# Input Transformation Based Efficient Zero-Knowledge Argument System for Arbitrary Circuits with Practical Succinctness

Frank Y.C. Lu

YinYao

**Abstract.** We introduce a new class of efficient transparent interactive zero knowledge argument system based on the input transformation concept. The idea of the input transformation concept is converting circuit inputs in Pedersen commitment form to linear polynomials in integer form so that verifiers can use standard integer operations to compute and verify the circuit output. While the verifier runtime of our protocol is linear to the size of the circuit, its practical performance compares favorably against state-of-the-art transparent zero-knowledge protocols with sub-linear verifier work. We therefore claim that our protocol achieves practical succinctness.

The input transformation concept replaces the constraint system often required in zero knowledge protocols. Once inputs are transformed, they can be used as inputs to a circuit that computes the output directly from inputs. This direct computation mechanism eliminates the need of a front end encoder to translate NP relation $R$ to some zero-knowledge friendly representation $\hat{R}$ (such as R1CS constraint system) before the relation can be converted to a proof system, making our protocol relatively easy to implement and likely easier to use compared to constraint system based protocols.

The asymptotic cost of our protocol is $O(m_p \log m_p)$ for prover work, $O(n)$ for verifier work, and $O(m_p^{1/2})$ for communication cost, where $n$ stands for the total number of all operations in a circuit and $m_p$ stands for the total number of multiplications performed on the path that leads to the circuit output (e.g. for a circuit with $n = 2^{20}$ sequential multiplications and one output, $m_p = n$).

Specifically, when running a circuit with $2^{20}$ sequential multiplication gates with 640 input bits on a single thread, the prover runtime of our protocol is 6 seconds, the verifier runtime is 23 ms and the communication cost is approximately 59 kbs, which shows significant improvement over the current approaches in verifier runtime while keeping the prover runtime and communication cost competitive with current state of art.

In this paper, we will first introduce a base version of our protocol in which the prover work is dominated by $O(m_p^2)$ field operations. Although field operations are significantly faster than group operations, they become increasingly expensive as $m_p$ value gets large. So in the follow up sections, we will introduce a mechanism to apply number theoretic transformation (NTT) to bring down the prover runtime to $O(m_p \log m_p)$.

**Keywords:** zero knowledge · interactive oracle proofs

## 1 Introduction

Ever since the discoveries of interactive proofs (IPs) [14] and probabilistically checkable proofs (PCPs) [5] [4] [3] [2] in the late last century, there has been tremendous amount of research in the area of proof systems. More recently, the rise Blockchain and Web3 has finally triggered real-world deployments of zero knowledge systems.

Popular zero knowledge systems are often divided into two phases: the first part, a "front-end" encoder converting a specification of an NP-relation $R$ into a "zero-knowledge friendly" representation $\hat{R}$ (e.g. rank-1 constraint system); and then another "back-end" system converting $\hat{R}$ to a zero-knowledge

proof system for $R$. The encoder based two-phased design has accelerated the development of zero knowledge system applications, but it has added cost of running the encoder to translate circuit logic to constraint system form.

Due to expensive computation during setup time of earlier SNARKs, it has become a significant interest to have the structured reference string (SRS) be constructible in a "universal and updatable" fashion, meaning that the same SRS can be used for statements about all circuits of a certain bounded size. Maller et al. constructed for the first time a universal fully succinct SNARK for circuit satisfiability called Sonic [15]. More recently developed protocols such as PLONK [12], MARLIN [11] are universal fully-succinct SNARK with significantly improved prover run time compared to the fully-succinct Sonic. However, there are two draw backs with these SNARKs: first, most of these universal succinct SNARKs systems require trusted setup; second, the prover run-time of these protocols are very expensive, which is prohibitive for many applications.

Protocols belong to the Goldwasser, Kalai, and Rothblum (GKR) class such as Hyrax [18], Virgo [21]; MPC-in-the-head class of Kushilevitz, Ostrovsky, and Sahai such as ZKBoo [13] and Ligero/Ligero++ [1] [8]; memory efficient VLOE protocols such as Wolverine [19], Mac'n'Chess [6], Quicksilver [20], offer efficient prover runprover runtimetime that are at least one order of magnitude more efficient than pairing based SNARKs, and many of these protocols do not require trusted setups. However, these protocols are largely ignored by the Blockchain community due to expensive verifier runverifier runtimetime and high communication cost (hundreds of KBs, or MBs for VLOE protocols) than fully succinct PIOP protocols such as STARK [7], PLONK, MARLIN, and Supersonic [10]. Furthermore, state-of-art GKR protocols such as Virgo has additional dependency on circuit depth where protocol complexity increases and performance significantly degrades as the circuit depth gets longer, making them less attractive to the industry where complex business logics are expected on smart contracts.

NIZKs such as SpartanNIZK [16] and later Lakonia [17] seems to offer a much more balanced approach, where it offers efficient prover runtime (6-18 seconds) and competitive communication cost for large circuits ($2^{20}$ constraints) and not being layer dependent. However, the downside of these protocols is that their verifier performance is still expensive, usually in the 400 ms range on a single thread CPU.

We aim to create a new transparent zero knowledge protocol designed to handle complex circuits and offers prover runtime and communication cost comparable to that of Spartan and Lakonia, but with verifier runtime significantly improved over the current state of the art systems.

## 1.1 Summary of Contributions

We introduce a new efficient, transparent, interactive zero-knowledge argument system that offers great verifier performance despite not being asymptotically succinct. We achieve this by transforming each committed input parameter of a circuit to some obfuscated scalar value in linear polynomial form, where verifiers can perform normal arithmetic operations (e.g., addition and multiplication) on these values as they do on integers. Since field operations are cheap, the verifier runtime our protocol compare favorably against state-of-the-art transparent zero knowledge protocols.

Another advantage of our design is that our protocol does not require a "front end" encoder to compile business logic relation $R$ into some zero-knowledge friendly representation $\hat{R}$. This construct makes our protocol relatively easy to implement and also makes it easier for end developers to apply zero knowledge design to real world applications.

The prover runtime of the base version (Protocol 1) of our protocol is dominated by $O(m_p{}^2 + m_p + l)$ field operations and $O(m_p)$ group exponentiations, where $m_p$ stands for the total number of multiplication gates in the path contain most multiplications and $l$ stands for the number of inputs to a circuit; the verifier runtime is dominated by $O(n)$ field operations and $O(m_p{}^{1/2} + l)$ group exponentiations; and the communication cost is dominated by $O(m_p{}^{1/2})$ group elements and $O(m_p{}^{1/2} + l)$ field elements.

The prover runtime will get increasingly expensive as $m_p$ gets large, so in the full version of our protocol (Protocol 2 and 3), we introduce a mechanism to apply number theoretic transform (NTT) to bring down the prover runtime to $O(m_p \log m_p)$ field operations and $O(l)\mathbb{G}$ group exponentiations.

Our protocol is specifically efficient for proving applications with complex business logic (e.g., a smart contract validating complex business trade rules) where circuit depth is high and the number of input parameters is much smaller than the circuit size.

We introduce our protocol in the interactive setting where all verifier challenges are random field elements. In practice, we assume that the Fiat-Shamir heuristic would be applied in order to obtain a non-interactive zero-knowledge argument in the random oracle model.

## 2 Preliminaries

### 2.1 Assumption

**Definition 1.** (Discrete Logarithmic Relation) For all PPT adversaries $\mathcal{A}$ and for all $n \geq 2$ there exists a negligible function $\boldsymbol{negl}(\lambda)$ s.t.

$$Pr\left[\begin{array}{c} \mathbb{G} = Setup(1^\lambda),\ g_0, ..., g_{n-1} \xleftarrow{\$} \mathbb{G} \\ a_0, ..., a_{n-1} \in \mathbb{Z}_p \leftarrow \mathcal{A}(g_0, ..., g_{n-1}) \end{array} \middle|\ \exists a_i \neq 0 \wedge \prod_{i=0}^{n-1} g_i^{a_i} = 1 \right] \leq \boldsymbol{negl}(\lambda)$$

The Discrete Logarithmic Relation assumption states that an adversary can't find a non-trivial relation between the randomly chosen group elements $g_0, ..., g_{n-1} \in \mathbb{G}^n$, and that $\prod_{i=0}^{n-1} g_i^{a_i} = 1$ is a non-trivial discrete log relation among $g_0, ..., g_{n-1}$.

### 2.2 Zero-Knowledge Argument of Knowledge

Interactive arguments are interactive proofs in which security holds only against computationally bounded provers. In an interactive argument of knowledge for a relation $\mathcal{R}$, a prover convinces a verifier that it knows a witness $w$ for a statement $x$ s.t. $(x, w) \in \mathcal{R}$ without revealing the witness itself to the verifier. When we say knowledge of an argument, we imply that the argument has witness-extended emulation.

**Definition 2.** (Interactive Argument) Let's say $(\mathcal{P}, \mathcal{V})$ denotes a pair of PPT interactive algorithms and $\boldsymbol{Setup}$ denotes a non-interactive setup algorithm that outputs public parameters $pp$ given a security parameter $\lambda$ that both $\mathcal{P}$ and $\mathcal{V}$ have access to. Let $\langle \mathcal{P}(pp, x, w), \mathcal{V}(pp, x) \rangle$ denote the output of $\mathcal{V}$ on input $x$ after its interaction with $\mathcal{P}$, who has knowledge of witness $w$. The triple $(\boldsymbol{Setup}, \mathcal{P}, \mathcal{V})$ is called an argument for relation $\mathcal{R}$ if for all non-uniform PPT adversaries $\mathcal{A}$, the following properties hold:

- **Perfect Completeness**

$$Pr\left[\begin{array}{c} (pp, x, w) \notin \mathcal{R} \text{ or} \\ \langle \mathcal{P}(pp, x, w), \mathcal{V}(pp, x) \rangle = 1 \end{array} \middle|\ \begin{array}{c} pp \leftarrow \boldsymbol{Setup}(1^\lambda) \\ (x, w) \leftarrow \mathcal{A}(pp) \end{array} \right] = 1$$

- **Computational Soundness**

$$Pr\left[\begin{array}{c} \forall w(pp, x, w) \notin \mathcal{R} \wedge \\ \langle \mathcal{A}(pp, x, s), \mathcal{V}(pp, x) \rangle = 1 \end{array} \middle|\ \begin{array}{c} pp \leftarrow \boldsymbol{Setup}(1^\lambda) \\ (x, s) \leftarrow \mathcal{A}(pp) \end{array} \right] \leq \boldsymbol{negl}(\lambda)$$

- **Public Coin** All messages sent from $\mathcal{V}$ to $\mathcal{P}$ are chosen uniformly at random and independently of $\mathcal{P}$'s messages

**Definition 3.** (Computational Witness-Extended Emulation) Given a public-coin interactive argument tuple $(\mathbf{Setup}, \mathcal{P}, \mathcal{V})$ and arbitrary prover algorithm $\mathcal{P}^*$, let $\boldsymbol{Recorder}$ $(\mathcal{P}^*, pp, x, s)$ denote the message transcript between $\mathcal{P}^*$ and $\mathcal{V}$ on shared input $x$, initial prover state $s$, and $pp$ generated by $\boldsymbol{Setup}$. Furthermore, let $\mathcal{E}$ $\boldsymbol{Recorder}$ $(\mathcal{P}, pp, x, s)$ denote a machine $\mathcal{E}$ with a transcript oracle for this interaction that can rewind to any round and run again with fresh verifier randomness. The tuple $(\boldsymbol{Setup}, \mathcal{P}, \mathcal{V})$ has computational witness-extended emulation if for every deterministic polynomial time $\mathcal{P}$ there exists an expected polynomial time emulator $\mathcal{E}$ such that for all non-uniform polynomial time adversaries $\mathcal{A}$ the following condition holds:

$$
\left| Pr\left[ \mathcal{A}(tr) = 1 \;\middle|\; \begin{array}{c} pp \leftarrow Setup(1^\lambda) \\ (x,s) \leftarrow \mathcal{A}(pp) \\ tr \leftarrow \boldsymbol{Recorder}(\mathcal{P}^*, pp, x, s) \end{array} \right] - \right.
$$

$$
\left. Pr\left[ \begin{array}{c} \mathcal{A}(tr) = 1 \;\wedge \\ tr \text{ accepting} \implies (x,w) \in \mathcal{R} \end{array} \;\middle|\; \begin{array}{c} pp \leftarrow Setup(1^\lambda) \\ (x,s) \leftarrow \mathcal{A}(pp) \\ (tr,w) \leftarrow \mathcal{E}^{\boldsymbol{Recorder}(\mathcal{P}^*, pp, x, s)}(pp, x) \end{array} \right] \right| \leq \boldsymbol{negl}(\lambda)
$$

**Definition 4.** (Perfect Special Honest Verifier Zero Knowledge for Interactive Arguments) An interactive proof is $(\boldsymbol{Setup}, \mathcal{P}, \mathcal{V})$ is a perfect special honest verifier zero knowledge (PSHVZK) argument of knowledge for $\mathcal{R}$ if there exists a probabilistic polynomial time simulator $\mathcal{S}$ such that all pairs of interactive adversaries $\mathcal{A}_1, \mathcal{A}_2$ have the following property for every $(x, w, \sigma) \leftarrow \mathcal{A}_2(pp) \wedge (pp, x, w) \in \mathcal{R}$, where $\sigma$ stands for verifier's public coin randomness for challenges

$$
Pr\left[ \mathcal{A}_1(tr) = 1 \;\middle|\; \begin{array}{c} pp \leftarrow Setup(1^\lambda), \\ tr \leftarrow \langle \mathcal{P}(pp, x, w), \mathcal{V}(pp, x) \rangle \end{array} \right] =
$$

$$
Pr\left[ \mathcal{A}_1(tr) = 1 \;\middle|\; \begin{array}{c} pp \leftarrow Setup(1^\lambda), \\ tr \leftarrow \mathcal{S}(pp, x, \sigma) \end{array} \right]
$$

Above property states that adversary chooses a distribution over statements $x$ and witnesses $w$ but is not able to distinguish between the simulated transcripts and the honestly generated transcripts for a valid statement/witnesses pair.

## 2.3 Polynomial Commitment Function

As in the case of other popular zero knowledge protocols that offer succinct proof size, our protocol uses a polynomial commitment evaluation protocol to construct most of our proof transcript. Our protocol uses a version of the polynomial commitment scheme defined by Bootle. et al. [9] Others have improved the square-root-based polynomial commitments by applying the inner product approach defined by Bunez et. al. and adding support for multilinear polynomials such as Hyrax [18] and Spartan [16]. Similar techniques may be used to improve our implementation in the future to reduce proof size in the expense of longer verifier runtime. The polynomial commitment function PolyCommitEval is defined as:

- $\boldsymbol{PolyCommitEval}(C, y, x; \vec{\tau}, \phi) \rightarrow boolean$ $C$ is the committed polynomial in $\mathbb{G}$ where $\vec{\tau}$ are its coefficients and $\phi$ is its blinding key. The function returns a boolean value "åtrue" if the polynomial can be correctly evaluated at point $x$ s.t. $y = f(x)$.

While most polynomial commitment evaluation schemes use constant sized commitment, the commitment of the scheme defined by Bootle. et al. [9] is a set of $m_p^{1/2}$ group elements. In order to not lose generality, we use a single element $C \in \mathbb{G}$ to denote a polynomial commitment in this paper.

## 2.4 Zero Knowledge Proof of Discrete Logarithm

For a prover to prove it has the knowledge of a discrete logarithmic $\phi$ of some group element $s = g^\phi \in \mathbb{G}$. We define the relation for this protocol as $\mathcal{R}_{PoD} = \{(g, s; \phi) : s = g^\phi\}$. We also define two functions $(\boldsymbol{ProveDL}, \boldsymbol{VerifyDL})$ for provers and verifiers to create and verify proof transcripts:

- $\boldsymbol{ProveDL}(g, \phi) \to tr_\phi$ generates proof transcript $tr_\phi$, where $\phi$ is the witness.
- $\boldsymbol{VerifyDL}(g, s, tr_\phi) \to b \in \{0, 1\}$ takes a proof transcript $tr_\phi$ and a pair of group elements with discrete log relation $(g, s \in \mathbb{G} \wedge s = g^\phi)$, and outputs $true$ if the knowledge of the relation is verified, $false$ otherwise.

In this paper, we assume the underlying implementation of the proof of discrete logarithm protocol is Schnorr's protocol. We know for a fact that Shnorr's protocol has perfect completeness, special honest verifier zero knowledge, and computational witness-extended emulation.

## 2.5 Notations

Let $\mathbb{G}$ denote any type of secure cyclic group of prime order $p$, and let $\mathbb{Z}_p$ denote an integer field modulo $p$. Group elements other then generators are denoted by capital letters. e.g., $C = u_1^{a_1} u_2^{a_2} ... u_n^{a_n} \in \mathbb{G}$ is a commitment commits to a vector $\vec{a}$ denoted by a capital letter, and $B \in \mathbb{G}$ is a random group element also denoted by a capital letter. For generators used as base points to compute other group elements in our protocol, such as $\vec{g}, h \in \mathbb{G}$, we use lower case letters to denote them. Greek letters are used to label hidden key values. e.g. $v$ is the blinding key for Pedersen commitment $P$ on generator $h \in \mathbb{G}$ s.t. $P = g^a h^v$. Finally, we use standard vector notation $\vec{v}$ to denote vectors. i.e. $\vec{a} \in \mathbb{Z}_p^n$ is a list of $n$ integers $a_i$ for $i = \{1, 2, ..., n\}$.

We write $\mathcal{R} = \{(Public\ Inputs\ ; Witnesses) : Relation\}$ to denote the relation $\mathcal{R}$ using the specified public inputs and witnesses.

# 3 Input Transformation Based Zero Knowledge Argument

In this section we will first introduce the base version of our protocol, and then we will present the improved version of the baseline protocol in section 4, which leverages number theoretic transform (NTT) to speed up polynomial multiplication operations.

The prover work of the baseline version of our protocol is $O(l + 1)$ group exponentiations and $O(m_p{}^2)$ field operations, where $m_p$ stands for the total number of multiplications included in the path leads to circuit output. Unlike GKR based protocols, layers of additive operations have no impact on the asymptotic performance of our protocol. This also implies that the worst case scenario of prover runtime of our protocol with $n$ gates is $n$ sequential multiplications. In section 4, we will introduce the full version of our protocol that uses NTT to reduce the asymptotic prover runtime for field operations to $m_p \log m_p$.

The verifier work is dominated by $O(n)$ field operations and $O(m_p{}^{1/2} + l)$ group operations (we are using the univariate polynomial commitment scheme defined by Bootle et al. [9]). Although running $O(n)$ field operations is not technically sub-linear, it is still still fast even for large circuits with $2^{20}$ multiplication gates, so we therefore claim that the verifier work of our protocol achieves practical succinctness.

The communication cost is dominated by $O(l)$ field elements and $O(m_p{}^{1/2})\mathbb{G}$ group elements when using the univariate polynomial commitment scheme based on the one developed by Bootle et al.[9]

### 3.1 Using Input Transformation Concept to Build a Zero Knowledge Argument Protocol For Arbitrary Circuits

We first define the relation for the base version of our protocol. For $l$ input parameters, let $\mathcal{C}_{\mathbb{F}}$ represents the set of arbitrary arithmetic circuits in $\mathbb{F}$, there exists a zero knowledge argument for the relation:

$$\{(g, h, R \in \mathbb{G}, \vec{P} \in \mathbb{G}^l, E_c = \mathcal{C}_{\mathbb{F}} \,;\, \vec{a}, \vec{v} \in \mathbb{Z}_p^l, r, \epsilon \in \mathbb{Z}_p) :$$
$$P_i = g^{a_i} h^{v_i} \; \forall_i \in [1, l] \; \wedge \; R = g^r h^\epsilon \; \wedge \; E_c(\vec{a}, v) = r, \epsilon\} \tag{1}$$

The above relation states that each input parameter is a commitment $P_i$ in $\mathbb{G}$ with committed value $a_i$ and blinding key $v_i$. The protocol checks whether $r, \epsilon$ of $R$ are computed from circuit $E_c$ using input witnesses $\vec{a}, \vec{v}$.

We update the relation above by introducing witnesses $\vec{\tau}$, which is a byproduct computed from witnesses $\vec{a}, \vec{v}$ s.t $E(\vec{a}, \vec{v}) = r, \epsilon, \vec{\tau}$. The prover commits to $\vec{\tau}$ so that verifiers can use polynomial evaluation protocol to verify them. The updated relation is as follows:

$$\{(g, h, R, C \in \mathbb{G}, \vec{u} \in \mathbb{G}^{m_p}, \vec{P} \in \mathbb{G}^l, E = \mathcal{C}_{\mathbb{F}} \,;\, \vec{a}, \vec{v} \in \mathbb{Z}_p^l, r, \epsilon \in \mathbb{Z}_p, \vec{\tau} \in \mathbb{Z}_p^{m_p}) :$$
$$P_i = g^{a_i} h^{v_i} \; \forall_i \in [1, l] \; \wedge \; R = g^r h^\epsilon \; \wedge \; C = \vec{u}^{\vec{\tau}} \; \wedge \; E(\vec{a}, v) = r, \epsilon, \vec{\tau}\} \tag{2}$$

The main idea is to transform committed inputs in Perdersen commitment form in $\mathbb{G}$ to linear polynomials in $\mathbb{F}$ so that both the prover and the verifier can perform addition and multiplication operations just as they add and multiply polynomials in $\mathbb{F}$. For an input commitment $P_i$ s.t. $P = g^{a_i} h^{v_i} \in \mathbb{G}$ where $a_i$ is the input value and $v_i$ is its blinding key. We use the same value pair to create its corresponding integer value in linear polynomial form $a_i' \in \mathbb{Z}_p$ :

$$a_i' = a_i + X v_i \in \mathbb{Z}_p \tag{3}$$

The linear polynomial $a_i'$ is obviously not binding to $a_i$ as we can easily manipulate the value of $a_i$ by altering its blinding key if the value of challenge $X$ is known. e.g. $a_i' = (a_i + \delta) + x(v_i - \delta/x)$ (the "committed" value $a_i$ is altered to $a_i + \delta$). To combat this, verifiers use the following equation to confirm the mapping between the scalar $a_i'$ and $P_i$ for some challenge $x$:

$$P_i / g^{a_i'} = \frac{g^{a_i} h^{v_i}}{g^{a_i + x v_i}} = (h/g^x)^{v_i} \tag{4}$$

If the prover can prove the knowledge of $v_i$ on generator $(h/g^x) \in \mathbb{G}$ using any proof of knowledge protocol, we have a concrete proof that the witnesses of $a_i'$ and $P_i$ must match for some challenge $x$ except for a negligible probability.

Before we move on, there are two issues in real world applications that we have to consider before we construct the base version of our protocol:

First, since each committed $P_i$ may be used multiple times as inputs to different circuits, an attacker can easily deduce the witness pair of $P_i$ from two different challenges $x_1$, and $x_2$. (e.g. for $P_i = g^{a_i} h^{v_i}$, its linear polynomial form value from the first challenge $x_1$ would be $a_i + x_1 v_i$, and from the second challenge $x_2$ would be $a_i + x_2 v_i$, subtracting the two will get $v_i(x_1 - x_2)$ where an attacker can trivially extract the witness pair $v_i$ and $a_i$).

Second, for a circuit with $l$ input parameters, it would be pretty inefficient to create $l$ proof of knowledge transcripts for all $l$ inputs, so we need some kind of batching mechanism to verify them in batch.

The prover can get around the first issue by creating new blinding keys $\alpha_i$ for every linear polynomial $a_i'$ s.t. $i = \{1, ..., l\}$, and then commit to the differences between each blinding key pair (e.g. $\alpha_i - v_i$). To batch verify them, the verifier use a random challenge $k$ to generate $l$ challenges $\vec{k} = k^1, ..., k^l$ s.t.:

$$\kappa = \sum_{i=1}^{l} (\alpha_i - v_i) k^i \in \mathbb{Z}_p \tag{5}$$

$$PK_\kappa = h^\kappa \in \mathbb{G} \tag{6}$$

$$tr_\kappa = ProveDL(h, \kappa) \tag{7}$$

If the prover can prove the knowledge of $\kappa$ on generator $h \in \mathbb{G}$ using any proof of knowledge (or proof of discrete logarithm) protocol, we know that only the sum of products of blinding keys (exponent of $h$, not the committed values on generator $g$) are updated after performing equation 8 except for a negligible probability.

$$P_t = (\prod_{i=1}^{l} P_i^{k^i}) \cdot PK_\kappa \in \mathbb{G} \tag{8}$$

The prover use the new blinding keys $\vec{\alpha}$ to create linear polynomials such that $a_i{}' = a_i + x\alpha_i$ for all $i$. After challenge $k$ is known, the prover can batch prove the mapping between committed values and their linear polynomial values by providing transcripts for $tr_{\alpha_t}$.

$$\alpha_t = \sum_{i=1}^{l} (\alpha_i) k^i \in \mathbb{Z}_p \tag{9}$$

$$tr_{\alpha_t} = ProveDL((h/g^x), \alpha_t) \tag{10}$$

The verifier computes the sum of products of $\vec{a}$ and powers of $k$. With sum of products of both $\vec{P}, \vec{a'}$ ($P_t, t$) available, the verifier can trivially compute $PK_{\alpha_t}$ s.t.:

$$t = \sum_{i=1}^{l} a_i' k^i \in \mathbb{Z}_p \tag{11}$$

$$PK_{\alpha_t} = P_t/g^t = (h/g^x)^{\alpha_t} \tag{12}$$

If the prover can prove the knowledge of $\alpha_t$ on generator $(h/g^x) \in \mathbb{G}$ using any proof of knowledge protocol, we know that the mapping between $\vec{P}$ and $\vec{a'}$ is correct except for a negligible probability.

The main philosophy of our protocol is that once we have transformed input parameters in linear polynomials, verifiers can just perform arithmetic operations on polynomials, which they can't do on Pedersen commitments. To provide zero knowledge proof for a circuit, the prover needs to to prove it knows all coefficients of the result polynomial after finish running the circuit. For example, adding two input values in $a_i'$ is the same as adding two polynomials:

$$o = a_1' + a_2' = r + X \cdot \epsilon \tag{13}$$

Where $r = (a_1 + a_2)$ and the blinding key is $\epsilon = (\alpha_1 + \alpha_2)$. Multiplying two values in $a_i'$ is the same as multiplying two polynomials:

$$o = a_1 \cdot a_2 = r + X \cdot \epsilon + X^2 \cdot \tau \tag{14}$$

Where $r = a_1 \cdot a_2$, $\epsilon = a_2\alpha_1 + a_1\alpha_2$, and $\tau = \alpha_1 \cdot \alpha_2$. We use the label "$o$" to represent the result polynomial after all circuit operations. The degree of the polynomial will increase after each multiplication operation, so the efficiency will drop as the total number of multiplications included in the path that leads to the circuit output ($m_p$) increase.

We still want to use a linear polynomial $r' = r + X\epsilon$ to represent the output of the circuit, which maps to the commitment $R = g^r h^\epsilon$. To do that, we need to subtract out all terms with degree higher than one. In the simple case above, the verifier needs to eliminate the term with coefficient $\tau$ and the prover needs to commit to $\tau$ before the challenge $x$ is known, so that verifiers can obtain $r'$ by subtracting $y = X^2 \tau$ from $o$ s.t.:

$$r' = o - y \tag{15}$$

We call $y$ the breaker of our protocol, because it subtracts all polynomial terms with degree higher than two from the output of circuit evaluation $o$. If we let $m_p$ to denote the total number of multiplications included in the path that leads to the circuit output, then $o$ will be a polynomial with degree $m_p + 2$. The constant term is the committed value $r$ and the coefficient of degree 1 term is the blinding key $\epsilon$. The prover uses vector commitment to commit to all coefficients with degree term higher than two. In order to not lose generality, we use one vector commitment to denote a polynomial commitment. In our implementation, the polynomial commitment we used is actually a set of $m_p^{1/2}$ vector commitments (or $\vec{C} \in \mathbb{G}^{m_p^{1/2}}$ see Bootle. et al. [9]).

$$C = \prod_{i=1}^{m_p} u_i^{\tau_i} \in \mathbb{G} \tag{16}$$

We now define the function Multiply just to show how coefficients are computed from a circuit multiplication operation, we can trivially observe the logic is the same as that of a polynomial multiplication operation. The output of the function Multiply is an array list $o[]$ of size $m_p + 2$, such that $o[1]$ is the value of $r$, $o[2]$ is the blinding key $\epsilon$, and $o[3], ..., o[m_p + 2]$ are values of $\vec{\tau}$.

The returned list $o[]$ may be used again as input to another multiplication or addition function.

$$Input : (lists \ o_l[], o_r[]) \tag{17}$$
$$Define \ a \ list \ o[] \ of \ size \ n = |o_r| + |o_l - 1| \tag{18}$$
$$Define \ a \ matrix \ o_t[][] \ of \ size \ |o_r| \times |o_l| \tag{19}$$
$$\textbf{for} \quad j = 1, ..., \textbf{size} \ o_r \tag{20}$$
$$\textbf{for} \quad i = 1, ..., |o_l| \tag{21}$$
$$o_t[j][i] = o_l[j] \cdot o_r[j] \tag{22}$$
$$\textbf{for} \quad j, ..., |o_r| \tag{23}$$
$$\textbf{for} \quad i = 1, ..., |o_l| \tag{24}$$
$$o[i + j - 1] = o[i + j - 1] + o_t[j][i] \tag{25}$$
$$\textbf{return} \ o[] \tag{26}$$

Function Multiply

Like that of function Multiply, function Add is polynomial addition operation and outputs the coefficients of result polynomial in array list $o[]$.

$$Input : (lists \ o_l[], o_r[]) \tag{27}$$
$$Define \ a \ list \ o[] \ of \ size \ n = \textbf{max length of} \ o_r, o_l \tag{28}$$
$$\textbf{for} \quad i = 1, ..., n \tag{29}$$
$$o[i] = o_l[i] + o_r[i] \tag{30}$$
$$\textbf{return} \ o[] \tag{31}$$

Function Add

We define two more functions for our protocol. function $\textbf{\textit{computeKeys}}$ is used by the prover to compute keys of a polynomial, and function $\textbf{\textit{computeEquation}}$ is used by verifiers to compute the value of the result polynomial at evaluation point $X$:

1. function $\textbf{\textit{computeKeys}}$(circuit, "input values", "input keys") take input values $\vec{a}$ and keys $\vec{v}$ to compute $r, \epsilon, \vec{\tau}$ (coefficients of $o$) using the circuit provided to the protocol. function computeKeys uses function Multiply and function Add defined above to compute coefficients of $o$.

2. function $\textbf{\textit{computeEquation}}$(circuit, "input values in linear polynomial form") trivially compute the result $o$ from the inputs provided as they are integer values.

Since the logic of these functions are trivial, we don't waste space describing them in detail here. With all the information available, we now formally introduce Protocol 1:

$$Input : (\vec{P} \in \mathbb{G}^n, g, h, u \in \mathbb{G}, \vec{a} \in \mathbb{Z}_p^l, v \in \mathbb{Z}_p) \tag{32}$$

$$\mathcal{P}'s\, input : (\vec{P}, g, h, u; \vec{a}, v) \tag{33}$$

$$\mathcal{V}'s\, input : (\vec{P}, g, h, u) \tag{34}$$

$$\mathcal{P}\, compute : \tag{35}$$

$$\alpha_i \xleftarrow{\$} \mathbb{Z}_p, \qquad i = \{1, ..., l\} \tag{36}$$

$$r, \varepsilon, \vec{\tau} = computeKeys(equation, \vec{a}, \vec{\alpha}) \in \mathbb{Z}_p^{m_p+2} \tag{37}$$

$$R = g^r h^\varepsilon \in \mathbb{G} \tag{38}$$

$$tr_\epsilon = ((h/g^x), \epsilon) \tag{39}$$

$$C = \prod_{i=1}^{m_p} u_i^{\tau_i} \in \mathbb{G} \tag{40}$$

$$\mathcal{P} \to \mathcal{V} : C, R, tr_\epsilon \tag{41}$$

$$\mathcal{V}\, compute : \tag{42}$$

$$x \xleftarrow{\$} \mathbb{Z}_p \tag{43}$$

$$\mathcal{V} \to \mathcal{P} : x \tag{44}$$

$$\mathcal{P}\, compute : \tag{45}$$

$$a_i' = a_i + x\alpha_i \in \mathbb{Z}_p \quad i = \{1, ..., l\} \tag{46}$$

$$y = \sum_{i}^{m_p} \tau_i \cdot x^{i+1} \in \mathbb{Z}_p \tag{47}$$

$$\mathcal{P} \to \mathcal{V} : \vec{a}', y \tag{48}$$

$$\mathcal{V}\, verify\, final\, output\, R : \tag{49}$$

$$o = computeEquation(equation, \vec{a}') \in \mathbb{Z}_p \tag{50}$$

$$r' = o - y \in \mathbb{G} \quad // \ r' = r + x \cdot \epsilon \tag{51}$$

$$PK_\epsilon = R/g^{r'} \in \mathbb{G} \quad //equal\ to\ (h/g^x)^\epsilon \tag{52}$$

$$\textbf{if } PolyCommitEval(C, y, x; \vec{\tau}), \textbf{ then } continue \tag{53}$$

$$\textbf{else } reject \tag{54}$$

$$\textbf{if } VerifyDL((h/g^x), PK_\epsilon, tr_\epsilon), \textbf{ then } continue \tag{55}$$

$$\textbf{else } reject \tag{56}$$

$$\mathcal{V}\, compute : \tag{57}$$

$$k \xleftarrow{\$} \mathbb{Z}_p \tag{58}$$

$$\mathcal{V} \to \mathcal{P} : k \tag{59}$$

$$\mathcal{P}\, compute : \tag{60}$$

$$\alpha_t = \sum_{i=1}^{l} \alpha_i k^i \in \mathbb{Z}_p \tag{61}$$

$$tr_{\alpha_t} = ProveDL((h/g^x), \alpha_t) \tag{62}$$

9

$$\kappa = \sum_{i=1}^{l}(\alpha_i - v_i)k^i \in \mathbb{Z}_p \tag{63}$$

$$PK_\kappa = h^\kappa \in \mathbb{G} \tag{64}$$

$$tr_\kappa = ProveDL(h, \kappa) \tag{65}$$

$$\mathcal{P} \to \mathcal{V} : PK_\kappa, tr_\kappa, tr_{\alpha_t} \tag{66}$$

$$\mathcal{V} \; verify \; inputs: \tag{67}$$

$$P_t = (\prod_{i=1}^{l} P_i^{k^i}) \cdot PK_\kappa \in \mathbb{G} \tag{68}$$

$$t = \sum_{i=1}^{l} a_i' k^i \in \mathbb{Z}_p \tag{69}$$

$$PK_{\alpha_t} = P_t/g^t \tag{70}$$

$$\textbf{if } VerifyDL(h, PK_\kappa, tr_\kappa), \tag{71}$$

$$\textbf{and } VerifyDL((h/g^x), PK_{\alpha_t}, tr_{\alpha_t}), \textbf{ then } accept \tag{72}$$

$$\textbf{else } reject \tag{73}$$

Protocol 1

**Theorem 1.** *(Zero Knowledge Argument with Practical Succinctness). The proof system presented in this section has perfect completeness, perfect special honest verifier zero-knowledge, and computational witness extended emulation.*

The proof for Theorem 1 is presented in Appendix A.

The main idea of Protocol 1 is to convert commitments $P_i$ to its linear polynomial form $a_i'$ so that the verifier can just take linear polynomials as input values to the circuit and use standard integer operations to compute the circuit. The computation result $o$ is a polynomial with $m_p+1$ degree, where $m_p$ is the total number of multiplications included in the path leads to circuit output. By subtracting out all term with degree greater than 2 as in equation 15 explained, the verifier will get the scalar value in linear polynomial form that maps to commitment $R$.

## 4   Input Transformation Based Efficient Zero Knowledge Argument with Practical Succinctness

Protocol 1's prover isn't efficient because $O(m_p{}^2)$ field operations in prover work can become expensive as $m_p$ gets big. In this section, we introduce a mechanism that allows us to use the number theoretic transform (NTT) to cut prover's field operation work to $m_p \log m_p$.

### 4.1   Using Number Theoretic Transform to Improve Prover Performance in Field Operations

The objective of NTT is to multiply two polynomials such that the coefficients of the resultant polynomials are calculated under a particular modulo in $m_p \log m_p$, a major improvement over $m_p{}^2$ runtime in protocol 1. However, a major drawback of NTT is that it normally requires a prime modulo $q$ of the form $q = r \cdot 2^k + 1$ to be the order of the group, where $k$ and $c$ are arbitrary constants. Since the order of widely used $\mathbb{G}$ in cryptography is usually not a prime with the aforementioned form, we need a mechanism to map linear polynomials with a prime modulo $q$ that satisfies the aforementioned form to any group with prime order $p$. $q$ is expected to be smaller than $p$ because: 1) computation in $p$ (e.g.

polynomial commitment evaluation) won't overflow 2) lower communication cost. In our benchmark testing, we set $q$ to a 62-bit number.

We redefine equation 3 s.t. $a_i'$ and its blinding key $\alpha_i$ are now in field $q$ instead of the larger field $p$.

$$a_i' = a_i + x\alpha_i \in \mathbb{Z}_q \qquad i = \{1, ..., l\} \tag{74}$$

We define a new blinding key $\omega_i \in \mathbb{Z}_p$ and mix that with blinding key $v_i$ in $P_i$ and its matching $\alpha_i$ in $a'$ to create $S_i, T_i$.

$$S_i = g^{\omega_i \cdot q} \in \mathbb{G} \qquad i = \{1, ..., l\} \tag{75}$$

$$T_i = g^{v_i - \alpha_i} \in \mathbb{G} \qquad i = \{1, ..., l\} \tag{76}$$

The prover then sends $S_i, T_i$ for $i = \{1, .., l\}$ to the verifier. When the challenge $x \in \mathbb{Z}_q$ is available, the prover sends $e_i$ s.t.:

$$e_i = ((x\alpha_i \bmod q) - x\alpha_i) \cdot x + \omega_i \cdot q \qquad i = \{1, ..., l\} \tag{77}$$

$e_i$ is not in $\mathbb{Z}_p$, but it is a good idea to keep $e_i$ smaller than $p$ to keep the communication cost low. The idea here is that when we subtract $e_i$ from $a_i$, we can subtract out the blinding modulo $q$ element $(x\alpha_i \bmod q)$ from $a_i'$ (e.g. $a_i' \cdot x - e_i = (a_i + x\alpha_i) \cdot x - \omega_i q$). The verifier can replace $x^2 \alpha_i - \omega_i q$ part with the new blinding element $x^2 v_i$ as the exponent of generator $g$ by adding the previously committed values $S_i, T_i$.

$$g^{a_i' \cdot x - e_i} \cdot T_i^{x^2} \cdot S_i = (g^x)^{a_i + x v_i} \in \mathbb{G} \qquad i = \{1, ..., l\} \tag{78}$$

With $(g^x)^{a_i + x v_i}$ available, the verifier can trivially divide each $P_i$ and taking their sum with powers of $k$ to get $PK_{v_t}$.

$$PK_{v_t} = \prod_{i=1}^{l} \left( \frac{P_i^x}{g^{a_i' \cdot x - e_i} \cdot T_i^{x^2} \cdot S_i} \right)^{k^i} \in \mathbb{G} \tag{79}$$

$PK_{v_t} = (h^x / g^x)^{v_t}$. The verifier can confirm the correctness of the transformation except with negligible probability if the prover can prove the knowledge of $v_t$ on generator $(h^x / g^x) \in \mathbb{G}$.

Finally, the verifier needs to make sure $e_i$ doesn't alter the value of $a_i$. This can be done by taking the modulus $q$ of $e_i$ and checking if it returns 0. This is trivial to understand since $a_i'$ is in $\mathbb{Z}_q$. If $e_i$ is a multiple of $q$ then it is obvious that it cannot alter the value of $a_i$.

$$\textbf{if } (e_i \bmod q) == 0, \textbf{ then } continue \tag{80}$$

$e_i$ does not leak any information to the verifier either. This is because the first part of $e_i$: $((x\alpha_i \bmod q) - x\alpha_i) \cdot x$ is a multiple of $q$, which is also equivalent to $s \cdot q$ for some $s$. $s$ value is perfectly hiding with the blinding term $w \cdot q$ in $e_i$.

We have so far skipped the overflow problem. If $a_i + (x\alpha_i \bmod q) > q$, then we will have an overflow problem in equation 78 79 when computing $a_i' \cdot x - e_i$. To get around this the prover simply needs to check if $a_i + (x\alpha_i) \bmod q$ overflows $q$, and subtracts $q \cdot x$ from $e_i$ if that's the case.

$$\textbf{if } a_i + (x\alpha_i \bmod q) > q, \textbf{ then } e_i = e_i - q \cdot x \qquad i = \{1, ..., l\} \tag{81}$$

We now merge the NTT conversion code introduced in this section and formally define the efficient version of our protocol in Protocol 2.

$$Input : (\vec{P} \in \mathbb{G}^n, g, h, u \in \mathbb{G}, \vec{a} \in \mathbb{Z}_p^l, v \in \mathbb{Z}_{p-q}) \tag{82}$$

$$\mathcal{P}'s\,input : (\vec{P}, g, h, u; \vec{a}, v) \tag{83}$$

$$\mathcal{V}'s\,input : (\vec{P}, g, h, u) \tag{84}$$

$$\mathcal{P}\,compute : \tag{85}$$

$$\alpha_i \xleftarrow{\$} \mathbb{Z}_p, \qquad i = \{1, ..., l\} \tag{86}$$

$$\omega_i \xleftarrow{\$} \mathbb{Z}_p, \qquad i = \{1, ..., l\} \tag{87}$$

$$r, \varepsilon, \vec{\tau} = computeKeys(equation, \vec{a}, \vec{\alpha}) \in \mathbb{Z}_p^{m_p+2} \tag{88}$$

$$R = g^r h^\varepsilon \in \mathbb{G} \tag{89}$$

$$tr_\epsilon = ((h/g^x), \epsilon) \tag{90}$$

$$C = \prod_{i=1}^{m_p} g_i^{\tau_i} \in \mathbb{G} \tag{91}$$

$$S_i = g^{\omega_i \cdot q} \in \mathbb{G} \qquad i = \{1, ..., l\} \tag{92}$$

$$T_i = g^{v_i - \alpha_i} \in \mathbb{G} \qquad i = \{1, ..., l\} \tag{93}$$

$$\mathcal{P} \to \mathcal{V} : \vec{S}, \vec{T}, C, R, tr_\epsilon \tag{94}$$

$$\mathcal{V}\,compute : \tag{95}$$

$$x \xleftarrow{\$} \mathbb{Z}_p \tag{96}$$

$$\mathcal{V} \to \mathcal{P} : x \tag{97}$$

$$\mathcal{P}\,compute : \tag{98}$$

$$a_i' = a_i + x\alpha_i \in \mathbb{Z}_q \qquad\qquad i = \{1, ..., l\} \tag{99}$$

$$e_i = ((x\alpha_i \bmod q) - x\alpha_i)x + \omega_i q \in \mathbb{Z}_p \qquad i = \{1, ..., l\} \tag{100}$$

$$\textbf{if } a_i + (x\alpha_i \bmod q) > q, \textbf{ then } e_i = e_i - q \cdot x \qquad i = \{1, ..., l\} \tag{101}$$

$$\mathbf{else}\ reject \tag{124}$$

<div align="center">Protocol 2</div>

**Theorem 2.** *(Efficient Zero Knowledge Protocol for Arbitrary Circuit with Practical Succinctness). The proof system presented in this section has perfect completeness, perfect special honest verifier zero-knowledge, and computational witness extended emulation.*

The proof for Theorem 2 is presented in Appendix B.

Since we are now evaluating the output polynomial at a smaller field $q$, the soundness error is increased due to existence of polynomial roots. The NTT acceptable prime we use in our implementation is $q = 1945555039024054273$, where $r = 27, k = 56, g = 5$ s.t. $q = r * 2^k + 1$. For a circuit with $2^20$ sequential multiplications ($m_p = n$), the soundness error is at most $2^{-41}$, acceptable in most real-life use cases.

Using the polynomial commitment evaluation protocol defined by Bootle et. al, the prover runtime of the complete version (Protocol 2) of our protocol is dominated by $O(m_p \log m_p + m_p + l)$ field operations and $O(m_p + m_p^{1/2} + l + l^{1/2})$ group exponentiations; the verifier runtime is dominated by $O(n + m_p^{1/2} + l + l^{1/2})$ field operations and $O(m_p^{1/2} + l^{1/2} + l)$ group exponentiations; and the communication cost is dominated by $O(m_p^{1/2} + l + l^{1/2})$ group elements and $O(m_p^{1/2} + l + l^{1/2})$ field elements.

The worst possible scenario for our protocol is when we have a sequence of multiplications where both multiplier and multiplicand are the product of the previous multiplication operation (e.g. $((a^2)^2)^2$ is technically 3 multiplications, but it will result in $m_p = 2^3$), in such case $m_p$ will grow exponentially. One way to tackle such problem is to break the circuit into segments of smaller sub-circuits so that $m_p$ value will be refreshed whenever it grows oversize, similar to the idea of bootstrapping in fully homomorphic encryption. One area worth investigate is whether we can batch process this bootstrapping technique so that the polynomial commitment(s) we need to evaluate is not linear to the number of sub-circuits.

## 5 Input Transformation Based Efficient Zero Knowledge Argument For Arbitrary Circuits With Practical Succinctness

The efficiency of protocol 2 introduced in the last section degrades as the total number of multiplications in the path computing the output ($m_p$ value) gets larger, a not-so-uncommon scenario for circuits with high depth. One potential way to get around this problem is to have $m_b$ number of breakers so that the number of polynomial terms will never exceed $b$, where $b = \frac{m_p}{m_b}$ (instead of just one breaker at term $m_p$ as in Protocol 2).

### 5.1 Batch Verification With Multiple Breakers

Each breaker $y_i$ is an evaluation at point $x$ for terms $x^2, ..., x^{b+1}$ of the polynomial accumulated thus far in the computation. Obviously, it is not efficient for us to commit and evaluate $m$ number of polynomials, where $m$ stands for the number of breakers we use to evaluate a circuit.

Fortunately, we just need to a little modification the polynomial commitment evaluation protocol defined by Bootle et al. to enable the prover and verifiers to evaluate $m_b$ breakers at once. We start by aligning each breaker $y_i$ to the coefficients of vector commitments (columns of the $m_b \times b$ matrix).

$$
\begin{matrix}
g_1^{y_1'} \\
g_2^{y_2'} \\
g_3^{y_3'} \\
. \\
. \\
g_{m_b}^{y_{m_b}'}
\end{matrix}
=
\begin{pmatrix}
g_1^{\tau_{1,1}} & g_1^{\tau_{1,2}} & . & . & g_1^{\tau_{1,b}} \\
g_2^{\tau_{2,1}} & g_2^{\tau_{2,2}} & . & . & g_2^{\tau_{2,b}} \\
g_3^{\tau_{3,1}} & g_3^{\tau_{3,2}} & . & . & g_3^{\tau_{3,b}} \\
. & . & . & . & . \\
. & . & . & . & . \\
g_{m_b}^{\tau_{m_b,1}} & g_{m_b}^{\tau_{m_b,2}} & . & . & g_{m_b}^{\tau_{m_b,b}}
\end{pmatrix}
\begin{pmatrix}
x^2 \\
x^3 \\
x^4 \\
. \\
. \\
x^{b+1}
\end{pmatrix}
$$

Figure 1

Let $y_i = (y_i') \bmod q$, we can observe from figure 1 that each $y_i'$ can be computed from the sum of products of exponents of $g_i$ (e.g. $y_i' = \tau_{i,1}x^2 + \tau_{i,2}x^3 + ... + \tau_{i,b}x^{b+1}$).

In our protocol, the prover commits to the columns of the matrix in figure 1 like that in Bootle et al.'s polynomial commitment evaluation scheme.

$$
C_j = \prod_{i=1}^{m_b} g_i^{\tau_{i,j}} \qquad \text{for} \qquad j = \{1, ..., b\} \tag{125}
$$

When the evaluation point $x$ is known, the verifier computes the powers of $x$ and multiplies them to the exponent of each $C_j$. If the equality below is true, all breakers are verified.

$$
\prod_{i=1}^{m_b} g_i^{y_i'} \stackrel{?}{=} \prod_{j=1}^{b} C_j^{x^{j+1}} \tag{126}
$$

Note that if each $x^{j+1} \in \mathbb{Z}_q$ and $\tau_{i,j} \in \mathbb{Z}_q$ and each breaker $y_i'$ is equal to the sum of products of $b$ terms, then we have $|y_i'| \approx |q| + |q| + |b|$. $y_i'$ can also be expressed as $y_i' = y_i + z \cdot q$ for some $z$ and $|z| \approx |q| + |b|$. Passing raw $y_i'$ values to the verifier may leak some information about the coefficients.

To cope with that, we make the prover commit to a blinding vector $\vec{\beta} \in \mathbb{Z}_z^m$ s.t. each $y_i'$ is now computed as:

$$
y_i' = \sum_{j=1}^{b} \tau_{i,j}x^{j+1} + q \cdot \beta_i \qquad \text{for} \qquad i = \{1, ..., m_b\} \tag{127}
$$

The value of $y_i$ is not being altered after applying mod q to $y_i'$ since $(q \cdot \beta_i) \bmod q = 0$ for any $\beta_i$. The updated equality graph is shown in figure 2 below.

$$
\begin{pmatrix} g_1^{y_1'} \\ g_2^{y_2'} \\ g_3^{y_3'} \\ \cdot \\ \cdot \\ g_{m_b}^{y_{m_b}'} \end{pmatrix}
=
\begin{pmatrix}
g_1^{\tau_{1,1}} & g_1^{\tau_{1,2}} & \cdot & \cdot & g_1^{\tau_{1,b}} \\
g_2^{\tau_{2,1}} & g_2^{\tau_{2,2}} & \cdot & \cdot & g_2^{\tau_{2,b}} \\
g_3^{\tau_{3,1}} & g_3^{\tau_{3,2}} & \cdot & \cdot & g_3^{\tau_{3,b}} \\
\cdot & \cdot & \cdot & \cdot & \cdot \\
\cdot & \cdot & \cdot & \cdot & \cdot \\
g_{m_b}^{\tau_{m_b,1}} & g_{m_b}^{\tau_{m_b,2}} & \cdot & \cdot & g_{m_b}^{\tau_{m_b,b}}
\end{pmatrix}
\begin{pmatrix} x^2 \\ x^3 \\ x^4 \\ \cdot \\ \cdot \\ x^{b+1} \end{pmatrix}
\cdot
\begin{pmatrix} g_1^{\beta_1} \\ g_2^{\beta_2} \\ g_3^{\beta_3} \\ \cdot \\ \cdot \\ g_{m_b}^{\beta_{m_b}} \end{pmatrix}^q
$$

<center>Figure 2</center>

Let $B = \prod_{i=1}^{m_b} g_i^{\beta_i}$, the equality in figure 2 can also be expressed using the equation below:

$$
\prod_{i=1}^{m_b} g_i^{y_i'} \stackrel{?}{=} \prod_{j=1}^{b} C_j^{x^{j+1}} \cdot B^q \tag{128}
$$

If the commitments $\vec{C}, B$ and vector $\vec{y}$ satisfy the equation above with a challenge $x$, then we know all the breakers $\vec{y}$ are valid. The verifier applies mod $q$ to each $y_i'$ to get the actual breakers $y_i$ used in computing $o$.

$$
y_i = (y_i') \bmod q \in \mathbb{Z}_q \qquad \text{for} \qquad i = \{1, ..., m_b\} \tag{129}
$$

We are now ready to introduce Protocol 3, which replaces the generic polynomial commitment evaluation in Protocol 2 with the multi-breaker mechanism we introduced in this section.

$$

Protocol 3

**Theorem 3.** *(Efficient Zero Knowledge Argument for Arbitrary Circuits with Practical Succinctness). The proof system presented in this section has perfect completeness, perfect special honest verifier zero-knowledge, and computational witness extended emulation.*

The proof for Theorem 3 is presented in Appendix C.

From line 154 to 158 in protocol 3 we assumed our circuit is a linear circuit where there is only one path because it is easy to model. In practice, binary circuits generally have multiple "bit" paths that executes in parallel.

## 5.2 Booleanity Check and Bit Decomposition/Reposition

A common occurrence in proof systems is the need to enforce input data $a_i \in \{0,1\}$ for some $i \in \{1, ..., l\}$. In practice, it is useful to decompose $l$ full integer inputs into $l \cdot 32$ bits (assuming we use 32 bits to represent a full integer, like the int type in Java) in order to perform comparison operations on input data. If a committed value $a_i$ is in $[0,1]$, then its linear polynomial form $a_i$ must have the following property:

$$(a_i' \cdot a_i' - a_i') = \beta_1 x + \beta_2 x^2 \tag{176}$$

Where $\beta_2 = \alpha^2$, and $\beta_1 = \alpha$ when $a_j$ is 1 and $\beta_1 = -\alpha$ when $a_j$ is 0. To prove the correctness for all $a_i \in \{0,1\}$, the prover commits to two polynomials $K_1, K_2$ s.t.

$$K_1 = u_1^{\beta_{1_1}} u_2^{\beta_{1_2}} ... u_l^{\beta_{1_l}} h^{\rho_1} \qquad and \qquad K_2 = u_1^{\beta_{2_1}} u_2^{\beta_{2_2}} ... u_l^{\beta_{2_l}} h^{\rho_2} \tag{177}$$

Where $K_1$ commits to coefficients on $x$ term for $i \in \{1, ..., l \cdot 32\}$ and $K_2$ commits to coefficients on $x^2$ term for $i \in \{1, ..., l \cdot 32\}$. The prover sends $K_1, K_2$ to the verifier. When the challenge $k$ is received, the prover sends the evaluation results $y_1, y_2$ to the verifier, and the verifier uses the polynomial commitment protocol to verify the correctness of $y_1, y_2$ at point $k$, and checks if the equality below is true:

$$y_1 \cdot x + y_2 \cdot x^2 = \sum_{j=1}^{l \cdot 32} (a_i' \cdot a_i' - a_i') \cdot k^i \tag{178}$$

Once we know all linear polynomials maps to either 0 or 1, it is trivial to recompose the linear polynomial form of a full integer input $a_i'$ from 32 decomposed bits $a_{i,j}'$ for $j = \{1, ..., 32\}$.

$$a_i' = \sum_{j=1}^{32} a_{i,j}' \cdot 2^j \tag{179}$$

In practice, we will conduct booleanity test on all $l \cdot 32$ bit values at once and then use equation 179 to convert them to $l$ full integer values so that we can perform the "linear polynomial to Pedersen commitment" mapping test explained in the last two sections.

# 6 Performance Comparison

We compare the performance of our protocol to some of the most popular transparent Zero Knowledge Protocols that open source codes are available. Our test runs are performed on Intel(R) Core(TM) i7-9750H CPU @ 2.60 Ghz. Only one core is being utilized, and all tests are run on a single CPU thread.

The baseline protocols we picked are Hyrax, Ligero, Aurora, and Spartan-NIZK. These protocols are chosen because they are the most representative of popular zero-knowledge protocols and can be verified with open source code. In particular, Aurora outperforms STARK in all key parameters (prover runtime, verifier runtime, proof size), and Spartan offers the most balanced performance across all performance parameters.

We didn't consider transparent protocols that highly depend on circuit depth such as GKR based protocols simply because they can't handle $2^{20}$ sequential multiplications. We also don't consider VOLE based protocols as they are only optimized for prover work. Other popular transparent schemes such as Bulletproofs are also not being considered because they have linear verifier runtime and therefore are not succinct.

Spartan++ and Lakonia are two more recent developments that we didn't include in our benchmark testing but are worth mentioning. The improvement of Spartan++ over SpartanNIZK is marginal, and the performance of Lakonia is largely comparable to that of SpartanNIZK (the prover performance of SpartanNIZK is approximately 3X more efficient, and the verifier performance is 1.5X more efficient than that of Lakonia, while Lakonia is 4X more efficient than SpartanNIZK in proof size).

We set inputs to 20 integers, and each input is represented by 32 bits so that there are a total of $20 \cdot 32 = 640$ input bits to the circuit. The performance of our protocol correlates with the total number of multiplications included in the path leads to the circuit output. The random circuit we use is to perform $n$ sequential multiplications on $l$ inputs, so we set $m_p = n$.

The NTT acceptable prime number we picked for our benchmark testing is $q = 1945555039024054273$, a 61-bit number that implies the soundness error will be at most $2^{-41}$ for a circuit with $2^{20}$ sequential multiplications where $m_p = n$, more than enough in most real-life applications.

To maximize the advantage of the NTT algorithm in computing sequential multiplications, we arrange our circuit in binary tree format, such tuning may not be required in real-world applications since large circuits should have multiplication gates somewhat balanced out across layers.

For group operations, we use curve25519-dalek implementation, and Pippenger acceleration is applied to all sum-of-product group operations. For field operations, we use Montgomery algorithm to accelerate modular multiplications on the 61-bit NTT prime $q$.

| Circuit size | $2^{10}$ | $2^{12}$ | $2^{14}$ | $2^{16}$ | $2^{18}$ | $2^{20}$ |
|---|---|---|---|---|---|---|
| Hyrax | 1 | 2.8 | 9 | 36 | 117 | 486 |
| Ligero | 0.1 | 0.4 | 1.6 | 4 | 17 | 69 |
| Aurora | 0.5 | 1.6 | 6.5 | 27 | 116 | 485 |
| SpartanNIZK | 0.02 | 0.05 | 0.16 | 0.6 | 1.7 | 6 |
| This Work($m_p = n$) | 0.6 | 0.8 | 1 | 1.5 | 2.7 | 6 |

Table 1: Prover performance comparison (seconds)

Table 1 shows that as the circuit size gets bigger, the prover performance of our protocol is becoming increasingly more efficient than all of our baseline protocols. SpartanNIZK seems to match that of our for circuits with $2^{20}$ constraints (which will also diminish as the circuit grows bigger) when compared to the worst case scenario version of our protocol ($m_p = n$) . However, this is not a fair comparison in our favor since we're comparing $2^{20}$ constraints in SpartanNIZK with the unlikely scenario of $2^{20}$ sequential multiplications in that of our protocol. Furthermore, our protocol doesn't use a constraint system; savings from eliminating copy constraints and constraint system encoder will likely further boost the actual performance of our protocol

Table 2 shows that the communication cost of our protocol dominates that of Ligero and Aurora, while largely comparable to SpartanNIZK and Hyrax. For higher input number counts, see Table 4 for more detail.

We can observe from table 1-2 that our protocol is largely comparable to the current state of art in prover runtime and communication cost. Table 3 demonstrates that our protocol achieves significant improvement by at least one order of magnitude in verifier runtime over all baseline protocols we are

| Circuit size | $2^{10}$ | $2^{12}$ | $2^{14}$ | $2^{16}$ | $2^{18}$ | $2^{20}$ |
|---|---|---|---|---|---|---|
| Hyrax | 14 | 17 | 21 | 28 | 38 | 58 |
| Ligero | 546 | 1,076 | 2,100 | 5,788 | 10,527 | 19,828 |
| Aurora | 477 | 610 | 810 | 1,069 | 1,315 | 1,603 |
| SpartanNIZK | 9 | 12 | 15 | 21 | 30 | 48 |
| This Work($m_p = n$) | 12 | 14 | 16 | 23 | 35 | 59 |

Table 2: Proof size comparison (kilobytes)

| Circuit size | $2^{10}$ | $2^{12}$ | $2^{14}$ | $2^{16}$ | $2^{18}$ | $2^{20}$ |
|---|---|---|---|---|---|---|
| Hyrax | 206 | 253 | 331 | 594 | 1.6s | 8.1s |
| Ligero | 50 | 179 | 700 | 2s | 7.5s | 33s |
| Aurora | 192 | 590 | 2s | 7.2s | 29.8s | 118s |
| SpartanNIZK | 7 | 11 | 17 | 36 | 103 | 387 |
| This Work($m_p = n$) | 8 | 9 | 10 | 13 | 17 | 25 |

Table 3: Verifier performance comparison (milliseconds)

comparing against. Like that of communication cost, the verifier runtime of our protocol will grow when the number of inputs to the protocol grows.

Some may consider 20 integer inputs and 640 input bits to a circuit too small, so in table 4 we list performance benchmarks for different number of inputs ($l$) to a circuit with $2^{20}$ multiplications.

| Input bits ($l \cdot 32$) | Input Integers ($l$) | Prover time(s) | Verifier time(ms) | Proof size(kb) |
|---|---|---|---|---|
| 960 | 30 | 6 | 23 | 63 |
| 1,280 | 40 | 6 | 23 | 67 |
| 1,600 | 50 | 6.1 | 24 | 71 |
| 1,920 | 60 | 6.1 | 24 | 76 |
| 2,240 | 70 | 6.1 | 25 | 80 |
| 2,560 | 80 | 6.1 | 26 | 84 |
| 2,880 | 90 | 6.1 | 27 | 87 |
| 3,200 | 100 | 6.2 | 28 | 91 |

Table 4: Performance comparison for different input numbers on circuits with $2^{20}$ multiplications and $m_p = \frac{n}{32}$

In table 4 we can observe that increases in prover runtime and verifier runtime are hardly noticeable as the input bits count approaching $3,200$. This is because the total input number is still small compared to the size of the circuit ( $2^{20}$ sequential multiplications ). Communication cost gets impacted the most as the input count gets higher. This is because the prover have to send $l \cdot 32$ linear polynomials to the verifier. Technically speaking, more inputs usually implies lower circuit depth and less complex business logic.

## Appendiex

### A. Proof for Theorem One

*Proof.* Perfect completeness follows from the fact that Protocol 1 is trivially complete. To prove perfect honest-verifier zero-knowledge, we define a simulator $\mathcal{S}$ to show that protocol 1 has perfect special honest verifier zero-knowledge for relation 2. $\mathcal{S}$ uses simulator $\mathcal{S}_S$ to simulate proof transcripts for

proof of knowledge (or proof of discrete logarithm) protocols, and simulator $\mathcal{S}_p$ to simulate proof transcripts for polynomial commitment evaluation function PolyCommitEval.

Simulator $\mathcal{S}$ generates random group elements for $C, R$, proof of knowledge transcript $tr_\epsilon$. After receiving challenge $x$ from the verifier, the simulator generates $l$ random integers to represent linear polynomials $\vec{a}'$ and one random integer to represent $y$ and sends them to the verifier.

The verifier follows the protocol to compute $PK_\epsilon$, then simulator $\mathcal{S}$ calls simulator $\mathcal{S}_S$ to interact with the verifier and generate all necessary transcripts to prove it knows the value of $\epsilon$. This makes sense since we already know for a fact that schnorr and many other proof of knowledge protocols have perfect special honest verifier zero-knowledge. Similarly, the simulator $\mathcal{S}$ calls simulator $\mathcal{S}_P$ to simulate the transcripts for proving $y$ is the evaluated value at point $x$ for polynomial commitment $C$.

The simulator then simulates the transcripts to prove it knows $\alpha_t$ and $\kappa$. The simulator simply sends randomly generated $PK_\kappa$ and random transcripts for $tr_\kappa$ and $tr_{\alpha_t}$, and calls simulator $\mathcal{S}_S$ to simulate transcripts needed to prove the knowledge of $\kappa$ and $\alpha_t$.

Simulator $\mathcal{S}$ chooses all proof elements and challenges according to the randomness supplied by the adversary from their respective domains or computes them directly as described in the protocol. Since all elements in proof transcripts are either independently randomly distributed or their relationship is fully defined by the verification equations, we can conclude that protocol 1 has perfect special honest verifier zero-knowledge.

To prove computational witness extended emulation, we construct an extractor $\mathcal{X}$, which uses extractor $\mathcal{X}$ to extract witnesses from proof of knowledge transcripts and extractor $\mathcal{X}$ to extract witnesses from polynomial commitments.

We validate the soundness of Protocol 1 in three steps. First, we show how to construct an extractor $\mathcal{X}$ for Protocol 1 s.t. on input $\vec{P} \in \mathbb{G}^l, R \in \mathbb{G}$, it either extracts witnesses $r, \epsilon, \vec{\tau}$ for relation 2, or discovers a non-trivial discrete logarithm relation among $g, h, \vec{u} \in \mathbb{G}$. Next, we show that the extractor $\mathcal{X}$ either extracts witnesses $\vec{a}, \vec{v}$ s.t. $\vec{v}$ maps to $\vec{\alpha}$ or discovers a non-trivial discrete logarithm relation between $g, h \in \mathbb{G}$. Finally, we validate the proof by checking if $r, \epsilon, \vec{\tau}$ can be computed from witnesses $\vec{a}, \vec{\alpha}$.

To begin, extractor $\mathcal{X}$ interacts with the prover in the same way as any verifier would and receives $C, R, tr_\epsilon$ from the prover.

Extractor $\mathcal{X}$ then generates a challenge $x_1$ and forwards it to the prover. After receiving $\vec{a}'_1, y_1$, the extractor rewinds the prover and sends another challenge $x_2$ to retrieve $\vec{a}'_2, y_2$.

The extractor then follows the protocol and computes $o$ and $PK_\epsilon$, then calls extractor $\mathcal{X}_S$ to extract $\epsilon$ from $tr_\epsilon$ and $PK_\epsilon$. With either $x_1$ or $x_2$, we can trivially retrieve $r, \epsilon$ from $r'$ since $r' = r + x \cdot \epsilon$, and validate if $R = g^r h^\epsilon$. To validate if $r, \epsilon$ is correctly computed from the circuit, extractor $\mathcal{X}$ calls extractor $\mathcal{X}_P$ to retrieve set $\vec{\tau}$ from polynomial commitment $C$.

We have now retrieved witnesses $r, \epsilon, \vec{\tau}$ using the prover committed values $C, R, tr_\epsilon$, and we know for a fact that $o$ must also be computed from $\vec{a}, \vec{\alpha}$ and evaluation point $x$ since:

$$o = r + \epsilon \cdot x + \sum_{i=1}^{n} \tau_i \cdot x^{i+1} \tag{180}$$

If the prover is honest, $r, \epsilon, \vec{\tau}$ must be computed by the prover from witnesses $\vec{a}, \vec{\alpha}$

Next, we validate if witnesses of $\vec{a}'$ used in computing $o$ maps to $\vec{a}, \vec{v}$ in $\vec{P}$ by checking if we can extract these witnesses. With $\vec{a}'_1$ and $\vec{a}'_2$ extractor $\mathcal{X}$ retrieved earlier, we can trivially retrieve $\vec{a}, \vec{\alpha}$ since for all $i = \{1, ..., l\}$ we have:

$$a'_{1_i} - a'_{2_i} = \alpha_i(x_1 - x_2)$$

We can extract witnesses $\vec{a}, \vec{v}$ using $\vec{a}'$ and input commitments $\vec{P}$. The extractor first generates $k_1$ and then follows the protocol to get $PK_{\kappa_1}, tr_{\kappa_1}, PK_{\alpha_{t1}}, tr_{\alpha_{t1}}$ from the prover. The extractor then calls

extractor $\mathcal{X}_S$ to retrieve $\kappa_1$ and $\alpha_{t1}$. Rewind and repeat this procedure for another $l$ times to retrieve $\kappa_2, ..., \kappa_{l+1}$ and $\alpha_{t2}, ..., \alpha_{tl+1}$ using evaluation points $k_2, ..., k_{l+1}$.

Through interpolation technique the extractor retrieves $(\alpha_i - v_i)$ and $\alpha_i$ for $i$ in $\{1, ..., l\}$. With these information, we can now trivially compute $\vec{v}$ and verify if they can be mapped $\vec{P}$ s.t. $P_i = g^{a_i} h^{v_i}$ unless we found a non-trivial relationship among generators $g, h$.

Finally, we must be able to re-compute witnesses $r, \epsilon, \vec{\tau}$ from $\vec{a}, \vec{\alpha}$ for equality 180 to be true except for a negligible probability or we found a non-trivial relationship among generators $g, h, \vec{u}$. We can therefore conclude Protocol 1 has computational witness extended emulation.

## B. Proof for Theorem Two

*Proof.* Perfect completeness follows from the fact that Protocol 2 is trivially complete. To prove perfect honest-verifier zero-knowledge, we define a simulator $\mathcal{S}$ to show that protocol 2 has perfect special honest verifier zero-knowledge for relation 2. $\mathcal{S}$ uses simulator $\mathcal{S}_S$ to simulate proof transcripts for proof of knowledge (discrete logarithm) protocols, and simulator $\mathcal{S}_p$ to simulate proof transcripts for polynomial commitment evaluation function PolyCommitEval.

The simulator $\mathcal{S}$ generates random group elements for $\vec{S}, \vec{T}, C, R$, proof of knowledge transcript $tr_\epsilon$. After receiving challenge $x$ from the verifier, the simulator generates $l$ random integers to represent $\vec{e}$, $l$ random integers to represent $\vec{a}'$, and one random integer to represent $y$ and sends them to the verifier.

The simulator follows the protocol to compute $o$ and $PK_\epsilon$, then the simulator $\mathcal{S}$ calls simulator $\mathcal{S}_S$ to interact with the verifier and randomly generate all necessary transcripts to prove it knows the value of $\epsilon$. This makes sense since we already know for a fact that schnorr and many other proof of knowledge protocols have perfect special honest verifier zero-knowledge. Similarly, the simulator $\mathcal{S}$ also calls simulator $\mathcal{S}_P$ to simulate transcripts for proving $y$ is the evaluated value at point $x$ for polynomial commitment $C$.

Next, simulator $\mathcal{S}$ simulates transcripts for proving the mapping from $\vec{a}'$ to $\vec{P}$. After challenge $k$ is received from the prover, the simulator follows the protocol to compute $PK_{v_t}$, then calls simulator $\mathcal{S}_S$ to simulate transcripts needed to prove knowledge of $v_t$.

The simulator chooses all proof elements and challenges according to the randomness supplied by the adversary from their respective domains or computes them directly as described in the protocol. Since all elements in proof transcripts are either independently randomly distributed or their relationship is fully defined by the verification equations, we can conclude that protocol 2 is perfect special honest verifier zero-knowledge.

To prove computational witness extended emulation, we construct an extractor $\mathcal{X}$, which uses extractor $\mathcal{X}$ to extract witnesses from proof of knowledge transcripts and extractor $\mathcal{X}$ to extract witnesses from polynomial commitment $C$.

Like that of Protocol 1, we validate the soundness of Protocol 2 in three steps. First, we show how to construct an extractor $\mathcal{X}$ for Protocol 2 s.t. on input $\vec{P} \in \mathbb{G}^l, R \in \mathbb{G}$, it either extracts witnesses $r, \epsilon, \vec{\tau}$ for relation 2, or discovers a non-trivial discrete logarithm relation among $g, h, \vec{u} \in \mathbb{G}$. Next, we show that the extractor $\mathcal{X}$ either extracts witnesses $\vec{a}, \vec{v}$ s.t. $\vec{v}$ maps to $\vec{\alpha}$ or discovers a non-trivial discrete logarithm relation between $g, h \in \mathbb{G}$. Finally, we validate the proof by checking if $r, \epsilon, \vec{\tau}$ can be computed from witnesses $\vec{a}, \vec{\alpha}$.

First, the extractor $\mathcal{X}$ interacts with the prover in Protocol 2 and receives $\vec{S}, \vec{T}, C, R, tr_\epsilon$ from the prover. The extractor $\mathcal{X}$ then generates a challenge $x_1$ and forward it to the prover. After receiving $\vec{e}_1, \vec{a}'_1, y_1$, the extractor rewinds the prover and sends another challenge $x_2$ to receive $\vec{e}_2, \vec{a}'_2, y_2$.

The extractor then follows the protocol and calls extractor $\mathcal{X}_S$ to extract $\epsilon$ from $tr_\epsilon$ and $PK_\epsilon$. With either $x_1$ or $x_2$, we can trivially retrieve $r$ from $r'$ since $r' = r + x \cdot \epsilon$ and validate $R = g^r h^\epsilon$.

Likewise, the extractor $\mathcal{X}$ calls extractor $\mathcal{X}_P$ using either $x_1, y_1$ or $x_2, y_2$ pair to retrieve coefficient set $\vec{\tau}$ from polynomial commitment $C$. Like that of Protocol 1, we can come $o$ from $r, \epsilon$ at any evaluation point $x$ as equality 180 states:

We have now retrieved witnesses $r, \epsilon, \vec{\tau}$ using transcripts $C, R, tr_\epsilon$. If the prover is honest, $r, \epsilon, \vec{\tau}$ are coefficients computed by the prover from $\vec{a}, \vec{\alpha}$, where as $\vec{\alpha}$ maps to blinding keys $\vec{v}$.

Next, we validate if witnesses of $\vec{a}'$ used in computing $o$ maps to $\vec{a}, \vec{v}$ in $\vec{P}$ by checking if we can extract these witnesses. The extractor first generates $k_1$ and then follows the protocol to get $PK_{v_{t1}}, tr_{v_{t1}}$, then calls extractor $\mathcal{X}_S$ to retrieve $v_{t1}$ . The extractor then rewinds and repeats the above step $l$ times to retrieve $v_{t2}, ..., v_{tl+1}$. Through interpolation the extractor retrieves witnesses $v_i$ for all $i$ in $\{1, ..., l\}$. Dividing dividing $P_i$ by $h^{v_i}$ we will get:

$$P_i/h^{v_i} = g^{a_i} \tag{181}$$

Using the two different challenges $x_1, x_2$ we mentioned earlier, the extractor gets $\vec{a}'_1$ and $\vec{a}'_2$ from the prover, which we can trivially retrieve $\vec{a}, \vec{\alpha}$ for all $i = \{1, ..., l\}$ since:

$$a'_{1_i} - a'_{2_i} = \alpha_i(x_1 - x_2)$$

If each $v_i$ maps to each $\alpha_i$, then $a_i$ must be the exponent of $g$ in equality 182 or we found a non-trivial relationship among generators $g, h$.

Finally, we must be able to re-compute witnesses $r, \epsilon, \vec{\tau}$ from $\vec{a}, \vec{\alpha}$ for equality 180 to be true except for a negligible probability or we found a non-trivial relationship among generators $g, h, \vec{u}$. We can therefore conclude Protocol 2 has computational witness extended emulation.

## C. Proof for Theorem Three

*Proof.* Perfect completeness follows from the fact that Protocol 3 is trivially complete. To prove perfect honest-verifier zero-knowledge, we define a simulator $\mathcal{S}$ to show that protocol 3 has perfect special honest verifier zero-knowledge for relation 2. $\mathcal{S}$ uses simulator $\mathcal{S}_S$ to simulate proof transcripts for proof of knowledge (or proof of discrete logarithm) protocols.

The simulator $\mathcal{S}$ generates random group elements to represent $\vec{S}, \vec{T}, \vec{C}, R$, and the proof of knowledge transcript $tr_\epsilon$. After receiving challenge $x$ from the verifier, the simulator generates $l$ random integers to represent $\vec{e}$, $l$ random integers to represent $\vec{a}'$, and $m_b$ random integers to represent breakers $\vec{y}$. The simulator sends them to the verifier.

The simulator follows the protocol to compute $r'$ and $PK_\epsilon$, then the simulator $mathcalS$ calls the simulator $\mathcal{S}_S$ to interact with the verifier and randomly generate all the necessary transcripts to prove it knows the value of $\epsilon$. This makes sense since we already know for a fact that schnorr and many other proof of discrete log protocols have perfect special honest verifier zero-knowledge.

Next, simulator $\mathcal{S}$ simulates transcripts for proving the mapping from $\vec{a}'$ to $\vec{P}$. After challenge $k$ is received from the verifier, the simulator randomly generates $tr_{v_t}$ and then follows the protocol to compute $PK_{v_t}$, then calls the simulator $\mathcal{S}_S$ to simulate transcripts needed to prove knowledge of $v_t$.

The simulator chooses all proof elements and challenges according to the randomness supplied by the adversary from their respective domains or computes them directly as described in the protocol. Since all elements in proof transcripts are either independently randomly distributed or their relationship is fully defined by the verification equations, we can conclude that protocol 3 is perfect special honest verifier zero-knowledge.

To prove computational witness extended emulation, we construct an extractor $\mathcal{X}$, which uses extractor $\mathcal{X}_S$ to extract witnesses from proof of knowledge transcripts.

Like that of Protocol 1 and 2, we validate the soundness of Protocol 3 in three steps. First, we show how to construct an extractor $\mathcal{X}$ for Protocol 3 s.t. on input $\vec{P} \in \mathbb{G}^l, R \in \mathbb{G}$, it either extracts witnesses $r, \epsilon, \vec{\tau}$ for relation 2, or discovers a non-trivial discrete logarithm relation among $g, h, \vec{u} \in \mathbb{G}$. Second, we show that the extractor $\mathcal{X}$ either extracts witnesses $\vec{a}, \vec{v}$ s.t. $\vec{v}$ maps to $\vec{\alpha}$ or discovers a non-trivial discrete logarithm relation between $g, h, \vec{u} \in \mathbb{G}$. Third, we complete validating the proof by checking if $r, \epsilon, \vec{\tau}$ can be computed from witnesses $\vec{a}, \vec{\alpha}$.

In the first step, the extractor $\mathcal{X}$ interacts with the prover in Protocol 3 and receives $\vec{S}, \vec{T}, \vec{C}, R$, $tr_\epsilon$ from the prover. The extractor $\mathcal{X}$ then generates at least $b+3$ challenges $\vec{x}$ and forwards them to the prover. After receiving $\vec{e}_1, \vec{a}_1', \vec{y}_1$, the extractor rewinds and repeats this step $b+2$ times to receive $\vec{e}_2, ..., \vec{e}_{b+3}$, $\vec{a}_2', ..., \vec{a}_{b+3}'$, and $\vec{y}_2, ..., \vec{y}_{b+3}$.

The extractor then follows the protocol and calls extractor $\mathcal{X}_S$ to extract $\epsilon$ from $tr_\epsilon$ and $PK_\epsilon$. With any two challenges $x_i, x_{i+1}$, we can trivially retrieve $r, \epsilon$ since $r' = r + x \cdot \epsilon$, which must match the witness $r, \epsilon$ retrieved from $R = g^r h^\epsilon$ and $PK_\epsilon$ using extractor $\mathcal{X}_S$ except with a negligible probability or discover a non-trivial discrete log relation among generators $g, h \in \mathbb{G}$.

With challenges $x_1, ..., x_{b+3}$ and evaluation (breaker) sets $\vec{y}_1, ..., \vec{y}_{b+3}$, we apply Lagrange polynomial interpolation to retrieve witnesses $\vec{\tau}$, coefficients of commitments $\vec{C}$.

We have now retrieved witnesses $r, \epsilon, \vec{\tau}$ using transcripts $C, R, tr_\epsilon$. If the prover is honest, $r, \epsilon, \vec{\tau}$ are coefficients computed by the prover from $\vec{a}, \vec{\alpha}$, where as $\vec{\alpha}$ maps to blinding keys $\vec{v}$.

In the second step, we validate if witnesses $\vec{a}, \vec{\alpha}$ of $\vec{a}'$ used in computing $o$ map to witnesses $\vec{a}, \vec{v}$ of $\vec{P}$ by checking if we can extract these witnesses and that $\vec{\alpha}$ map to $\vec{v}$. The extractor first generates $k_1$ and then follows the protocol to get $tr_{v_{t1}}, PK_{v_{t1}}$, then calls the extractor $\mathcal{X}_S$ to retrieve $v_{t1}$. The extractor then rewinds and repeats this step $l$ times to retrieve $v_{t2}, ..., v_{tl+1}$. Through interpolation, the extractor retrieves witnesses $v_i$ for all $i$ in $\{1, ..., l\}$. Dividing dividing $P_i$ by $h^{v_i}$ we will get:

$$P_i / h^{v_i} = g^{a_i} \tag{182}$$

Using any two different challenges $x_i, x_{i+1}$ we mentioned earlier, the extractor gets $\vec{a}_1'$ and $\vec{a}_2'$ from the prover, which we can trivially retrieve $\vec{a}, \vec{\alpha}$ for all $i = \{1, ..., l\}$ since:

$$a_{1_i}' - a_{2_i}' = \alpha_i(x_1 - x_2)$$

If each $v_i$ maps to each $\alpha_i$, then $a_i$ must be the exponent of $g$ in equality 182 or we found a non-trivial relationship among generators $g, h$.

In the final step, we validate the proof by checking if $r, \epsilon, \vec{\tau}$ can be computed from witnesses $\vec{a}, \vec{\alpha}$. This must be true for equality 180 to be true except for a negligible probability or we found a non-trivial relationship among generators $g, h, \vec{u}$. We can therefore conclude Protocol 3 has computational witness extended emulation.
