish mining attack was later found to be feasible in some PoS protocol as well [5, 7, 19, 31]. To the best of our knowledge, selfish mining attack has not been identified in Ethereum.

### 3 Review of Ethereum Proof-of-Stake

In this section, we review the Proof-of-Stake (PoS) protocol used by Ethereum 2.0 [11, 35]. Our notations largely follow the specifications by Ethereum foundation [39].

#### 3.1 System Model

Nodes that participate in the PoS protocol are called *validators*. To become a validator, one must deposit at least 32 ETH as an initial stake in its account. Each validator’s voting power is weighted by its stake. There are  $N$  validators  $\{v_1, v_2, \dots, v_N\}$ , where  $N$  may change over time as validators join and leave the system. Each validator holds a private/public key pair, and it may be Byzantine and arbitrarily deviate from the protocol. Non-faulty validators are called honest validators. Ethereum PoS assumes that the stake controlled by Byzantine validators is limited to less than one-third of the total stake.

To facilitate the description of our attack and without loss of generality, we assume that  $N$  does not change and each validator is assumed to hold at least 32 ETH. In this way, we normalize each validator’s balance to  $1$  unit [11]. This enables us to tally the number of attestations instead of taking into consideration the fractions of the validators’ balance. Accordingly, let  $f$  be the number of Byzantine validators, we assume  $f < N/3$ . We believe this assumption is reasonable as

according to the data from *beaconcha.in*, the average actual balance of the validators is 32.13 ETH<sup>①</sup>.

Ethereum PoS assumes that the network is partially synchronous [17], i.e., there exists an unknown upper bound  $\Delta$  for message transmission and processing delay. However, our attack can be launched even if the network is synchronous, i.e., the value of  $\Delta$  is known to every validator.

#### 3.2 Terminology and Notation

Ethereum PoS proceeds in epochs, and each epoch consists of 32 slots. Given a slot number  $t$ , every validator is able to obtain epoch number  $e \leftarrow \lfloor \frac{t}{32} \rfloor$ . Each slot lasts for 12 seconds in the current production system. Within a slot, only a single block can be proposed. A *block*  $b$  consists of the slot number, a hash pointer to the parent block, a batch of transactions, and a set of attestations (i.e., votes, to be described shortly). Given a block  $b$ , the *branch* led by  $b$  is the path from  $b$  to the *genesis block* (the first block of the blockchain history). Each validator maintains a tree-based view about the blocks proposed by the validators in the form of a *block tree*  $\mathcal{T}$ . Additionally, a *checkpoint* is a special type of block and there is one checkpoint block per epoch. By default, the checkpoint is the first block proposed in each epoch. If such a block does not exist, the most recent preceding block becomes the checkpoint. We use  $\text{ep}(b) \leftarrow \lfloor \frac{t}{32} \rfloor$ , to denote the epoch number of block  $b$  proposed in slot  $t$ .

Ethereum PoS consists of Hybrid Latest Message Driven Greedy Heaviest-Observed Sub-Tree (HLMD GHOST) and Casper FFG [11]. HLMD GHOST is a fork-choice rule that recursively chooses the root of *heaviest subtree* and outputs the leaf block as *head*. The chain led by head is also called the *canonical chain*. Each honest validator will only vote for the head of the canonical chain it is aware of or create a new

<sup>①</sup>Data source (accessed in Oct 2023): [https://www.beaconcha.in/charts/average\\_balance](https://www.beaconcha.in/charts/average_balance)

block by extending the canonical chain. Additionally, Casper FFG helps finalize the checkpoints, and once a checkpoint is finalized, all the blocks on the chain led by the checkpoint are finalized. As attestations are contained in blocks, we can also say that the attestations are finalized on-chain.

**Attestor and proposer.** In each epoch,  $N$  validators are randomly and evenly divided into 32 validator sets (determined by the RANDAO protocol<sup>①</sup>). Each validator set is allocated for one slot of the epoch and validators (also called *attestors*) in this set are allowed to vote. Additionally, in each slot, one validator is randomly selected as the *proposer*, also according to RANDAO. The proposer is the only validator that is allowed to propose a block in the slot. Our work simply assumes RANDAO is a pseudorandom function that randomly determines the roles of the validators, i.e., the expected number of honest attestors in each slot is  $(N - f)/32$ . Every validator is able to determine its role in each slot of an epoch and verify the roles of other validators one epoch in advance. A message from validator  $v_i$  is considered invalid if  $v_i$ 's role is not verified.

**Attestation.** In Ethereum, a vote is also called an *attestation*. An attestation (*att*) by validator  $v_i$  consists of a slot number, two checkpoints (*source* and *target*), and the hash of a block  $b$ . We say *att* is an attestation for block  $b$ . By default, *source* is  $v_i$ 's *last justified checkpoint* (i.e., *LJ*, to be described shortly). The *target* field is the highest checkpoint block in  $v_i$ 's canonical chain. In practice, hashes of the checkpoints are included in the attestation. In this paper, we use the checkpoints instead for ease of understanding. Notably, the block  $b$  is the output of the HLMD GHOST.

**Justification and finalization.** The justification and finalization rules are defined in Casper for checkpoints only. Specifically, if attestations from more than two-thirds validators with the same *source* and *target* are received, the *target* checkpoint is *justified*. Additionally, if the descendant checkpoint of a checkpoint  $cp$  is justified,  $cp$  becomes *finalized*. If  $cp$  is finalized, all the blocks on the chain led by  $cp$  are finalized and the order of the finalized blocks will never be reversed.

Given a branch  $c$  in  $v_i$ 's block tree  $\mathcal{T}$ , we use  $V(c)$ ,  $J(c)$ , and  $C(c)$  to denote the number of attestations included in chain  $c$ , the last justified checkpoint based on  $V(c)$ , and the highest checkpoint block in  $c$ , respectively. Given a block  $b$  and a branch  $c$  led by  $b$ 's parent block, if the slot numbers of  $b$  and  $b$ 's parent block indicate that  $b$  is from a new epoch, *LJ* is updated to  $J(c)$ . Ideally, *LJ* is updated at the beginning of an epoch and is not changed during the epoch. In contrast,  $J(c)$  is updated as  $V(c)$  is updated throughout the protocol.

**Fork choice rule.** The fork choice rule HLMD GHOST defines the canonical chain and HLMD GHOST outputs the head of the canonical chain. In particular, the block each attestor votes for is the head of its canonical chain. Meanwhile, a block proposer will extend the head of the canonical chain

when creating a new block  $b$ , i.e., by setting the hash pointer of  $b$  as the hash of the head. Given a block tree  $\mathcal{T}$ , the canonical chain is defined as follows (an example is provided in Figure. 1):

1. Prune any branch  $c \in \mathcal{T}$  such that  $J(c)$  is lower than *LJ*. Then calculate the *weight* of each block in the chain. Here, weight is determined by the attestations. In particular, if there exists an attestation for block  $b$ , the weight of  $b$  is incremented by one.
2. Recursively calculate the sum of weights of each sub-branch. The branch with the largest accumulative weight is considered *the heaviest subtree* and becomes the canonical chain.

Figure 1: Example of the fork choice rule HLMD GHOST. Attestations are represented in dashed rounded rectangles and blocks are represented in solid rectangles. The number shown in each attestation denotes the weight of the attestation and the number shown in each block denotes the weight of the subtree. The rightmost branch is the canonical chain.

### 3.3 Workflow of Ethereum PoS

We summarize the workflow of Ethereum PoS in Figure. 2. Each validator maintains three local parameters: the last justified checkpoint *LJ*, a set of received attestations *Atts*, and the block tree  $\mathcal{T}$ . In slot  $t$ , if  $v_i$  is the proposer, it broadcasts a (PROPOSE,  $t, v_i, H(\text{head}), \text{newatts}, \text{txs}$ ) message to all validators (lines 2-10). Here, *head* is the output of HLMD GHOST and  $H(\text{head})$  is the hash of *head*, serving as a hash pointer of the parent block. The *newatts* consists of a set of attestations  $v_i$  has received. Given the canonical chain  $c$ , any attestation that satisfies the following two requirements will be included in *newatts*: 1) the attestation has not been included in  $c$  so far; 2) the *source* is the same as *LJ* and the *target* is the same as  $C(c)$ . If  $v_i$  is an attestor, it waits until 1/3 time of slot  $t$  has elapsed (i.e., 4 seconds). Then,  $v_i$  prepares an attestation message (ATTEST,  $t, v_i, H(\text{head}), LJ, C(c)$ ) and sends it to all validators, where *LJ* is the *source*, and the highest checkpoint  $C(c)$  is the *target* (lines 11-16).

Upon receiving a block  $b$  from the proposer  $v_j$  of slot  $t'$ ,  $v_i$  checks: 1) whether the epoch number of  $b$  is higher than the epoch number of  $b$ 's parent block; 2) whether the epoch number of  $J(c)$  is higher than *LJ*, where  $c$  is the branch led

<sup>①</sup>RANDAO: <https://github.com/randao/randao>

by  $b$  (line 21). If so,  $v_i$  updates  $LJ$  to  $J(c)$ . Validator  $v_i$  then processes the attestations included in  $b$  and updates its block tree  $\mathcal{T}$ , i.e., for each branch  $c \in \mathcal{T}$ , update  $J(c)$ ,  $V(c)$ , and  $C(c)$  (lines 24-28). Last, if  $b$  is a block from the prior epoch and  $\text{ep}(J(c)) > \text{ep}(LJ)$ ,  $v_i$  also updates its  $LJ$  (lines 30&31).

According to the finalization rules, before epoch  $e$  begins, the epoch number of  $LJ$  of any validator (honest or not) is at most  $e - 2$ . Indeed, the rule of how checkpoints are finalized is defined in Casper, inspired by the design of conventional BFT protocols [40, 46].

### 3.4 The Attestation Incentive Mechanism

The incentive mechanism consists of *rewards* that encourage active participation and *penalties* that discourage inactive behavior [11, 39]. Validators with attestations finalized on-chain will get rewards, and validators who do not have their attestation finalized on-chain (after a sufficiently large number of slots) will get penalties. Note that penalties differ from the *slashing conditions* [11]: slashing conditions penalize behaviors such as equivocation, while penalties only act on inactive behavior. The slashing condition is also part of the incentive mechanism of the system. We thus use attestation incentives to denote rewards and penalties in this paper.

Generally speaking, the rewards and penalties of each validator depend on its own stake, the total amount of stake, and the corresponding attestation. For each validator  $v_i$ , a *base reward*  $I_{base}$  is first decided, which is an equation of  $v_i$ 's stake and stake of all validators. Both rewards and penalties are then calculated based on  $I_{base}$ . The reward is  $R \times W_r I_{base}$ . Here,  $R$  is the *rewards scale with participation*, which is related to  $v_i$ 's stake and the total stake of attestors who have their attestations finalized on-chain.  $W_r$  is the weight determined by the *source*, *target*, and block in the attestation. Additionally, the penalty is  $W_p I_{base}$ , where  $W_p$  is the weight determined by the *source* and *target* of the attestation  $v_i$  is supposed to send.

## 4 An Attack on the Incentive Mechanism

In this section, we present staircase attack, an attack on the incentive mechanism of the Ethereum PoS protocol. The goal of this attack is to make honest validators suffer from penalties, even if the network is synchronous and honest validators strictly follow the specification of the PoS protocol.

We begin with a warm-up attack where a single Byzantine validator can make  $(N - f)/32$  honest validators suffer from penalties. We then extend the warm-up attack and show that if Byzantine validators (owning 29.6% of the total stake) collude, half of the honest validators will be penalized. After the attack is started, it can be launched in *every* epoch. Eventually, *all* honest validators will lose their incentives. In contrast, Byzantine validators do not suffer from any penalties. The only cost is that the incentives Byzantine validators can obtain during the attack are slightly lower than their fair share.

The Ethereum Protocol for Validator  $v_i$

**global parameters:** slot  $t$   
**local parameters:** block tree  $\mathcal{T}$ , attestation set  $Atts$ , last justified checkpoint  $LJ$ .

Figure 2: The Ethereum PoS Protocol. Codes are shown for validator  $v_i$ .  $H()$  denotes the hash function.

We show in Figure. 3 the meaning of legends used in the figures of this paper.

### 4.1 Overview of the Attack Methodology

Our attack exploits the fact that even if the network is synchronous,  $LJ$  might still be changed in the middle of an epoch. Indeed, honest validators may not necessarily have received the blocks and attestations from Byzantine validators. Accord-

Legend	Meaning
	attestations from honest validators with <i>source</i> lower than the checkpoint block of the previous epoch
	attestations from honest validators with <i>source</i> as the checkpoint block of the previous epoch
	attestations from Byzantine validators with <i>source</i> as the checkpoint block of the previous epoch
	discarded attestations
	a block proposed by an honest validator that includes
	a block proposed by an honest validator that includes
	a block proposed by a Byzantine validator that includes
	a pruned block
	a block that will be received at time $t$
	a withheld and released block
	attestations included in the block

Figure 3: The meaning of legends used in the figures of this paper. Figures in this paper are best viewed in color.

ing to the PoS protocol, a validator  $v_i$  updates  $LJ$  in two cases. First,  $v_i$  receives the first block in some epoch  $e$  such that  $J(c)$  is higher than its  $LJ$  (lines 20-22 in Figure. 2). Second, although  $v_i$  already enters epoch  $e$ , it has received a sufficiently large number of attestations for an epoch lower than  $e$  (e.g., included in the blocks withheld in previous epoch(s) and released in epoch  $e^{\text{①}}$ ) such that  $J(c)$  is higher than its  $LJ$  (lines 29-31 in Figure. 2).

We illustrate three examples in Figure. 4 to show three possible cases of a validator when it enters an epoch  $e$ . Before epoch  $e$ ,  $LJ$  is set as  $cp$ , and attestations by all honest validators in epoch  $e$  have *target* set as block 0.

- **Case 1:  $LJ$  is updated upon receiving the first block of an epoch.** As shown in Figure. 4a, in epoch  $e$ ,  $v_1$  receives block 0 to block 31. The attestations of all honest validators are included in the blocks. As attestations from all honest validators are received, the condition  $V(c)[0] > 2N/3$  is satisfied so  $J(c)$  is updated to block 0. In epoch  $e+1$ ,  $v_1$  receives block 32 in the first slot. As the epoch number of  $J(c)$  is greater than  $LJ$ ,  $LJ$  is updated as block 0 (line 21 in Figure. 2).
- **Case 2:  $LJ$  is not updated in an epoch.** As shown in Figure. 4b,  $v_2$  receives block 0 to block 31, but no blocks have been received in epoch  $e+1$ . In this case, the  $LJ$  is not updated.
- **Case 3:  $LJ$  is updated in the middle of an epoch.** As shown in Figure. 4c, validator  $v_3$  has received block 0 to block 16 in epoch  $e$ . In epoch  $e+1$ ,  $v_3$  receives block 33, the parent of which is block 16. Different from the case for validator  $v_1$ ,  $v_3$  has not received  $2N/3$  attestations and  $J(c)$  is still  $cp$ , where  $c$  is the chain led by block 33. Later in slot

<sup>①</sup>Note that according to the design of the system, a block tagged with epoch  $e'$  where  $e' < e$  can still be accepted by validator  $v_i$  even if  $v_i$  already enters epoch  $e$ .

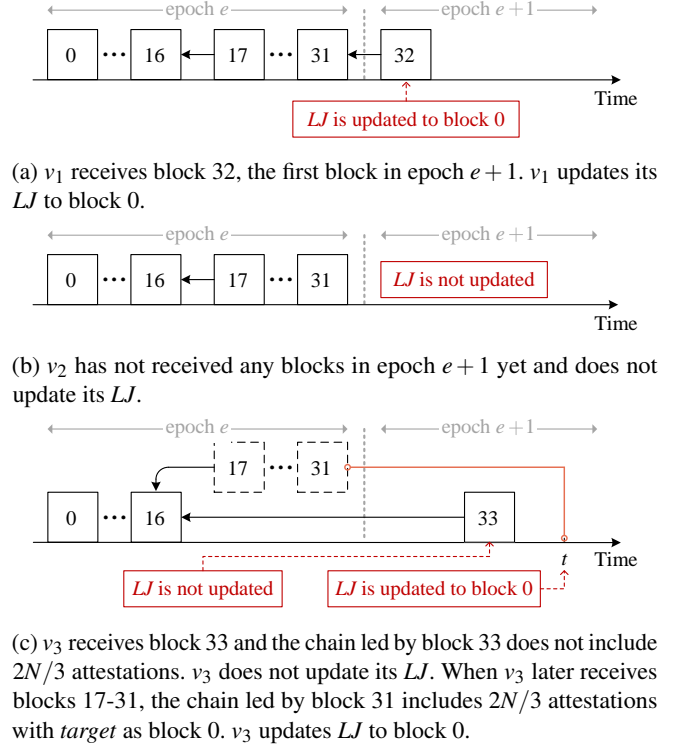

Figure 4: Examples of updating  $LJ$ .

$t$  of epoch  $e+1$ ,  $v_3$  receives blocks 17 to 31, blocks created in epoch  $e$  but received by  $v_3$  in slot  $t$  of epoch  $e+1$ . Now, the blocks on the branch led by block 31 include enough attestations in epoch  $e$ . Therefore,  $J(c)$  and  $LJ$  are updated to block 0 (line 30 in Figure. 2).

It is worth mentioning that after  $LJ$  is updated, any branch  $c$  such that  $J(c)$  is lower than  $LJ$  will be pruned in the block tree, and HLMD GHOST will not output a block from a pruned branch. Take the case for validator  $v_3$  as an example, we show the block tree of  $v_3$  in Figure. 5 after  $v_3$  receives blocks 17-31. In this example, before  $v_3$  receives blocks 17-31, branch  $c_2$  is the canonical chain. After  $LJ$  is updated to block 0, branch  $c_1$  led by block 31 becomes the canonical chain. Branch  $c_2$  led by block 33 will then be pruned as  $J(c_2) = cp$ , lower than  $LJ$  (block 0).

Figure 5: Validator  $v_3$ 's block tree.

Our attack essentially utilizes this fact to *force* honest validators to prune a branch led by a block from an honest val-

idator, so the attestations on the pruned branch are discarded, e.g., the attestations included in block 33 in Figure. 5. Moreover, these attestations will never be finalized on-chain, as their *source* is lower than *LJ* (lines 5-7 in Figure. 2) and the corresponding validators will be penalized. In the following, we show that one Byzantine validator is able to make the attestations from  $(N - f)/32$  honest validator be discarded. We then show that if all Byzantine validators collude, they can utilize the re-organization of the chain to make *half* honest validators suffer from penalties in every epoch.

## 4.2 The Warm-up Attack

We now present a warm-up attack, where a single adversarial validator  $v_i$  can launch the attack, and  $(N - f)/32$  honest validators are expected to be penalized. To kick-start the attack,  $v_i$  waits for an *opportune epoch*. An epoch  $e$  is deemed opportune if  $v_i$  is eligible to propose in the first slot of epoch  $e$  (let the slot number be  $t$ ). Before epoch  $e$ , honest validators maintain a consistent view of the canonical chain, and *LJ* of all honest validators is the same checkpoint. According to the discussion in §3, we know that before epoch  $e$  begins, the epoch number of *LJ* is  $e - 2$ , and we use  $cp_{e-2}$  to denote the *LJ* of all validators. We also use  $cp_{e-1}$  to denote the checkpoint block proposed in the first slot of epoch  $e - 1$  and assume that all validators receive  $cp_{e-1}$  in epoch  $e - 1$ . Given such an opportune epoch  $e$ , the attack strategies of  $v_i$  are summarized below.

- (1) (Figure. 6a) Validator  $v_i$  first creates a block  $b_i$  that extends the head of the canonical chain  $c$  and withholds  $b_i$ . According to our assumption, the canonical chain  $c$  consists of blocks from all proposers in epoch  $e - 1$ . As none of the validators has received any block in epoch  $e$  yet, case 2 mentioned in §4.1 is satisfied: *LJ* is not updated and is still  $cp_{e-2}$  for all honest validators. Thus, attestors of slot  $t$  (i.e., attestors that belong to the validator set in slot  $t$ ) will then send attestations using  $cp_{e-2}$  as *source* to all validators.
- (2) (Figure. 6b) At the end of slot  $t$ , validator  $v_i$  sends  $b_i$  to all validators. Here, the epoch number of block  $b_i$  is greater than  $b_i$ 's parent block. Additionally, the chain  $c$  led by  $b_i$ 's parent block consists of the attestations from all validators in epoch  $e - 1$ , so  $J(c)$  is already set as  $cp_{e-1}$ . As the epoch number of  $J(c) = cp_{e-1}$  is greater than  $LJ = cp_{e-2}$ , case 1 in §4.1 is satisfied and all honest validators update their *LJ* to  $cp_{e-1}$  (lines 20-22 in Figure. 2).
- (3) (Figure. 6c) After slot  $t$ , attestations created by honest attestors in slot  $t$  will be discarded by all honest validators. To see why, given any attestation  $att$  mentioned in step (1), the source of  $att$  is  $cp_{e-2}$ . However, the *LJ* of all honest validators is  $cp_{e-1}$ . When any proposer creates a new block,  $att_j$  will be filtered (lines 6&7 in Figure. 2). Therefore, all honest attestors in slot  $t$  will be penalized. According to our discussion in §3.2, the expected number of honest attestors penalized is thus  $(N - f)/32$ .

(a) Step 1:  $v_i$  withholds block  $b_i$  and honest validators do not update their *LJ*. Honest attestors in slot  $t$  create attestation with  $cp$  as source.

(b) Step 2:  $v_i$  releases  $b_i$  and all honest validators update their *LJ* to  $b_i$ .

(c) Step 3: Attestations with *source* different from  $b_i$  will be discarded and honest attestors in slot  $t$  will eventually be penalized.

Figure 6: Warm-up attack where  $v_i$  is the Byzantine validator. Before epoch  $e$  begins, the *LJ* of all validators is assumed to be  $cp_{e-2}$ , the checkpoint block proposed in the first slot of epoch  $e - 2$ . Additionally, all validators receive the checkpoint block proposed in the first slot of epoch  $e - 1$ .

## 4.3 The Staircase Attack

We are now ready to present our staircase attack, in which Byzantine validators collude to launch the attack. Here, we assume the adversary controls a set of Byzantine validators to launch the attack and later discuss the number of Byzantine validators the adversary needs to control. The goal is that half of the honest validators will be penalized in *each* epoch after the opportune epoch  $e$ . Note that in the warm-up attack, only one Byzantine validator launches the attack. In our staircase attack, all Byzantine validators withhold their attestations and blocks, trying to make *LJ non-frozen* and updated in the middle of an epoch. After that, the attestations released before *LJ* is updated are not included in the canonical chain, resulting in penalties for the corresponding honest validators.

**Notations.** We define several notations to assist the explanation of our attack. We divide each epoch  $e$  into two periods: the first period consists of slots before *LJ* is updated; the second period consists of the rest of the slots in epoch  $e$ . Honest attestors in the first period create attestations with some checkpoint  $cp$  as the *source*, while honest attestors in the second

period create attestations with  $cp'$  as the *source*, where  $cp'$  is higher than  $cp$ . We partition attestations from all validators into three sets:  $A_1$  denotes the attestations from honest attestors in the first period;  $A_2$  denotes the attestations from honest attestors in the second period;  $A_3$  denotes the attestations from all Byzantine attestors in epoch  $e$ . Our goal is to make the attestations in  $A_2$  and  $A_3$  share the same *source* and *target*, and the number of attestations in  $A_2 \cup A_3$  is greater than  $2N/3$ , so the canonical chain can be *manipulated* by the adversary and attestations in  $A_1$  will be discarded. As illustrated in Figure. 3, we use green, blue, and red rounded rectangles to represent the attestations in  $A_1$ ,  $A_2$ , and  $A_3$ , respectively.

We use  $c_{adv}$  to denote the branch withheld by Byzantine validators. In our attack, after  $c_{adv}$  is released,  $LJ$  is updated by all honest validators. Similarly,  $c_{hon}$  is the branch seen by honest validators before  $c_{adv}$  is released.

**The (one-time) attack.** To kick-start a staircase attack, Byzantine validators also need to wait for an opportune epoch, the condition of which is exactly the same as our warm-up attack: the proposer  $v_i$  of the first slot  $t$  in epoch  $e$  is Byzantine. Similar to our warm-up attack, we use  $cp_{e-2}$  to denote the  $LJ$  of all validators and  $cp_{e-1}$  to denote the checkpoint block proposed in the first slot of epoch  $e-1$ . The strategies of our staircase attack are summarized below.

(1) (Figure. 7a) In slot  $t$  of epoch  $e$ ,  $v_i$  replays the warm-up attack:  $v_i$  withholds its block  $b_i$  and releases  $b_i$  at the end of slot  $t$ , after which all honest validators update their  $LJ$  as  $cp_{e-1}$ . In epoch  $e$ , the Byzantine validators have two strategies. First, *all* Byzantine validators in epoch  $e$  withhold their attestations (i.e.,  $A_3$ ), regardless of which slot each validator is the designated attestor. Second, the *last* Byzantine proposer  $v_j$  in slot  $t_j$  (all proposers in the rest of epoch  $e$  are honest<sup>①</sup>) in epoch  $e$  includes the attestations from the Byzantine validators in its block  $b_j$  and withholds  $b_j$ . Note that not *all* the attestations from Byzantine validators are included in  $b_j$  (as according to the protocol, a block in some slot cannot include attestations with a higher slot number). In this case, the attestations not included in  $b_j$  can simply be included in blocks proposed in epoch  $e+1$  and the corresponding validators will still receive their rewards. At the end of epoch  $e$ , the chain  $c$  seen by all honest validators consists of the attestations from all honest attestors from slot  $t+1$  to  $t+31$  (the last slot in epoch  $e$ ) where *source* of these attestations is  $cp_{e-1}$ . The expected number of attestations on chain  $c$  is then  $31(N-f)/32$ , equal to the number of honest attestors from slot  $t+1$  to  $t+31$ . Note that even if the attestations from honest attestors in slot  $t+31$  are received by all honest validators and the proposer of the first block in epoch  $e+1$  includes these attestations, the maximum number of attestations with  $b_i$  as *target* is still  $31(N-f)/32$ . Namely, as we assume  $f = N/3$ , the

<sup>①</sup>According to the RANDAO protocol, the roles of each validator in epoch  $e$  can be predicted before epoch  $e$  begins.

number of attestations is  $\frac{31}{32} \times \frac{2N}{3} < \frac{2N}{3}$ , the requirement for validators to update their  $J(c)$ . Therefore, at the end of epoch  $e$ ,  $LJ$  and  $J(c)$  of *all* honest validators is  $cp_{e-1}$ .

(2) (Figure. 7b) In epoch  $e+1$ , we divide the epoch into two periods. Let  $t'$  be the first slot in epoch  $e+1$ , i.e.,  $t' = t + 32$ . For now, we assume the first period ends at the end of slot  $t_{adv} - 1$  and discuss the value of  $t_{adv}$  later. The adversary's strategy in the first period is to create two forks of the chain, branch  $c_{hon}$  seen by honest validators and branch  $c_{adv}$  withheld by Byzantine validators. In the first period, Byzantine validators prepare attestations with  $b_i$  as *source* and  $b_j$  as *target* and withhold their attestations. The branch  $c_{hon}$  thus consists of blocks from honest proposers for slots  $[t', t_{adv} - 1]$ . The attestations included in  $c_{hon}$  will all have *source* as  $cp_{e-1}$ , and we let the set of attestations be  $A_1$ .

(3) (Figure. 7c) At the beginning of slot  $t_{adv}$  (i.e., the second period), the adversary releases the withheld chain  $c_{adv}$  and our goal here is for all honest validators to update their  $LJ$  to  $b_i$  and make  $c_{adv}$  become the canonical chain. Here, we need to dive into the attestations in  $c_{adv}$ . According to the discussion in step (1), the branch from  $b_i$  to  $b_j$  consists of the attestations (with *source* as  $cp_{e-1}$  and *target* as  $b_i$ ) from *all* attestors (Byzantine and honest) between slot  $t$  and  $t_j$  (the slot of  $b_j$ ). If the number of the attestations is greater than  $2N/3$  (i.e.,  $V(c_{adv})[b_i] > 2N/3$ ), all honest validators will set their  $J(c_{adv})$  as  $b_i$ . Therefore, we know that if  $\frac{t_j - t - 1}{32} > \frac{2}{3}$ , the condition  $V(c_{adv})[b_i] > 2N/3$  will be satisfied. We show in Lemma 1 that this happens with a probability of 98.84% if the adversary controls  $f = N/3$  validators.

As  $J(c_{adv})$  is updated to  $b_i$  after  $c_{adv}$  is released, it is not difficult to see that  $LJ$  will be updated to  $b_i$  in the middle of an epoch! Moreover, as  $J(c_{hon})$  is still  $cp_{e-1}$  in the second period of epoch  $e+1$ , the branch  $c_{hon}$  (up to  $b_i$ ) will be pruned and  $c_{adv}$  becomes the canonical chain. Any attestations in  $A_1$  will be discarded since the *source* field in  $A_1$  is different from  $LJ$  of validators in the second period and attestation in  $A_1$  will be filtered. Thus, the corresponding attestors will be penalized.

As discussed in step (1), as  $J(c_{hon})$  will never be updated to  $b_i$  in our attack, the branch  $c_{hon}$  (up to  $b_i$ ) will be pruned anyway. Therefore, to maximize the number of honest attestors that will be penalized (i.e.,  $|A_1|$ ), we can set up  $t_{adv}$  as large as possible. In fact,  $t_{adv}$  can be the last slot in epoch  $e+1$ , so almost *all* honest validators will be penalized.

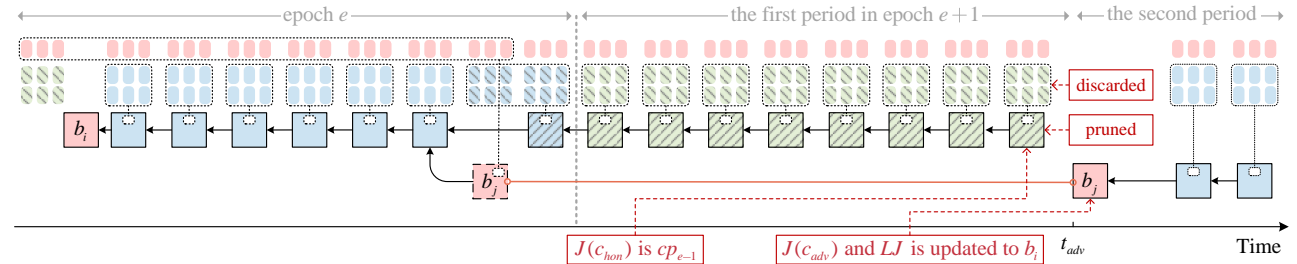

**Lemma 1.** *Assuming that slot  $t$  is the first slot of epoch  $e$  and  $f = N/3$ . Given the last slot  $t_j$  of epoch  $e$  in which the proposer  $v_i$  is Byzantine (all proposers in the rest of epoch  $e$  are honest), the probability that  $\frac{t_j - t - 1}{32} \geq 2/3$  is at least 98.84%.*

*Proof.* According to the definition,  $\frac{t_j - t - 1}{32} < 2/3$  happens only if any proposer in slot  $t_j + 1$  to slot  $t + 31$  is honest, i.e.,  $\lfloor \frac{32}{3} \rfloor = 11$ . We now calculate the probability that the

(a) Step 1: In epoch  $e$ , the first Byzantine proposer  $v_i$  replays the warm-up attack. All Byzantine validators withhold their attestations. The last Byzantine proposer  $v_j$  includes the attestations from the Byzantine validators in its block  $b_j$  and withholds  $b_j$ .  $LJ$  and  $J(c)$  of all honest validators are  $cp_{e-1}$ .

(b) Step 2: In the first period of epoch  $e+1$  (before slot  $t_{adv}$  begins), branch  $c_{hon}$  is seen by honest validators and branch  $c_{adv}$  is withheld by Byzantine validators.  $LJ$  is not updated and is still  $cp_{e-1}$  during this period. The attestations  $A_1$  included in  $c_{hon}$  have  $cp_{e-1}$  as the source.

(c) Step 3: At the beginning of slot  $t_{adv}$ , Byzantine validators release  $c_{adv}$ . As  $c_{adv}$  includes a sufficiently large fraction of attestations with target as  $b_i$ ,  $LJ$  is updated to  $b_i$ . In the second period,  $c_{hon}$  is pruned and  $c_{adv}$  becomes the canonical chain. Attestations included in  $c_{hon}$  are discarded and the corresponding validators will be penalized.

Figure 7: One-time staircase attack where all Byzantine validators collude. We assume that before epoch  $e$  begins, the  $LJ$  of all validators is  $cp_{e-2}$  and the (checkpoint) block proposed in the first slot of epoch  $e-1$  is  $cp_{e-1}$ .

proposers in the last 11 slots in epoch  $e$  are all honest. As the proposer of each slot is selected pseudorandomly according to the RANDAO protocol, the probability of the above situation is:

$$\left(\frac{N-f}{N}\right)^{11} \approx 1.16\%.$$

The probability that there is at least one Byzantine proposer in one of the last 11 slots is thus:

$$P_{succ} = 1 - \left(\frac{N-f}{N}\right)^{11} \approx 98.84\%.$$

□

**Repeating the attack for every epoch.** Our attack above can in fact be continued in every epoch after  $e+1$ . This is achieved by simply having the last Byzantine validator in each epoch  $e'$  withhold its block just as  $v_j$  does and then repeat steps (2) and (3) in epoch  $e'+1$ . For instance, in epoch  $e+1$  of the (one-time) attack, the last Byzantine validator  $v_k$  in slot  $t_k$  starts to withhold its block  $b_k$  and all Byzantine attestors in the rest of epoch  $e+1$  withhold their attestations. In epoch  $e+2$ , branch  $c_{hon}^{e+2}$  that extends the canonical chain is seen by all honest validators and Byzantine validators withhold a branch  $c_{adv}^{e+2}$  led by  $b_k$ . After the end of the first period of

$e+2$ , the withheld branch is released, in the hope that  $J(c_{adv}^{e+2})$  and  $LJ$  is updated to the first block in epoch  $e+1$  (denoted as  $cp_{e+1}$ ) and  $J(c_{hon}^{e+2})$  is still  $b_i$  (the first block in epoch  $e$ ). After  $LJ$  of honest validators is updated to  $cp_{e+1}$ ,  $c_{hon}^{e+2}$  will be discarded.

Notably, same as our one-time attack, only the attestations in  $A_2$  and  $A_3$  can be included in  $c_{adv}^{e+2}$ . Therefore, we need to ensure that  $J(c_{adv}^{e+2})$  can be updated to  $cp_{e+1}$  (and also every epoch after  $e+2$  as well). Now it becomes clear why we additionally need to define  $A_2$  and  $A_3$  in addition to  $A_1$ . We already know that the set of attestations from Byzantine validators is  $A_3$  and  $|A_3| = f$ , which is at most  $N/3$ . To ensure that the branch  $c_{adv}^{e+2}$  consists of  $2N/3$  attestations, set  $A_2$  must consist of more than  $2N/3 - f$  attestations. To satisfy this condition, we can set the three sets  $A_1$  to  $A_3$  with roughly the same size and set  $t_{adv}$  as the middle of an epoch  $e'$ , i.e.,  $t_{adv} = 16 + t'$ , where  $t'$  is the first slot in  $e'$ .

**Lemma 2.** In our staircase attack, honest attestors that create attestations in  $A_1$  will be penalized and  $|A_1| \leq N/3$ , regardless of the fraction of  $f$  in  $N$ .

*Proof.* Let  $|A_3|$  be  $f$ .  $|A_2|$  must be greater than  $2N/3 - f$  for the branch by the adversary to become the canonical chain,

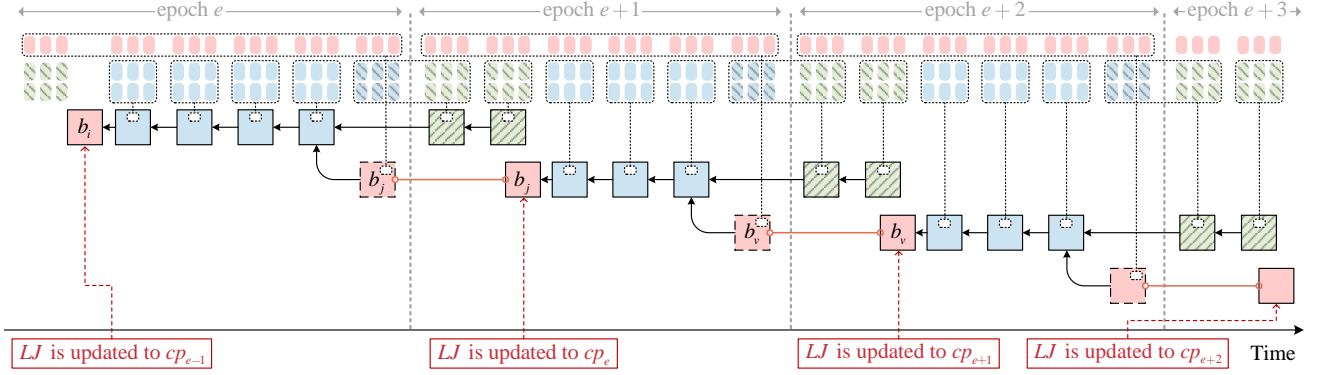

Figure 8: Staircase attack where the attack is repeated in every epoch.

following the discussion above. Therefore, the size of  $A_1$  must no more than  $N - |A_2 \cup A_3| = N/3$ .  $\square$

**Theorem 1.** *According to the configuration in Ethereum where  $W_r \leq 27W_p/20$  (see Appendix A for more details), the expected incentive of any honest validators becomes lower than 0 when  $f \geq 8N/27 \approx 29.6\%N$ .*

*Proof.* The incentive each validator receives is the difference between the rewards and the penalties. According to our attack, attestors that create attestations in  $A_2$  will receive rewards and attestors that create attestations in  $A_1$  will suffer from penalties. Therefore, to lower the expected incentives received by honest validators, we can simply let  $|A_1| = N/3$  according to Lemma 2. According to our discussion §3.4, to determine the concrete amount, we also need to calculate  $R$ , the rewards scale with participation. As attestations in  $A_2$  and  $A_3$  are included in the canonical chain,  $R = |A_2 \cup A_3|/N \approx 2/3$ . Therefore, the reward received by each honest validator is  $R \times W_r I_{base} = \frac{2}{3} W_r I_{base}$  and the penalty of each validator is  $W_p I_{base}$ . Therefore, the incentives received by all honest validators are  $(\frac{2}{3}|A_2|W_r - |A_1|W_p)I_{base}$ . Our goal is to learn the expected incentives received by any honest validator. As the number of honest validators is  $|A_1 \cup A_2|$ , the expected incentives of each validator becomes:

$$I_{hon} = \left( \frac{2}{3}|A_2|W_r - |A_1|W_p \right) \frac{I_{base}}{|A_1 \cup A_2|}.$$

As  $|A_1| = N/3$  and  $|A_1 \cup A_2| = N - f$ , we have:

$$I_{hon} = \left( \frac{4}{15}N - \frac{9}{10}f \right) \frac{W_p I_{base}}{N - f} \leq 0.$$

We can simply set  $\frac{4}{15}N - \frac{9}{10}f \leq 0$  to satisfy the equation above, so  $f \geq 8N/27$ .  $\square$

On the contrary, Byzantine validators do not suffer from penalties. However, the rewards they receive will be decreased. Following the discussion in Theorem 1, the reward each Byzantine validator receives is  $I_{adv} = \frac{2}{3}W_r I_{base}$  in each epoch, about 33% lower than the fair share.

## 5 Implementation and Evaluation

**Implementation.** We implement our attack using *Prysm*<sup>①</sup>, one of the most widely adopted Ethereum 2.0 beacon chain implementations written in Golang. We modify the codes in the Prysm as specified in Figure. 9, where changes we make on top of the PoS protocol are highlighted in red and the files we modify are included as comments. Our implementation has exactly the same effect as the attack mentioned in §4.3 while the actual implementation is slightly different. We have made the scripts for our attacks and the logs of our experiments available<sup>②</sup> and will open source them soon.

**Experiment configuration.** We establish a local *testnet* with 1,000 validators connected through a P2P LAN network and vary the fraction of Byzantine validators to understand the impact of our attack. We choose the LAN network as the communication delay is negligible, demonstrating that our attack can be launched even in a fully synchronous network.

We vary the number of Byzantine validators using  $f = 296$  (i.e.,  $f \approx 8N/27$ ),  $f = 315$ , and  $f = 333$  and assess the incentives received by the validators. In each experiment, we fix the identities of  $f$  Byzantine validators, run our testnet for one day (225 epochs), and collect the attestation incentive of each honest validator from their logs. As a comparison, we also run the testnet for one day without launching the attack and collect the incentives of all validators, the value of which is also known as the *fair share*.

**Evaluation results.** We evaluate the *incentive loss rate* of honest validators. In each experiment, we report the loss rate of an honest validator in Figure. 10. The incentive loss rate is calculated as follows. The incentive loss of an honest validator is the difference between its fair share and the incentives it receives when the attack is launched. The percentage of incentive loss in the fair share is called the incentive loss rate. The incentive loss rate can be interpreted as follows. If the

<sup>①</sup>Prysm: <https://github.com/prysmaticlabs/prysm>

Figure 9: The workflow of a Byzantine validator  $v_k$ . The main changes made on top of Figure. 2 are highlighted in red.

attack is not launched, the incentive loss rate is supposed to be 0%. If the incentive loss rate is close to 100%, all honest validators will lose their incentives.

Our results show a notable trend: as the attack is being launched, the incentive loss rate of each honest validator increases significantly and then stabilizes. For  $f = 296$ , the loss rate eventually stabilizes at 100%, matching our results in Theorem 1. For  $f = 315$  and  $f = 333$ , the incentive loss rate exceeds 100% and all the honest validators are expected to suffer from stake loss. For instance, when  $f = 333$ , the incentive loss rate is close to 120%, i.e., honest validators suffer from a 20% stake loss compared to their fair share.

Figure 10: The incentives loss rate of an honest validator for experiments with 1,000 validators and  $f$  Byzantine validators. Each experiment is launched for one day (225 epochs).

## 6 Attack Feasibility and Analysis

In this section, we analyze the feasibility of our attacks in the current Ethereum system beyond 1,000 validators, assuming  $f = N/3$ . Indeed, Ethereum has more than 850,000 validators as of today<sup>①</sup>, we thus analyze whether our attacks can be launched in such a large-scale system. So far, we have presented three attacks on the incentive mechanism of Ethereum: a warm-up attack where a single Byzantine validator can launch the attack and make some honest validators suffer from penalties; a one-time attack where Byzantine validators collude to make all honest validators suffer from penalties; the full staircase attack where Byzantine validators continuously launch the attack in every epoch and all honest validators lose their incentives. For the warm-up attack, the Byzantine validator only needs to delay its block. Therefore, the warm-up attack is feasible in the real Ethereum system. We thus focus on our one-time attack and the full staircase attack.

Our analysis reveals a somewhat surprising result: the feasibility of the attacks is directly related to the number of validators and the maximum number of attestations in each block. Ethereum currently employs a committee-based scheme to aggregate the signatures for attestations using the BLS signature [6]. Recall that every slot has  $N/32$  validators randomly selected by RANDAO. The validators in each slot are further divided into several committees [39]. In every slot, matching attestations (same *target*, *source*, and *head*) in the same committee are aggregated into one aggregated attestation. We use  $N_c$  to denote the number of committees in each epoch and  $N_a$  to represent the number of aggregated signatures in every block.

In the most recent configuration of Ethereum,  $N_a$  is limited by the parameter MAX\_ATTESTATIONS (MAXATT for short), the maximum number of attestations included in each block [39]. The value of  $N_c$  is determined as follows (also as shown in Figure. 11), where MAXCOM is the maximum number of committees in a slot (the actual parameter name is MAX\_COMMITTEES\_PER\_SLOT [39]):

$$N_c = \begin{cases} N/128, & \text{if } N \leq 4096 \times \text{MAXCOM}; \\ 32 \times \text{MAXCOM}, & \text{otherwise.} \end{cases} \quad (1)$$

Currently, the parameter MAXATT is 128 and the parameter MAXCOM is 64. Thus we have  $N_a = \text{MAXATT} = 128$ ,  $N_c = 32 \times \text{MAXCOM} = 2048$ , and  $N_c = 16N_a$ .

**Lemma 3.** To launch staircase attack,  $N_a \geq N_c$ .

*Proof.* In our staircase attack, the block proposed by the last Byzantine validator in an epoch includes attestations from all Byzantine validators. Therefore,  $N_a$  is no less than the number of aggregated attestations from Byzantine validators.

<sup>①</sup>Data source (accessed in Oct 2023): <https://www.beaconcha.in/charts/validators>

Figure 11: The value of  $N_c$  as  $N$  grows. We use  $\epsilon_c$  to denote MAXCOM.

According to the RANDAO protocol, Byzantine attestors are randomly distributed among  $N_c$  committees. Since attestations across committees cannot be aggregated, the number of aggregated attestations from Byzantine validators is no less than  $N_c$ , i.e.,  $N_a \geq N_c$ .  $\square$

Based on Lemma 3, we now analyze the impacts of system parameters and the number of validators to our attack. We also provide a modified attack to make our attack feasible in today’s Ethereum system.

**Impacts of the maximum number of attestations to our attack.** To satisfy the condition  $N_a \geq N_c$  specified in Lemma 3, we need either a larger  $N_a$  or a smaller  $N_c$ . We have the following observations:

- If the MAXATT parameter increases from 128 to 2,048, a block can include aggregated attestations from *all* Byzantine validators. This is mainly because  $N_c = 16N_a$  in the current system, and a 16-fold increase in MAXATT would make  $N_a = N_c$ . Alternatively, we can also set MAXCOM to MAXCOM/16 to achieve the same result (as  $N_c$  depends on MAXCOM), i.e., by decreasing MAXCOM from 64 to 4.
- There are many alternative ways for  $N_a = N_c$  to be satisfied. For instance, if the parameter MAXATT increases from 128 to 512 and the parameter MAXCOM decreases from 64 to 16, the condition  $N_a \geq N_c$  is also satisfied.

Such a counter-intuitive finding shows that the values of system parameters such as MAXATT and MAXCOM are not an easy engineering decision and should be set up carefully.

**Impacts of the number of the number of validators to our attack.** If we fix the MAXATT and MAXCOM parameters, our attack can be launched with fewer than 16,384 validators. This is because when we fix the value of parameters, we need to set  $N_c \leq N_a = 128$  according to Lemma 3. According to equation (1), setting  $N_c$  as  $32 \times \text{MAXCOM}$  will never make  $N_c \leq 128$ . As a result, we can set  $N_c = N/128$  for  $N_c \leq N_a = 128$  to hold. Accordingly,

$$N \leq 128 \times 128 = 16384.$$

Namely, if we do not change the system parameters, Ethereum becomes vulnerable to our attack when the number of validators is below 16,384.

**A modified attack on the current system.** We can modify our attack to be feasible in the current Ethereum system. The

main reason why our attack might fail in the current system is that a block cannot include attestations from all Byzantine validators. Our major modification is that attestations from Byzantine validators do not have to be included in one block. In particular, the attestations from Byzantine validators in the first 28 slots are directly sent to all validators in the system. Only the attestations from Byzantine validators in the last 4 slots are withheld. Among them, attestations in 2 slots are included in the block proposed by the last Byzantine proposer (mainly because a block may include attestations from attestors in at most 2 slots, see Appendix B for more information). Therefore, we require the slot of the last Byzantine proposer to be one of the last 4 slots. Under the assumption of  $f = 0.33N$ , the probability of repeating the attack is:

$$P_{succ} = 1 - \left(\frac{N-f}{N}\right)^4 \approx 80.25\%.$$

We provide the details of the modified attack in Appendix B. If the attack cannot be repeated in the next epoch, the adversary can wait for another opportune epoch to restart the attack. Recall that our attack can be started if the proposer of the first slot of an epoch is Byzantine. The probability of starting an attack is thus 33%.

Combining the discussion above, we show the attestation incentives of honest validators in Theorem 2 in Appendix B. Specifically, if the adversary controls 33% of the total stake, the attestation incentives of an honest validator become only 28.9% of the fair share.

## 7 Conclusion

We present staircase attack, the first attack on the incentive mechanism of the Ethereum Proof-of-Stake (PoS) protocol. Without considering the constraints of system parameters such as the number of validators, we show that an adversary that controls 29.6% stake can launch the attack and eventually *all* honest validators lose their attestation incentives. As the fraction of stake controlled by the adversary increases, honest validators may even suffer from stake loss. Moreover, considering the values of system parameters, the feasibility of our attack is closely related to two parameters: the number of validators and MAX\_ATTESTATIONS, the maximum number of attestations included in each block. With the current Ethereum setup (850,000 validators and MAX\_ATTESTATIONS = 128), we show that an adversary that controls 33% stake can make honest validators suffer from no incentives with a probability of 80.25%. Our attack shows that in addition to the safety and liveness properties considered in conventional consensus protocols, properties regarding the incentives might also be worth investigating in today’s blockchain systems.

## A Rewards and Penalties in Ethereum

In this section, we provide more details on attestation rewards and penalties [39]. The reward weight of a validator  $W_r$  is set to 54 if the corresponding attestation is finalized on-chain and the *head* field in the attestation is correct (i.e., the block matches the head of the canonical chain). If the attestation is finalized on-chain but the *head* in the attestation is incorrect, the reward weight  $W_r$  is set to 40. Finally, if the corresponding attestation is not finalized on-chain<sup>①</sup>, the penalty weight of a validator  $W_p$  is set to 40.

<sup>①</sup>The value can be found at <https://github.com/ethereum/consensus-specs/blob/dev/specs/altair/beacon-chain.md#incentivization-weights>

As mentioned in §4, the attestations in  $A_2$  are finalized on-chain, so the reward weights of the corresponding attestors  $W_r$  are at most 54. Meanwhile, the attestations in  $A_1$  are discarded, so the penalty weight of the corresponding attestors  $W_p$  is 40. Thus, we have  $W_r \leq 27W_p/20$ .

## B Modified Staircase Attack

In this section, we provide a modified staircase attack. The modified attack can be launched based on the latest system configuration of Ethereum. We show the workflow of the modified attack in Figure. 12. Compared to the attack presented in §4.3, we make three major changes. First, as shown in Figure. 13, there are now three statuses for each Byzantine validator: idle, repeat, and stop. The status is *idle* if the attack is not being launched. The status is *repeat* if the attack is being launched and can be repeated to the next epoch. The status is *stop* if the attack cannot be repeated and will be stopped at the end of the epoch. Here, the last epoch of the attack becomes similar to that in our one-time staircase attack. Second, the attestations from Byzantine validators in the first 28 slots are not withheld. Instead, they are directly sent to all validators in the system. The attestations from the Byzantine attestors in the last four slots are sent to the last Byzantine proposer  $v_j$ . Third, to continuously launch the attack, slot  $t_{adv}$  when the last Byzantine proposer  $v_j$  releases the block  $b_j$  is not set to the middle of an epoch. Instead, it is set to the beginning of the 14-th slot of an epoch.

We also introduce a function called *judge* (lines 41-45). Briefly speaking, given an epoch  $e$ , the *judge* function returns 1 if the attack can be repeated in the next epoch and 0 otherwise.

**Lemma 4.** *If the adversary controls 33% of the total stake and the attack is being launched, all honest validators lose their incentives or even suffer from stake loss.*

*Proof.* We consider the attestations from honest validators in epoch  $e$  while the attack is being launched. The attestations from honest validators in the first period of epoch  $e$  are included in the branch  $c_{hon}^e$ . The attestations from honest validators in the last four slots are included in the branch  $c_{hon}^{e+1}$ . The rest attestations from honest validators are included in the branch  $c_{adv}^e$  and  $c_{adv}^{e+1}$ . We thus consider the following three cases.

- (1) The branch  $c_{hon}^e$  in the first 13 slots is pruned in epoch  $e$ . Attestations from the honest attestations in the first 13 slots are thus discarded.
- (2) The branch  $c_{hon}^{e+1}$  in the last 4 slots is pruned in epoch  $e+1$ . The attestations from the honest attestations in the last 4 slots are thus discarded. Block  $b_j$  can include attestations with a number roughly equal to the number of attestations in most 2 slots. This is because a block can include attestations from 128 committees (i.e., MAXATT =128) and there are 64

Figure 12: The workflow of a Byzantine validator  $v_k$ .

committees (i.e., MAXCOM =64) in a slot. Therefore, the attestations from honest attestations in the last 2 slots are discarded.

- (3) The branches  $c_{adv}^e$  and  $c_{adv}^{e+1}$  are not pruned, and the attestations from the honest validators in  $c_{adv}^e$  and  $c_{adv}^{e+1}$  are

Figure 13: The status of the attack. Line numbers refer to those in Figure. 12.

finalized on-chain.

Thus, the fraction of discarded attestations from honest validators in total attestations is  $R_{hon} = (13 + 2)/32$ . The expected incentives of an honest validator is then  $I_{hon}$  is

$$\left( \left( (1 - R_{hon}) \frac{N - f}{N} + \frac{f}{N} \right) (1 - R_{hon}) W_r - R_{hon} W_p \right) \times I_{base}.$$

Let  $f = 0.33N$  and  $W_r = 27W_p/20$ , we have the incentive  $I_{hon} \approx -0.0382 \times W_r I_{base} < 0$ , where  $W_r I_{base}$  is the fair share of an honest validator.  $\square$

**Theorem 2.** *If the adversary controls 33% of the total stake, our modified attack makes the incentives of an honest validator decrease to 28.9% of its fair share.*

*Proof.* The incentive of an honest validator in each epoch can be modeled as a discrete-time Markov chain. In particular, there are three states of the attack: the *idle* status (staircase attack is not launched), the *repeat* status (staircase attack is launched and being repeated in every epoch), and the *stop* state (staircase attack can not be repeated and conduct a one-time attack to penalize all honest validators). In each state, the incentives of honest validators are  $W_r I_{base}$ ,  $I_{hon}$ , and  $-W_p I_{base}$ , respectively. Meanwhile, the transition matrix is shown as follows:

$$\mathbf{P} = \begin{pmatrix} 2/3 & P_{succ}/3 & (1 - P_{succ})/3 \\ 0 & P_{succ} & 1 - P_{succ} \\ 1 & 0 & 0 \end{pmatrix}.$$

By applying the matrix to a  $n$ -epoch transition, we have matrix  $\mathbf{P}^{(n)} = \mathbf{P}^n$ . The  $\mathbf{P}^{(n)}$  becomes stable after  $n = 27$ , we have

$$\mathbf{P}^{(n)} \approx \begin{pmatrix} 0.372 & 0.504 & 0.124 \\ 0.372 & 0.504 & 0.124 \\ 0.372 & 0.504 & 0.124 \end{pmatrix},$$

for  $n \geq 27$ . Thus, the incentive of an honest validator is equal to any entry in the matrix  $\mathbf{P}^{(n)}$  multiplied by  $(W_r I_{base}, I_{hon}, -W_p I_{base})^T$ , which is approximately  $0.289 \times W_r I_{base}$ .  $\square$
